We were both fortunate to have Ron Hambleton as our advisor at the University of Massachusetts Amherst. We would like to acknowledge Ron as a teacher, as a leader in the field, and as a friend. His determination to advance the science of educational measurement through his teaching and his research was extraordinary. We shall forever be thankful for what he gave to us in both our professional and our personal lives.

Linda would also like to dedicate the book to her dear husband, Daniel Eignor. Dan was both a friend and a colleague to her. She is grateful for his support and friendship in the years they were able to have together.

Mary would also like to thank her parents, Thomas and Catherine Pitoniak, for their support of her education and their belief in her capabilities. She also thanks her canine companions throughout the years for their unconditional support of psychometrics.

Linda L. Cook
Mary J. Pitoniak

List of Tables	XI
List of Figures	XV
Foreword	XIX
Acknowledgments	XXI
Contributor List	XXIII

PART I: SETTING THE CONTEXT

CHAPTER 1	Factors Influencing Education and Educational Measurement	3
	<i>Linda L. Cook and Mary J. Pitoniak</i>	
CHAPTER 2	The History of Educational Measurement	33
	<i>Brian E. Clauser, Jerome C. Clauser, and Amanda L. Clauser</i>	
CHAPTER 3	The Sociocultural Context of Educational Assessment	115
	<i>Kadriye Ercikan and Guillermo Solano-Flores</i>	

PART II: FOUNDATIONAL CONCEPTS

CHAPTER 4	Validity and Validation	191
	<i>Suzanne Lane and Scott F. Marion</i>	
CHAPTER 5	Reliability in Educational Measurement	277
	<i>Won-Chan Lee and Deborah J. Harris</i>	
CHAPTER 6	Fairness in Educational Measurement: Theory and Concepts	383
	<i>Rebecca Zwick</i>	

PART III: DEVELOPING, ADMINISTERING, AND SCORING ASSESSMENTS

CHAPTER 7	Designing and Developing Educational Assessments	441
	<i>Kristen Huff, Paul Nichols, and M. Christina Schneider</i>	
CHAPTER 8	Test Administration and Scoring	513
	<i>Mark D. Shermis, Allan S. Cohen, and Jordan M. Wheeler</i>	
CHAPTER 9	Technology-Based Assessment: Validity, Modeling, and Analysis Issues	581
	<i>Randy E. Bennett, Michelle LaMar, and John Mazzeo</i>	
CHAPTER 10	Modeling Data From Educational Assessments	655
	<i>Li Cai, Mark Hansen, Minjeong Jeon, and Michael C. Edwards</i>	
CHAPTER 11	Scaling, Equating, and Linking	735
	<i>Tim Moses</i>	
CHAPTER 12	Standard Setting: A Cognitive and Social Model	821
	<i>Steve Ferrara, Susan Davis-Becker, Priya Kannan, and Katherine Reynolds</i>	
CHAPTER 13	Reporting Scores and Other Results	895
	<i>April L. Zenisky, Francis O'Donnell, and Ronald K. Hambleton</i>	
CHAPTER 14	Realizing Fairness Through Accessibility for All Test Takers and for Specific Groups	959
	<i>Michael C. Rodriguez and Martha L. Thurlow</i>	

PART IV: SPECIFIC APPLICATIONS OF ASSESSMENT

CHAPTER 15	Assessment to Inform Teaching and Learning	1017
	<i>Susan M. Brookhart and Charlie DePascale</i>	
CHAPTER 16	Test-Based Accountability in K–12 Education	1113
	<i>Andrew D. Ho and Morgan S. Polikoff</i>	
CHAPTER 17	Assessment for Admission, Placement, and Outcomes in Higher Education	1189
	<i>Wayne J. Camara, Ou Lydia Liu, and Krista Mattern</i>	
CHAPTER 18	Assessment for Licensing and Certification	1265
	<i>Melissa J. Margolis, Rebecca S. Lipner, and Chad W. Buckendahl</i>	

CHAPTER 19	Assessment of Social-Emotional, Soft, Character, Behavioral, and Intrapersonal and Interpersonal Skills	1339
	<i>Patrick C. Kyllonen and Jiyun Zu</i>	
CHAPTER 20	Large-Scale Assessments in International Contexts	1423
	<i>Henry I. Braun and Irwin Kirsch</i>	
 PART V: MEASUREMENT AS A SCIENCE		
CHAPTER 21	On the Nature of Measurement	1513
	<i>Derek C. Briggs, Andrew Maul, and Joshua A. McGrane</i>	
	 Index	 1579

List of Tables

4.1	Messick's Facets of Validity	205
4.2	Interpretation and Use Argument and Validity Argument Components for Culturally Responsive Assessments	247
4.3	Interim Assessment Uses	250
5.1	Variance and Covariance Components for the Extended Multivariate Design Example	308
5.2	Variance-Ratio Reliability Coefficients for the Maximum Likelihood Estimator	315
5.3	Estimators of Conditional Standard Errors of Measurement Based on a Single Test Administration	336
7.1	Various Characterizations of Cognition Related to Assessment	457
7.2	Example Range Performance-Level Descriptors	464
7.3	Claims and Evidence in Principled Assessment Design	487
7.4	Validation Framework and Criteria for Performance-Level Descriptors, Design Patterns, and Item Development	490
8.1	Comparison of English-Based Automated Essay Scoring (AES) Systems	535
8.2	Comparison of Non-English-Based Automated Essay Scoring (AES) Systems	559
10.1	An Overview of More Specialized Models in the General Framework	661
10.2	Descriptive Statistics of Sum Scores of Pretest and Posttest by Condition	701
10.3	Hierarchical Linear Model Results Based on Test Sum Scores	703
10.4	Classical Item Statistics	704
10.5	Unidimensional Item Response Theory Model Item Parameters	705
10.6	Unidimensional Item Response Theory Model: Marginal X^2 and Standardized Local Dependence X^2 Statistics	706
10.7	Model Fit Statistics: Unidimensional Item Response Theory Model Versus Bifactor Model	708
10.8	Model Fit Statistics: Single-Level Bifactor Model Versus Two-Level Bifactor Model	709
10.9	Q-Matrix Specified for Diagnostic Classification Models	710
10.10	Top Five Estimated Proportions of Attribute Profiles in Diagnostic Classification Models	711
10.11	Two-Level Item Response Theory Growth Model With Treatment and Control Groups in Separate Data Columns: Data Structure	712
10.12	Two-Level Item Response Theory Growth Model With Treatment and Control Groups in Separate Data Columns: Factor Pattern	713

10.13	Descriptive Statistics of Latent Pretest Score and Latent Change Score by Condition	715
10.14	Two-Level Item Response Theory Growth Model With Condition Indicator as a Predictor: Data Structure	715
10.15	Two-Level Item Response Theory Growth Model With Condition Indicator as a Predictor: Key Results	716
10.16	Cross-Classified Item Response Theory Model With Individuals and Items as Crossed Factors: Data Structure	717
10.17	Cross-Classified Item Response Theory Model With Individuals and Items as Crossed Factors: Key Results	717
10.18	Summary of Alt ELPA Grade 2–3 Item Characteristics	719
10.19	Model Fitting Summary and Key Results: Multidimensional Item Response Theory (IRT) Model Versus Cross-Classified IRT Model	720
10.20	Cross-Classified Item Response Theory Model: Data Structure (Example 2)	721
11.1	Summary of Data Collection Designs for Scaling, Equating, and Linking	738
11.2	Summary of Types of Equating	761
11.3	Summary of Nonequating Types of Linking	787
11.4	Summary of Recent Linking Examples	787
12.1	Selected Milestones in the History of Standard Setting	825
12.2	Taxonomy of Cognitive-Judgmental Tasks With Key Elements of Eight Standard-Setting Methods (and Two Variations), Including Paraphrased Statements of Cognitive-Judgmental Tasks	835
12.3	Framework to Guide Workshop Design and Gather Validation Evidence to Support Claims About the Interpretation of Cut Scores	857
12.4	Proposed Proactive Training Strategies to Reduce Deleterious Effects on Panelist Judgment and Decision-Making of Judgmental Heuristics and Cognitive Biases (or “Debiasing”)	862
13.1	Updated Evaluation Form for Reviewing Reports	932
15.1	Framework Relating Formative Assessment Strategies to the Formative Assessment Process and Its Agents	1021
15.2	Examples of Classroom Formative Assessment	1024
15.3	Construct Map Showing a Learning Progression for Student Understanding of Earth in the Solar System	1065
16.1	An Example of a Categorical Model From Delaware’s 2009–2010 School Year	1151
17.1	ACT and SAT Content, Testing Time, and Item Counts	1207
17.2	Percentage of U.S. Applications and Enrollment by Selectivity at 4-Year Institutions for 2017–2018	1209
17.3	Estimated Number and Percentage of U.S. High School Graduates Taking College Admissions Tests in 2017	1212

17.4	Graduate and Professional Admissions Tests	1216
17.5	Reliability of Undergraduate and Graduate Admissions Tests	1223
17.6	Validity of Undergraduate and Graduate Admissions Tests for Predicting First-Year Grade Point Average (GPA)	1225
17.7	Estimated Percentage of U.S. Postsecondary Institutions Using Selected Math and Reading Tests for Placement in Fall 2011	1235
19.1	Principal Component Analysis of 21st-Century Skills and Big Five Alignment	1349

21.6	Public Dissemination of National Assessment of Educational Progress Reading Results in the Metric of Percentage <i>Proficient</i> or <i>Advanced</i>	1558

Foreword

Over the 74 years since the publication of the first edition of *Educational Measurement*, this volume has become a signature contribution of the National Council on Measurement in Education (NCME). It is the handbook of our field. Its various chapters provide authoritative definitions of terms, clarify essential concepts, review what we know and have learned, and identify fruitful areas for debate and further study. Whereas the American Council on Education led or partnered with NCME on former editions, this edition is the first that NCME led from conception to delivery.

The NCME Board appointed Dr. Linda L. Cook and Dr. Mary J. Pitoniak as coeditors in 2018. They have steered this volume, its authors, and its reviewers through global disruptions in health, politics, technology, and the central context of this volume, education. In stormy seas, how can we know where we are or where we are going? Drs. Cook and Pitoniak have been intrepid navigators, guiding authors and reviewers through uncharted waters and finding safe harbor to land this volume where it can make its deserved impression on the field. On behalf of NCME, I extend my gratitude and express my admiration for their leadership and accomplishments.

Many people—103 in total—were involved with this volume, some playing multiple roles. They include 52 authors, 63 reviewers, and 19 editorial board members. Like the coeditors, these individuals received no financial compensation for their considerable efforts to develop and improve these chapters. The many hours, days, weeks, months, and years of unpaid work that they contributed reflect their commitment to scholarship itself as a form of public and professional service. NCME, the field, and the public can honor their contributions by reading, engaging, citing, applying, and advancing their work in future research, policy, and practice.

One of these contributors was Stephen (Steve) Ferrara. Steve served as an author of Chapter 12 in this volume, an editorial advisory board member, and a reviewer. Steve also authored a chapter in the fourth edition of this volume and has made innumerable contributions to NCME as an organization, including as a board member and an editor. Steve passed away in 2024 after a prolonged illness. In his honor, Susan Trent and the Ferrara family have made a generous contribution to make this volume freely available to the public. Thanks to their generosity and in Steve's memory, all scholars, students, practitioners, professionals, and citizens have equal access to this signature NCME contribution, regardless of their financial means. Thank you to Susan and the Ferrara family, and thank you, Steve.

On behalf of the NCME community and our field, I extend my gratitude to the coeditors, editorial board members, authors, and reviewers for their generous contributions. The organization is committed to advancing their work to benefit scholarship and society.

Andrew D. Ho
President (2024–2025)
National Council on Measurement in Education

Acknowledgments

An undertaking of this size cannot reach a successful conclusion without the effort and talent of many different people. For the fifth edition of *Educational Measurement* (EM5), we would like to acknowledge first the contributions of the 52 authors who worked diligently to provide the very best exploration and documentation of the most important topics in our field. We would also like to acknowledge the contributions of the 63 reviewers of the 21 chapters appearing in this volume. We were extremely impressed by the thoughtful and insightful comments they provided. The quality of the content of EM5 is reflective of the patience, professionalism, and hard work of these reviewers as well as the responsiveness of the authors to the reviews.

We would like to acknowledge the invaluable advice and guidance we received from the 19 members of the Editorial Advisory Board. Their breadth of talent and experience helped us set the direction for the volume and maintain our goals throughout the process. Each member also served as an additional reviewer of a chapter.

In addition, we would like to acknowledge the National Council on Measurement in Education (NCME) Board for the unending support that they provided throughout the creation of this volume. We would also like to acknowledge the support and guidance of the NCME publications committee.

We are fortunate to have had excellent support and guidance from our colleagues at Oxford University Press: Abby Gross, Sarah Ebel, Hayley Singer, and Katharine Pratt. Their expertise and patience were an immense help to us as we prepared our final drafts of EM5.

We would like to acknowledge the generous support of ETS, which made it possible for the editors to have the time it takes for a project of this magnitude. We would also like to acknowledge the excellent editorial assistance of ETS staff members Jodi Thompson and Kimberly Fryer. Last, we would like to thank two of ETS's officers, Ida Lawrence and Karen Barton, for the many ways they showed their support during the creation of this volume.

Contributor List

In this section, we list and thank the many people involved in conceptualizing, writing, and reviewing this volume.

Author List, by Chapter

1. Linda L. Cook, ETS (Retired)
Mary J. Pitoniak, ETS
2. Brian E. Clauser, NBME (Retired)
Jerome C. Clauser, American Board of Internal Medicine
Amanda L. Clauser, NBME
3. Kadriye Ercikan, ETS
Guillermo Solano-Flores, Stanford University
4. Suzanne Lane, University of Pittsburgh (Emerita)
Scott F. Marion, National Center for the Improvement of Educational Assessment
5. Won-Chan Lee, University of Iowa

Part I

Setting the Context

Factors Influencing Education and Educational Measurement

Linda L. Cook

ETS (Retired)

Mary J. Pitoniak

ETS

The past four editions of *Educational Measurement* began by comparing the then-current status of the science of educational measurement with the status of the science during the periods when the previous edition(s) were published. For this edition, we have chosen instead to reflect on the status of society, mostly in the United States, that has influenced both education and educational measurement at the time the chapters in this book were written. We focus particularly on the factors impacting education and educational measurement that we think have been unique influencers during the decade prior to the publication of this book (2014–2024), as compared to the time periods when previous editions were written.

Many of the chapters in this volume were written during one of the most challenging periods in recent U.S. and world history. The outbreak of COVID-19, which began in Wuhan, China, sometime in the fall of 2019, had a profound impact on education and educational measurement as it is practiced in the United States and around the world. As this chapter is being written, the full impact of the pandemic on student learning and other aspects of child development, as well as the impact on society in general, is still being measured and may never be completely known.

Another important factor that is far more complex and difficult to evaluate than the influence of the pandemic on education and educational measurement is the polarized cultural/political climate in the United States, which has intensified the cultural differences impacting what is taught and tested in schools in the early 21st century. Many of the institutions that serve our society, particularly our schools, have experienced changes in policies and practices that reflect conservative cultural preferences, which are sometimes highly controversial.

Finally, and closely connected to the previously mentioned factors, are issues related to social justice. We believe that these issues, which have always been prominent in U.S. society, have intensified and had a more prominent effect on education and educational measurement over the decade prior to the publication of this book (2014–2024) than in previous periods in our history. This well-justified concern about social justice has led to the questioning of many of our institutions and how they serve all members of U.S. society. The increasing awareness of how our society addresses social justice for all our citizens has profound implications for the future of educational measurement.

Although these three factors were not the only factors impacting the science of educational measurement during the past decade, we believe they represent significant societal influences that were not strongly present when the fourth edition of *Educational Measurement* was published in 2006. Some of the chapters in this volume reflect these influences more directly than others and contain explicit descriptions of how the influences affected their topics. Other chapters were influenced by one or more of these factors in some way, but the influence may not be as apparent.

The following section contains a short discussion of the impact of the pandemic, cultural disagreements, and the social justice movement on the recent practice of education and educational measurement in the United States. This discussion is followed by

an overview of each of the five parts in this volume and a short summary of the chapters included in each part. We are hopeful that this material will provide a context for the chapters in this volume, as well as a guide to help readers choose chapters that are most interesting to them or most appropriate to inform their work.

THE PANDEMIC (COVID-19) AND EDUCATION AND EDUCATIONAL MEASUREMENT

The fifth edition of *Educational Measurement* was written and edited during one of the most unique periods in U.S. history that either of the editors has experienced. This period was marked by a worldwide pandemic, COVID-19, which began impacting life in the United States in early 2020. The impact of the pandemic continues to be felt in many ways.

As we write this chapter, for most people, the danger from the disease itself has been reduced to no more than that of a bad cold. However, everyone remembers those terrifying months before a vaccine was developed when young and old alike were succumbing rapidly to the disease.¹

Society as we had experienced it basically stopped functioning. In the early months of the pandemic, businesses closed, schools shut down, residents fled cities, and entertainment centers were shuttered. Sporting events were carried out without an audience. Cardboard cutouts placed in the stadium seats took the place of fans to create the feeling of an audience for those watching the event on television. Sick individuals were isolated and tragically passed away, with their families having only a tablet device or phone to use for their final communications, if they were able to have any communication at all.

We think it is important to understand the fear and despair that gripped U.S. citizens as well as international populations during the early stages of the pandemic. The heartbreak and emotions brought about by the spread of COVID-19 had a lasting effect on the well-being and mental health of the parents, children, and educators who struggled to continue with student learning through the first few years of the pandemic. People lost family members, their jobs, their incomes, and their homes. This loss was not uniformly felt across subpopulations, which exacerbated previously existing societal issues.

Many K–12 schools in the United States coped with the pandemic by rapidly transitioning from an in-person setting to remote instruction offered over the Internet. However, a few schools continued to operate completely in person, while others offered a hybrid approach to classes: 1 or 2 days a week with in-person instruction and the remaining days with remote learning. According to Camara (2020), school closures due to COVID-19 in the spring of 2020 “affected at least 124,000 of the estimated 132,000 U.S. public and private schools and over 56 million students” (p. 10).

As just mentioned, the impact of COVID-19 was not uniform. According to the Center for Reinventing Public Education (2021), “the human losses and financial tolls were more commonly experienced by Black, Hispanic/Latinx, and indigenous students from

lower-income communities” (p. 5). These researchers pointed out that in the spring of 2021, only 47% of high-minority schools had resumed in-person schooling as compared to 61% of low-minority districts.

School closures caused a particular problem for spring state-accountability assessments. Gathering students for assessment in the spring of 2020 was impossible in most situations. Many states simply did not test in the spring of 2020 or even in the fall of that year. Some states experimented with their accountability assessments by administering them individually via the Internet. According to Camara (2020),

In early spring 2020 the vast majority of US colleges and schools closed for the year due to COVID-19. . . . School closures and associated health concerns halted large scale admissions testing and required alternative models such as remote proctoring at home, additional flexibility in test sites . . . and additional testing dates for the fall. . . . It is clear that access to admissions testing has been greatly reduced despite these efforts resulting in extended deadlines in graduate admissions and the wide-scale adoption of test-optional policies in undergraduate admissions. (p. 10)

As we write this chapter, some of the alternative models just referred to have been adopted as a regular part of test administration processes. For example, remotely administered exams have persisted and new ways of protecting the security of these exams have been developed, some more successful than others. In addition, in the spring of 2024, the SAT moved almost completely to online administration, providing more flexibility in the face of school closings in the future.

Researchers will continue to study the impact of the pandemic on student learning for many years. The lack of state assessment data collected during the pandemic years has complicated things considerably. Early indications were for sizeable math and reading drops, exacerbating test score gaps between students in low-poverty compared to those in high-poverty elementary schools (Kuhfeld et al., 2022). However, these researchers were optimistic about some improvements in learning if the school district took advantage of resources from the Elementary and Secondary School Emergency Relief Fund established as part of the Coronavirus Aid, Relief, and Economic Security (CARES) Act in March 2020 (U.S. Department of the Treasury, 2020).

Results from the National Assessment of Educational Progress (NAEP) also provided information about student performance related to the pandemic. In 2022, NAEP results made news across many major platforms:

U.S. students in most states and across almost all demographic groups have experienced troubling setbacks in both math and reading, according to an authoritative national exam released on Monday, offering the most definitive indictment yet of the pandemic’s impact on millions of schoolchildren. (Mervosh & Wu, 2022, para. 1)

However, more recent data are encouraging. In a recent report, *New Data Show How the Pandemic Affected Learning Across Whole Communities* (Education Recovery

Scorecard, 2024), researchers noted that both math and reading scores for elementary and middle school students are showing recovery. The results differ from state to state, with some states showing considerably better recovery than others.

The editors also feel some degree of optimism. We are hopeful that the lessons we have learned from coping with the pandemic, as well as an increased awareness of some of the inequities in our society that were made so apparent as we attempted to address the many COVID-related issues associated with learning and assessment, will result in improvements in how we teach and assess. (The reader is referred to Chapters 3, 6, 9, 11, 16, 17, and 20 for further discussion of the effect of COVID-19 on society, education, and educational measurement.)

THE POLITICAL/CULTURAL CLIMATE AND EDUCATION AND EDUCATIONAL MEASUREMENT

The political/cultural climate in the United States has a long history of affecting both education and educational measurement. A well-known example is the teaching of evolution in public school science classes. The Scopes trial of 1925 is often regarded as a landmark in the battle to teach evolution in American public schools. A high school teacher in Dayton, Tennessee, John T. Scopes, was charged with violating state law by teaching Charles Darwin's theory of evolution. According to "Scopes Trial" (2024, para. 1), "the trial's proceedings helped to bring the scientific evidence for evolution into the public sphere while also stoking the national debate over the veracity of evolution that continues to the present day." In 1987, the Supreme Court ruling in *Edwards v. Aguillard* struck down a Louisiana law requiring schools to teach creation science whenever students learn about evolution: "In issuing its ruling in *Edwards*, the court effectively closed the door on efforts to teach the biblical creation story in public school science classes" (Masci, 2007, para. 1). However, according to a recent article in *Scientific American*, despite the 1987 ruling and the 2013 introduction of the Next Generation Science Standards, there is still reason for concern:

More than one in six high school biology teachers, 17.6 percent, are still presenting creationism as a scientifically credible alternative to evolution. And almost as many high school biology teachers, 15 percent, are still failing to emphasize the broad scientific consensus on evolution, despite its general prevalence in state standards and despite encouragement from professional organizations. (Branch & Reid, 2020, p. 5)

Another example of how cultural differences have affected education in public schools was the concern about socialism or Marxism in the early and mid-20th century. Groups like the American Legion pressured schools to eliminate the use of progressive textbooks that encouraged students to think about economic inequality; later, the John Birch Society raised many of the same criticisms of school curricula (Birnbach, 2021).

Cultural differences and opinions about what should be taught and tested in public schools have been prominent during the drafting of the chapters in this volume, and these differences may be even stronger in the early 21st century than in 1925 when the teaching of evolution was an issue or in the mid-20th century when the concern regarded teaching about economic inequality. A current cultural issue impacting what is taught and tested in schools is *wokeness*, basically understood as liberal views on race and gender. A major concern in many schools has been the teaching of critical race theory.² According to an article in *Education Week*,

since January 2021, 44 states have introduced bills or taken other steps that would restrict teaching critical race theory or limit how teachers can discuss racism and sexism. . . . Eighteen states have imposed these bans and restrictions either through legislation or other avenues. (Schwartz, 2021, para. 5)

States with conservative legislatures, such as Florida, have focused on “scrubbing textbooks.” These states are concerned about textbooks promoting a “leftist agenda” in the classroom (Mervosh & Goldstein, 2023). The Florida Department of Education said in a news release that they rejected 82 of 101 submitted textbooks because of what they considered “inaccurate material, errors and other information that was not aligned with Florida law” (Mervosh & Goldstein, 2023, para. 2). Textbooks are being rejected because they include topics such as critical race theory and social-emotional learning. Examples of topics that are being removed from some textbooks are those focusing on the Black Lives Matter movement³ and the murder of George Floyd⁴ and its impact on society.

Harris (2024) reported on a nationwide surge in book bans affecting memoirs and novels that address experiences of people in the lesbian, gay, bisexual, transgender, and queer (LGBTQ) community or deal with race. The source of the data was a report released by the American Library Association (2023), which described an “explosion” of book bans across the country, resulting in 4,200 challenged titles in 2023. This number represents a 65% increase over the number of challenges raised in 2022. In the years leading up to 2021, when bans began to escalate, the average number of books challenged in a year was about 275.

A highly controversial example of scrubbing textbooks was the state of Florida’s challenge of the pilot version of the College Board’s Advanced Placement (AP) curriculum for African American studies. According to Hartocollis and Fawcett (2023, para. 5), “the College Board’s decision to try to build a curriculum covering one of the most charged subjects in the country—the history of race in America—may have all but guaranteed controversy.” The attack on the AP pilot curriculum began in Florida when the governor announced in January 2024 that he would ban the curriculum. Hartocollis and Fawcett (2023) wrote, “State education officials said it was not historically accurate and violated state law that regulates how race-related issues are taught in public schools.” It should be noted that the curriculum had input from, and was celebrated by, many eminent scholars as an “affirmation of the importance of African American studies” (Hartocollis & Fawcett, 2023). According to these authors,

the study of contemporary topics—including Black Lives Matter, incarceration, queer life and the debate over reparations—is downgraded [in the revised curriculum]. The subjects are no longer part of the exam and are simply offered on a list of options for a required research project. (para. 15)

One of the writers expunged from the AP curriculum was Kimberlé W. Crenshaw, a law professor at Columbia, whose work the university cites as being “foundational in critical race theory” (Hartocollis and Fawcett, 2023, para. 17). Crenshaw said she was disappointed because “she had believed the course would capitalize on a hunger of young students to learn ways of thinking about things like police brutality, mass incarceration and continuing inequalities” (Hartocollis & Fawcett, 2023). Instead, she said, “the very same set of circumstances that presented the need for the course also created the backlash against the content that people don’t like” (Hartocollis & Fawcett, 2023, para. 20).

The changes in the curriculum did not completely satisfy conservatives either. For example, Ilya Shapiro, director of constitutional studies at the Manhattan Institute, criticized the curriculum for omitting conservative or independent Black thinkers like John McWhorter, Shelby Steele, Thomas Sowell, and Justice Clarence Thomas of the Supreme Court (Hartocollis & Fawcett, 2023).

THE SOCIAL JUSTICE MOVEMENT AND EDUCATION AND EDUCATIONAL MEASUREMENT

According to a report from the United Nations (2006), “Social justice may be broadly understood as the fair and compassionate distribution of the fruits of economic growth” (p. 7). The same report that provides this definition also provides a brief global history of social justice. According to this report, the idea of social justice was first noted in Western politics soon after the Industrial Revolution, along with the development of the socialist doctrine. The concept of social justice developed further as a protest of what was then thought to be the capitalist exploitation of labor. The concept of social justice continued to develop and became central to most leftist and centrist political parties around the world by the mid-20th century.

Wikipedia lists over 140 social justice movements that are active as we write this chapter (“List of Social Movements,” 2024). These movements range from the well known, such as the Black Lives Matter movement and the civil rights movement, to the lesser known, such as movements like the sunrise movement⁵ and the slow movement.⁶

Following World War II, the civil rights movement had a very important effect on multiple groups that were protesting for equal rights. These groups included women, Black people, and gay people. One movement that has had considerable impact on current society and education and educational assessment is Black Lives Matter, which we described earlier. Education and educational testing have also been influenced by the LGBTQ social movements.

The gay liberation movement, which began in the 1960s, was founded to encourage gay men and lesbians to engage in radical action to promote gay pride (Bill of Rights Institute, 2024). One of the most noted landmarks in the history of the gay liberation movement was the resistance to the police raid of the Stonewall Inn in New York City that occurred in 1969. This incident was a significant milestone in organizing LGBTQ people to become more active politically and accomplish much for the civil rights of the LGBTQ community (Bill of Rights Institute, 2024).

As we write this chapter, there is a growing global pro-Palestinian protest that has risen out of the Israel– Hamas war. The protests in the United States are located mostly on college campuses. The protesters are demanding an end to Israel’s war in Gaza, which at the time of this writing had killed more than 34,000 Palestinians. In addition, they are making other demands: for example, that universities divest themselves from financial ties with Israel or from companies that may profit from the war in Gaza. The protests have disrupted college and university classes and graduation ceremonies and led to a number of arrests.

In addition, the protests have sparked a debate over freedom of speech on campuses that has resulted in the resignation of two presidents of prominent universities. Four university presidents have been asked by Congress to testify about “rampant antisemitism” on their campuses. The four presidents were from the University of Pennsylvania, Harvard, the Massachusetts Institute of Technology, and Columbia. At the time of this writing, two of the four presidents have resigned from their university positions. The president of Columbia, Minouche Shafik, warned, “If colleges and universities cannot better define the boundaries between free speech and discrimination, government will move to fill the gap, and in ways that do not necessarily protect academic freedom” (Forgash, 2024, para. 7).

At present, those involved in educational assessment have responded mostly to social justice movements focused on groups such as people of color and those associated with gender, disability, or sexual orientation. Often “equity indicators” are used to discuss and evaluate the fairness and equity of education and assessment for these groups (Edley et al., 2019). In contrast, Vo (2021) used a social justice frame rather than an equity frame to examine the design and interpretation of opportunity-to-learn indicator systems. She argued that an equity frame “maintains a traditional view of opportunity-to-learn, OTL, that does not explicitly consider the complexities of how knowledge is acquired or measured” (p. 1). She contrasted an equity frame with a social justice frame using an example from Edley et al. (2019). She noted that as an indicator of equity in a school setting, the authors described using “disparities in engagement in schooling” (Vo, 2021, p. 25), which they quantified as 15 or more unexcused days absent from school in 1 year. Vo pointed out that this is also the most common school quality and student success indicator used in the Every Student Succeeds Act (U.S. Department of Education, 2015).

Vo (2021) continued by postulating that using an equity frame “could lead to interpreting and labeling a student as ‘disengaged’ but neglecting to understand the factors

why students might not be attending school in the first place” (p. 2). She made the point that a social justice frame would “challenge the definition of ‘student engagement’” (p. 2) and would examine the idea of engagement by looking at the cultural experiences of individuals who are Black, Indigenous, and people of color. As an example, she described a student who is self-employed, living with a single parent, and helping to provide child care and income for the family. If the school were to apply a social justice frame rather than an equity frame to this student’s situation, they would look at the sociocultural context. By doing this, the school might conclude that the student’s lack of engagement is a result of his family and community experiences. Using this frame, the school might be able to provide support to the student, both in and outside school, that would result in improved school engagement.

Michael Russell (2024), in his book addressing systemic racism and educational measurement, began his chapter on the “White racial frame” with a quote taken from Elias and Feagin (2016):

White racial framing involves the explanation and construction of social reality from the perspective of dominant whites, one normally steeped in Eurocentrism, thereby creating a long-lasting white racial frame. This white racial frame is a meta-structure that develops and reinforces ideas, actions, networks, institutions, and social structures according to the views and practical racial-group interest of white people. (p. 7)

Russell devoted an entire chapter in his book to exploring the White racial frame and how it influences educational measurement. He concluded this chapter by making the point that “while the racist beliefs that dominated the thinking of the field’s pioneers no longer operate in an overt manner, the framing of questions, methods, and narratives were carried forward to influence educational measurement as it operates today” (p. 126).

In his book, Russell (2024) referred frequently to the work of Jennifer Randall. Randall, the founding president of the Center for Measurement Justice, focuses her work on “[disrupting] white supremacist, racist logics in assessment through justice-oriented practices that are explicitly and unapologetically antiracist” (Randall, 2021). Randall (2021) discussed an “antiracist framework for construct definition and representation via an approach that actively disrupts current white supremacist social, economic, and political ideologies that reproduce racial privilege in society through the promotion of white, racist, hegemonies” (p. 82). In this article, she argued that the current practice of “committing to neutrality (or an absence of racism) is, in effect, sustaining white supremacist logics and continues to actively harm minoritized students” (Randall, 2021, p. 83). She went on to say that “the foundational assessment design’s commitment to neutrality—operationalized by our fierce eradication of anything that could be considered ‘construct-irrelevant variance’—is, in effect, sustaining the inherent whiteness as superior bias of our assessment design practices” (Randall, 2021, p. 84). She continued this argument in a discussion of assessment validation

(Randall et al., 2022). Randall and her colleagues made the point that “the validation process, arguably the most important process in educational measurement, has served as one of measurement’s primary weapons of racist oppression and marginalization” (Randall et al., 2022, p. 171). The authors went on to propose a justice-oriented, anti-racist validity framework that is “built on foundational theories and practices related to justice oriented perspectives, critical race theory, and antiracist assessment” (Randall et al., 2022, p. 171). Randall et al. (2022) made a critical observation that “what is construct-relevant behavior is dependent on the eye of the beholder” and pointed out that what validity theory has been missing is a set of questions that “ground and initiate assessment design and validation” (p. 173). They note that Mislevy (2018) argued that “tasks, performances, and criterion situations need to be examined through the lens of targeted LCS (linguistic, cultural, and substantive) patterns and practices” (Randall et al., 2022, p. 173). For example, Randall et al. asked “whose LCS patterns are being privileged by an assessment, whose LCS patterns are being devalued, omitted, suppressed, or marginalized?” (p. 173).

References to and discussions of the relationship between social justice and assessment are also found in Chapters 2, 3, 4, 6, 14, 15, and 17.

OVERVIEW OF THE VOLUME

Part I: “Setting the Context”

Part I consists of three chapters. In this chapter, Chapter 1, “Factors Influencing Education and Educational Measurement,” we attempt to provide some societal context for the 20 other chapters that appear in this volume. The other 2 chapters in this part are Chapter 2, “The History of Educational Measurement,” and Chapter 3, “The Socio-cultural Context of Educational Assessment.” The chapters in Part I provide a more in-depth discussion of the historical and societal factors influencing education and educational measurement in general. Chapter 2 provides a comprehensive discussion of the history of the science of educational measurement and Chapter 3 includes a thoughtful discussion of how educational measurement influences and is influenced by the society it serves.

Brian E. Clauser, Jerome C. Clauser, and Amanda L. Clauser, the authors of Chapter 2, provide a quote by Howard Wainer (2005, p. 118), attributed to Aristotle: “We understand best those things we see grow from their very beginnings.” They go on to say that “if we wish to understand the field of educational measurement, we would be well served by understanding how it developed” (p. 92). They point out that the history of educational measurement is not a simple one, but rather multiple related histories. To accommodate this complex history, they have separated their chapter into eight sections. They cover topics such as early foundations, intelligence testing, the impact of the U.S. government on educational testing practice, test theory, scaling, item response theory, and the use of tests for selection and accountability.

An important discussion in Chapter 2 that helps us understand concerns about testing and social justice in the early 21st century focuses on the fact that many of the early, and most prominent, thinkers in statistics, psychometrics, and educational measurement were closely aligned with the eugenics movement. They point out that

viewing measurement and testing in the context of an early history that is closely tied to intelligence testing and eugenics is likely to help us understand the skepticism of and resistance to testing that has been present since the 1920s. (p. 35)

Another important point the authors make related to the topic of social justice is to

suggest that the emphasis that Cronbach (1971, 1989b) and Messick (1975, 1989) placed on fairness and consequences as part of test validity can be accounted for (at least in part) by the social context created by the civil rights movement and the war on poverty. (pp. 34–35)

Chapter 2 also includes an insightful discussion of the political forces that have shaped testing over the years. As we discussed in the previous section, the political climate in the United States, as in other parts of the world, is key to the direction taken by our social institutions such as education. The authors of the chapter point out that as early as 1860, the U.S. government made important decisions about what to support and not support in testing. They point to the civil service commission and the army testing program as examples. Readers, particularly those interested in the nexus of policy, social justice, and assessment, will find many of the insights presented in the chapter timely and informative.

Kadriye Ercikan and Guillermo Solano-Flores, the authors of Chapter 3, “The Sociocultural Context of Educational Assessment,” begin their chapter by stating that their goal is to make clear that education and the sociocultural context within which it takes place have a bidirectional relationship. They highlight this relationship as it manifests in different ways for measurement professionals, researchers, decision-makers, and practitioners. They point out that

contexts determined by conditions such as legislation, educational policy and practices, technological advances, social inequities, and unexpected events such as the COVID-19 pandemic affect assessment practices . . . In turn, assessment impacts education policy, teaching practices, and the learning, career, and life opportunities of individuals. (p. 116)

The authors discuss three notions that drive their reasoning about the bidirectional relationship of assessment and sociocultural contexts: first, culture and language influence how test takers engage with tests, process information presented on tests, and formulate solutions and responses to test tasks; and second, because tests and testing are social products, they are a reflection of the societies in which they originate; test content is a reflection of the kinds of knowledge, reasoning, and skills valued in a society. They make the important point that “tests tend to be written in a standard, formal variety of the language in which they are administered This type of language usage is not common among certain test takers—and especially so for test takers from

a non-native language background in the language of a test” (p. 117). The third notion they discuss is that assessment has different meanings and roles for different cultures. They point out that

views of tests and testing and the consequences that tests and performance on tests have on people’s lives vary across societies. This creates differences across societies in the ways in which individuals prepare for taking tests, how they interpret test items and their demands, the level of effort they put into responding to tests, and the pace with which they solve problems during a test. (pp. 117–118)

The editors of this volume believe that it is important for those who practice educational measurement to have a thorough understanding of how the science of educational measurement is influenced by history as well as by past and present sociocultural conditions. It is our intention that the chapters found in Part I of this volume provide that opportunity for our readers.

Part II: “Foundational Concepts”

Three chapters appear in Part II; they focus on the foundational topics of reliability, validity, and fairness. It is important to point out that the fifth edition of *Educational Measurement* contains two fairness chapters. The chapters differ in their focus, and because of these differences, they are placed in different parts of the volume. Chapter 6, “Fairness in Educational Measurement: Theory and Concepts,” which appears in Part II, focuses on fairness as a broad foundational concept underlying all aspects of assessment. The second chapter on fairness, Chapter 14, “Realizing Fairness Through Accessibility for All Test Takers and for Specific Groups,” found in Part III, focuses more on recognizing the diversity of test-taking populations and promoting fairness for all test takers through universally designed accessible assessments.

Chapter 4, “Validity and Validation,” authored by Suzanne Lane and Scott F. Marion, is the first chapter in Part II. The chapter expands the argument-based approach to validity discussed by theorists such as Cronbach (1988), Kane (2013), and Shepard (1993). The authors provide an excellent review of how validity, as described in previous chapters of *Educational Measurement*, has evolved. For example, they refer to Kane’s (2006) presentation of an argument-based approach to validity found in the fourth edition of *Educational Measurement* and expand the discussion of the importance consequences have for validation and the validity process. They illustrate this discussion by tying the importance of interpretation and use arguments (IUAs) and validity arguments to different testing programs, including K–12 assessments and credentialing exams.

Chapter 4 also contains a section on culturally responsive and situated assessment practices that includes a discussion of providing meaningful and equitable score interpretations and uses for individuals from diverse cultural backgrounds at a time of “heightened recognition of the long-standing systemic inequities in our assessment and education systems” (p. 194). The authors close their chapter by saying,

We support the call for a justice-oriented framework for conceptualizing constructs and identifying construct-irrelevant sources of variance to better promote diverse cultural and linguistic ways of knowing and doing. . . . Similarly, we must ensure that the design of the IUA and validity argument addresses any inherent biases so these arguments are designed to better ensure valid score inferences and test use for traditionally marginalized cultural and linguistic groups. (p. 261)

The second chapter in Part II is Chapter 5, “Reliability in Educational Measurement,” authored by Won-Chan Lee and Deborah J. Harris. The authors focus on the concept, quantification, and estimation of reliability and errors of measurement and consider these factors primarily under three measurement theories: classical test theory (CTT), generalizability theory (GT), and item response theory (IRT). Reliability is considered based on the concept of *replication*, and a conceptualization estimation framework is suggested for reliability analysis.

The sections in Chapter 5 that focus on CTT and GT build on treatments in chapters appearing in previous versions of *Educational Measurement*. The section on IRT consolidates and expands the work around reliability in IRT, which was not present in previous editions. Special emphasis is placed on conditional standard errors of measurement, with a dedicated section covering their various estimators. The reliability of classification consistency/accuracy is also discussed.

Additionally, Chapter 5 reviews a series of issues related to how we address reliability. These include how to use structural equation models to determine the appropriate precision coefficient when dimensionality is an issue, how speededness may affect reliability in computer adaptive testing, and how reliability is estimated when automated scoring is used with test-taker responses.

The chapter concludes by noting that

since the fourth edition of *Educational Measurement*, there has been relatively little literature published on the integration of IRT, GT, and CTT. . . . Hopefully, this chapter is a meaningful response to that goal, though there is still plenty of room for additional progress. (p. 368)

The third and final chapter in Part II is Chapter 6, “Fairness in Educational Measurement: Theory and Concepts.” Rebecca Zwick begins the chapter by providing a brief context for the fairness discussion that follows. She creates this context by writing about some current factors that are influencing how we think about fairness in the United States in the early 21st century. She discusses the pandemic, which led to the widespread elimination of admissions testing requirements and to large-scale remote testing in other settings. In addition, she points out the increasing awareness of systemic racism in the United States that, in turn, has brought focus on “the role that test scores can have in limiting educational and occupational opportunities” (p. 384). She also provides a historical context with a discussion of the imperial civil service exams that began in China 1,500 years ago. She draws an interesting parallel between the fairness

and validity issues faced by these early exams and the issues associated with many of the assessments we administer today.

Chapter 6 consists of six sections. The first section is historical and sets the context for the following five sections. The second section considers the relationships among the concepts of test fairness, validity, and bias. The third section focuses on the legal perspectives of test fairness and includes a discussion of four landmark cases involving test construction practices, test disclosure policies, the annotation of test scores resulting from nonstandard administrations, and the equitability of college admissions tests. The fourth section presents a statistical perspective on fairness that describes different types of analyses that are currently used to evaluate fairness. The fifth section describes some psychometric models that have been proposed to improve the fairness of selection procedures, and the sixth section includes the chapter summary and conclusion.

In the summary and conclusion section, the author makes it clear that she will not provide a single simple definition of fairness. She points out that the never-ending debate about college admissions, discussed in this chapter, “is an illustration of the fact that there will never be consensus on the definition of test fairness” (p. 426). She does, however, provide a very cogent set of general fairness principles. She suggests, as do the authors of Chapter 4, the first chapter in Part II, that fairness be considered a component of a larger validity argument that is being constructed for an assessment.

Part III: “Developing, Administering, and Scoring Assessments”

There are eight chapters in Part III: “Developing, Administering, and Scoring Assessments.” Some of the chapters in this part—Chapters 7, 8, and 11–14—describe important operations carried out for an assessment, that is, procedures and practices that must take place to design, develop, and administer an assessment and those required to report reliable, fair, and valid inferences from assessment results. These chapters are updates of previous chapters appearing in *Educational Measurement* and include new theories, changes in practice, and technological advances. The two remaining chapters in this part, Chapters 9 and 10, focus on theory and methods that are designed to support the operations described in the other chapters in Part III. These two chapters present new concepts and ideas that are not found in previous versions of *Educational Measurement*.

In the first chapter in this section, Chapter 7, “Designing and Developing Educational Assessments,” Kristen Huff, Paul Nichols, and Christina Schneider focus on large-scale interim and summative assessments. They discuss the evolving complexity of educational assessments and make the point that “contemporary educational testing is faced with additional complex challenges that routine design practices simply cannot meet” (p. 442). The authors group these challenges into four categories: the complexity of target constructs, using assessment results for multiple purposes, assessment quality, and accessibility for increasingly diverse student populations. They argue that assessments designed with conventional approaches do not adequately address these challenges.

They point out that conventional approaches to assessment design and development are fragmented and that there is a need for these processes to be integrated and supplemented. The authors offer principled assessment design as an approach that addresses these issues. They describe the procedures and processes used in the approach and give many practical examples of its application.

The second chapter in Part III is Chapter 8, “Test Administration and Scoring.” Mark D. Shermis, Allan Cohen, and Jordan Wheeler begin the chapter by emphasizing the connection between test administration, scoring, and validity. They point out that “ultimately, test administration and scoring procedures should support the intended interpretations of test scores. When test administration or scoring problems occur, they can undermine the validity of score inferences” (p. 514). The chapter focuses on current and emerging practices in test administration and item-level scoring. The authors discuss ways to maintain the integrity of the test administration through test security. They also talk about human scoring and machine-based scoring built on human models or artificial intelligence. The chapter provides examples of machine-based scoring systems, as well as new technologies for determining text and speech content. The chapter ends with a discussion of research conducted on machine scoring systems and the importance of providing evidence of the appropriateness of the interpretations of the scores produced by these systems.

Chapter 9, “Technology-Based Assessment: Validity, Modeling, and Analysis Issues,” is the third chapter in Part III. Randy E. Bennett, Michelle LaMar, and John Mazzeo define technology-based assessment as “a measurement used for decision-making primarily in education, but also in the workplace, that employs digital computing in most, if not all, aspects of its creation, delivery, presentation, scoring, or reporting” (p. 582). The chapter’s first main section concerns assessments designed to support consequential decision-making purposes, such as NAEP, the GRE General Test, and the Law School Admissions Test (LSAT). The authors discuss four kinds of innovative assessment designs used in such assessments—technology-enhanced items, extended interaction items, scenario-based tasks, and simulation-based performance tasks—and explore some of the validity issues raised by these innovations. The chapter’s second major section focuses on assessments employed for in-the-moment instructional decisions or for describing what students know and can do so that near-term instructional next steps can be taken. The last main section explores the idea of combining these divergent purposes in the same assessment.

The fourth chapter in Part III is Chapter 10, “Modeling Data From Educational Assessments.” Li Cai, Mark Hansen, Minjeong Jeon, and Michael C. Edwards set the context for the chapter by making the points that “data from educational assessments can take on a variety of forms and be collected for a variety of purposes. The models and modeling required to infer meaning from assessment data are also varied.” (p. 656). The authors describe various sources and features of educational assessment data, discuss some fundamental concepts pertinent to statistical modeling, and introduce a general framework that places modeling within a larger validation process. They

present two examples. In the first example, they “take a deep dive” into a complex data set collected from a randomized, controlled multisite trial of a math intervention with pre and post measures. This example illustrates issues around model building, selection, and fit appraisal through the use of a realistically complex scenario. In the second example, the authors use data from a recently developed educational assessment program to highlight the need for advanced statistical modeling in a context that is greatly constrained by legal requirements and practical considerations.

Chapter 11, “Scaling, Equating, and Linking,” notes that it would be difficult to over-emphasize how important reported scores are for a large-scale assessment program. Therefore, “as a testing program’s most visible and widely used products . . . it is essential to understand and document how reported scores are produced, maintained, and, at times, related to the scores reported by other testing programs” (p. 736), material that this chapter covers thoroughly. In the second section of the chapter, Tim Moses updates the discussions of reporting scales found in the previous four volumes of *Educational Measurement*, focusing on approaches to setting scales for large-scale testing programs. The third section covers equating approaches for alternative versions of the same test, and the fourth section describes approaches for relating scores and scales of different tests. The author discusses the relationship between the scaling and equating operations presented in the second through fourth sections and other testing program operations such as test development, scoring, and administration.

The author of Chapter 11 points out that recent trends in testing have created challenges in establishing and maintaining score scales of educational tests. One important challenge discussed in this chapter is the impact of the COVID-19 pandemic, which has resulted in an increase in alternative online administrations with mixed effects on reported scores.

A particularly timely discussion in Chapter 11 focuses on the challenge of addressing increasingly diverse testing populations that has, in turn, led to calls to develop and administer tests under less standardized conditions (Sireci, 2020), including ways that are adapted to test takers’ sociocultural backgrounds (Mislevy, 2018). The author recommends that, in part, these challenges be addressed by testing organizations being forthcoming in communicating the scaling and linking procedures they use, the assumptions they are making, and the extent to which comparability of scores is supported.

Chapter 12, “Standard Setting: A Cognitive and Social Model,” is the sixth chapter in Part III. Steve Ferrara, Susan Davis-Becker, Priya Kannan, and Katherine Reynolds begin the chapter by providing a historical overview of standard setting, highlighting the evolution of methods and policies around setting cut scores. The rest of the chapter focuses on the concept of panelists’ cognitive judgmental task as the kernel of various standard-setting methods. The authors draw on findings in judgment and decision-making research literature and use this information to “consider what may be going on in the minds of standard-setting panelists when they participate in standard-setting workshops and make judgments about cut scores” (p. 823).

To support this framework, the authors of Chapter 12 provide a proposed cognitive and social model of standard setting, a taxonomy of standard-setting methods defined by the underlying cognitive-judgmental tasks, and a comprehensive research agenda that raises various questions for scholars, including the influences of the facilitator on the panelists, interpanelist interactions and group dynamics, and a consideration of the larger sociopolitical context of standard setting. The authors provide suggestions for parsing these sociopolitical influences into those that may be desired and undesired, as well as strategies for designing and leading standard-setting activities to minimize the influence of undesired influences.

The seventh chapter in Part III is Chapter 13, “Reporting Scores and Other Results.” The purpose of this chapter is to “provide readers with a broad theoretical context for understanding reporting and reporting choices and to draw on the growing body of research on reporting test results that is relevant to practical problems” (p. 896). April L. Zenisky, Francis O’Donnell, and Ronald K. Hambleton make the point that when ordinary people think about tests, they are not thinking about models or theories; rather, they are thinking about test scores: What do they mean? People want to know whether they passed the test or whether their child passed the test. The score report is what answers these questions.

The authors of Chapter 13 point out that the topic of reporting test results cuts across the fields of psychometrics, marketing, communications, graphic design, cognitive science, and information processing. They introduce a seven-step model for reporting based on a synthesis of the work done by Hambleton and Zenisky (2013). The chapter includes insightful discussions of challenges and opportunities for score reporting such as next-generation assessments, subscore reporting, technology-based reporting, advances in data visualization, and situations where reporting formative interpretations are prioritized.

Chapter 14, “Realizing Fairness Through Accessibility for All Test Takers and for Specific Groups,” is the eighth and final chapter included in Part III and is authored by Michael C. Rodriguez and Martha L. Thurlow. This chapter is the second of two chapters in this volume that focus on fairness in testing. The first chapter, Chapter 6, appears in Part II, “Foundational Concepts,” and has a broader focus on fairness, emphasizing the importance of documenting evidence to support a combined valid/fair interpretation of test scores. The purpose of Chapter 14 is more focused and, to quote the authors, “is to apply the theory and concepts of a fairness argument to all test-taking populations, both in general and for specific groups of test takers” (p. 960).

The authors of Chapter 14 focus on two critical concepts: accessibility and an expanded version of universal design for assessment that includes universal design for learning. They make the point that fairness challenges are less about the characteristics of the test taker and more about the quality, inclusiveness, and responsiveness of test design and implementation. The chapter includes multiple examples that focus on fairness implications for both practice and research.

A final section in Chapter 14 addresses the “promise of culturally and linguistically responsive assessment to provide accessibility and achieve greater test

fairness” (p. 961). This section includes topics such as the role that cultural and linguistic backgrounds play in testing, CLR construct and domain definitions, test and item specifications that support CLR and assessment for social justice.

Part IV: “Specific Applications of Assessment”

Part IV, “Specific Applications of Assessment,” contains six chapters that focus on current issues in large-scale national and international assessments, licensing and certification, and social-emotional skills. A broad range of topics are covered in Part IV, including accountability, admissions, selection, placement and outcomes assessment, and assessments to inform instruction and learning. The chapters in this part are intended to appeal to a broad audience of educational measurement professionals.

The first chapter in Part IV is Chapter 15, “Assessment to Inform Teaching and Learning.” Susan M. Brookhart and Charles A. DePascale begin the chapter by making the point that in recent years, “expectations have risen that all assessments—not just those designed to be used formatively—should inform teaching and learning” (p. 1018). They describe and evaluate many of the assessments that stakeholders use to inform teaching and learning, both those designed for this purpose and those that have been designed for other purposes.

Eight general types of assessment are explored in Chapter 15: classroom formative assessment, interim assessment, common formative assessment, grading, state summative assessment, curriculum-based measurement, student learning objectives, and assessment based on learning progressions. The authors point out that these types of assessment vary in the nature of the measurement information they provide, their effectiveness, their quality, and their assessment literacy requirements. They emphasize that there is a public belief that any information that is available about student achievement should be used to inform teaching and learning and that this belief puts pressure on vendors and districts to produce products such as subscores and interim assessments.

The authors of Chapter 15 point out that the demand for information to inform teaching and learning requires that assessments are designed to be more student specific and to produce valid and reliable information about individual learners as well as groups. In addition, this information needs to be instructionally sensitive and situation specific so that it is relevant to, and can serve, a learning community, most often a classroom. They acknowledge that assessments need to continue to serve institutional, accountability, or administrative decision-making and produce reliable and valid data for groups within units such as schools, districts, and states. However, the authors suggest that these latter purposes are beginning to be overtaken by the formative purposes of assessment. They point out that this is happening in both effective and ineffective ways and that the field of educational measurement needs to understand this and work to support quality assessment in the face of increasing demands for assessment that supports teaching and learning.

Chapter 16, “Test-Based Accountability in K–12 Education,” is the second chapter in Part IV and is authored by Andrew D. Ho and Morgan S. Polikoff. It is important to note that the first three editions of *Educational Measurement* did not contain a chapter on accountability. The first chapter on accountability, which appeared in the fourth edition, was authored by Daniel M. Koretz and Laura S. Hamilton (2006) and provided a history of accountability in the United States from the 1980s through the No Child Left Behind Act of 2001. Chapter 16 extends this history through the following three national accountability policy periods.⁷ The authors provide a thoughtful discussion of how each of these periods brought its own set of measurement challenges.

Chapter 16 includes 10 sections that focus largely on assessment for accountability in the United States, including NAEP. The authors note that in contrast to the users of individual student scores, “accountability systems often incorporate many actors, and many derived scores, at many levels of an educational system. Who is holding whom accountable? By what mechanism? Using which scores? For what purpose?” (p. 1114). Issues addressed in the chapter include the historical development of K–12 test-based accountability, public accountability as reflected in NAEP, student and teacher accountability, and the impact of accountability policies on K–12 education. Also addressed are derived accountability scores, including growth models; evaluation of the alignment of assessments for accountability; validation of test-based inferences in accountability systems; accountability testing for special populations; and fairness and equity in accountability testing.

The chapter extends the framework and principles developed by Koretz and Hamilton (2006) and Koretz (2008) in relation to the validity of evidence collected under low-stakes administration conditions for accountability to the wide range of derived scores common in modern accountability systems. All topics in this chapter are covered in a clear and thorough nontechnical manner that is very accessible to a broad audience. The discussion of derived scores is particularly notable, with information presented in a nontechnical manner that provides a very accessible means for readers to gain insight into these important models.

The third chapter in Part IV is Chapter 17, “Assessment for Admission, Placement, and Outcomes in Higher Education,” authored by Wayne J. Camara, Lydia Liu, and Krista Mattern. The chapter describes the history, use, and design of many of the tests employed for admissions, placement, and outcomes assessment in the United States in the early 21st century. The authors also discuss the research on the validity, fairness, and reliability of these tests.

In Chapter 17, the authors point out that the role of standardized tests in U.S. higher education has undergone profound changes in the past few years as a result of COVID-19 and the social justice movement, the continued trend toward test-optional policies, and renewed challenges to affirmative action.

They refer to this situation as “a near-perfect storm, which further fueled alternative admissions processes without test scores” (p. 1194).

Chapter 17 includes an extensive discussion of the impact of both COVID-19 and the social justice movement on admissions testing and on higher education in general. In addition, the authors discuss some of the current legal challenges involving admissions testing, including the Varsity Blues case⁸ that resulted in the prosecution and conviction of an admissions consultant and several parents for using fraudulent means to gain advantage in the college admissions process for their children.

The authors conclude Chapter 17 by acknowledging that the use of tests in higher education, particularly for college admissions, remains one of the most controversial test uses in the United States. They point out that the accumulated evidence of validity, reliability, and fairness of the use and interpretation of test scores often has little positive persuasive effect on the general public. They end by saying that

in the next few years, we anticipate the release of additional research, which can better help us evaluate the efficacy and utility of admissions testing, and we hope such research will also address the efficacy and consequences of admissions practices and decisions made based on other factors. (p. 1243)

The fourth chapter in Part IV is Chapter 18, “Assessment for Licensing and Certification,” authored by Melissa J. Margolis, Rebecca S. Lipner, and Chad W. Buckendahl. This chapter includes sections that focus on a historical perspective for licensing and certification, fairness and legal issues, test development, reliability, validity, and setting standards, and it closes with a discussion of the future of assessment for licensing and certification.

The authors begin Chapter 18 by reviewing a number of terms—regulation, credentialing, licensure, certification—that are used to refer to different aspects of occupational oversight intended to protect practitioners, the profession, and the public from harm. They describe each of the terms and explain the nuances that contribute to their meaning. The authors of Chapter 18 point out that licensing and certification tests have differences that set them apart from tests used for other applications. They explain that, in part, these differences result from the higher stakes associated with licensing and certification examinations and the risks associated with granting credentials to unqualified candidates, which could pose serious dangers to the public. This is compared to the risks associated with creating barriers to employment and thus limiting the public’s access to services that could be provided by competent practitioners.

The authors describe the history of licensing and certification assessments and how perspectives and practice in this area have changed over time. They review legal considerations in licensing and certification contexts, particularly with respect to the ability to challenge testing practices and outcomes, and explore fairness considerations with respect to factors such as testing accommodations.

The majority of Chapter 18 is devoted to investigating the importance of fundamental assessment considerations in licensing and certification contexts. Some of the issues discussed relate to test development, including a discussion of “the importance of clearly

specifying the purpose of the test and focusing on test development as a data-driven process informed by an understanding of the knowledge and skills that one must demonstrate in the context relevant to the specific credential” (p. 1269). The topics of reliability, validity, and standard setting also are discussed, with a focus on factors that are particularly important in credentialing contexts, including classification accuracy, extrapolation from test performance to performance in practice, and procedural standard-setting considerations in credentialing contexts. The chapter concludes with a discussion of factors that have influenced change in credentialing assessment. These factors, comprising technological advancements, the rise of competency-based education, the move to integrate learning and assessment, and the rise of antitest and anti-regulation sentiments, have catalyzed recent change.

Chapter 19, “Assessment of Social-Emotional, Character, Behavioral, and Intrapersonal and Interpersonal Skills,” is the fifth chapter in Part IV. Patrick C. Kyllonen and Jiyun Zu begin by stating that studies suggest that measures of noncognitive skills are as predictive of educational, workforce, and everyday life outcomes as measures of cognitive skills are. The authors review what is known about these skills and how best to measure them. They discuss frameworks for key skills and uses of noncognitive skills measures for both high- and low-stakes tests. The authors review the predominant measurement approaches: self- and other-report ratings, anchoring methods, forced-choice and ranking methods, situational judgment tests, and games and simulations.

The authors of Chapter 19 point out that one roadblock to the adoption of noncognitive measures in schools is the belief that personality traits are immutable. They disagree with this characterization and argue that research shows that personal qualities such as work ethic and social skills can be changed with good teaching and appropriate support. They state that “what has largely distinguished noncognitive skills is not the nature of the constructs per se as much as it is the measurement method—cognitive skills tend to be measured with tests and noncognitive skills with ratings” (p. 1391). They conclude by noting that the level of interest in using noncognitive measures in both education and workplace settings “has outpaced the field’s ability to provide adequate measures of those skills” (p. 1392) and that “it is essential that the educational measurement community meets that interest [in noncognitive measures] with appropriate tools” (p. 1392).

The final chapter in Part IV is Chapter 20, “Large-Scale Assessments in International Contexts.” Henry Braun and Irwin Kirsch begin by defining international large-scale assessments (ILSAs) as group score assessments that typically focus on in-school K–12 students or adults 16–65 years of age living in households. These surveys assess and compare the knowledge, skills, experiences, behaviors, and attitudes of populations in multiple jurisdictions and languages. Since their inception, these assessments have experienced remarkable growth in participation and salience. The authors attribute this growth to perceptions of increased utility of the assessment results by policy makers and key stakeholders, resulting from the rapid changes taking place in the early 21st century. There is a continuing need

to respond to these changes with regard to the constructs being assessed and how best to measure them. This includes the introduction of new constructs, as well as the modification of existing constructs in both the cognitive instruments and the background questionnaires. The authors refer to these ongoing enhancements as a virtuous spiral.

Chapter 20 presents a historical context for ILSAs, as well as a framework that provides developers and users of ILSAs with a set of design criteria that can be used to evaluate the potential utility of the assessments. This framework, originally developed by Samuel Messick, is adapted by the authors. The chapter includes a discussion of new technologies and how they impact the management, development, and implementation of ILSAs, along with advances in methodology that impact scaling and data analysis. In addition, there is a discussion of a range of issues, including ways to evaluate the impact of ILSAs, some key technical challenges that must be addressed in future cycles, and political challenges that the growth of these assessments have raised. The authors conclude that

although it is certain that ILSAs will continue to face a number of challenges, we believe that the path along the virtuous spiral will continue to provide innovations that will enable ILSAs to address new and more complex questions. We expect that answers to these questions will lead to continued appreciation for the utility for such surveys. (p. 1491)

Part V: "Measurement as a Science"

Part V, "Measurement as a Science," contains only Chapter 21, "On the Nature of Measurement," authored by Derek C. Briggs, Andrew Maul, and Joshua A. McGrane. The purpose of Part V is to consider the practice and process of educational measurement as a special case practiced in the broader context of measurement in the psychological and physical sciences. In this final part of the volume, different perspectives from the philosophy of science are described and the status of measurement in education is considered from these perspectives.

The authors engage with the question of how educational measurement can be understood with respect to measurement more broadly and whether and how instances of educational measurement earn this claimed trustworthiness. In the second section of the chapter, they trace some key historical developments that help to explain how the concepts and terminology of measurement came to be invoked in educational and psychological contexts. In the third section, they argue that "whether one is speaking of measurement in an educational context, in psychology, or in the physical sciences, the activity will involve a common set of elements that serve to justify its claimed trustworthiness" (p. 1515)

The authors of Chapter 21 introduce a framework for understanding measurement with respect to four central components: theory, instrumentation, scales and units, and modeling. They illustrate and apply the framework briefly to the physical science context of measuring temperature and then more extensively to the educational

context of measuring reading comprehension. Although the central components of measurement are present in each context, there are unique challenges in education. In the fourth section, they take a closer look at three of these challenges that are likely to remain areas for discussion and debate in the future: (a) the meaning of validity and how it should inform measurement practices, (b) evolving conceptualizations of measurement error and uncertainty, and (c) the role of measuring scales and units in the evaluation of magnitudes.

SUMMARY

We congratulate all of the authors in this volume for the thoughtful, informative, and interesting chapters that they have produced for the fifth edition of *Educational Measurement*. We are hopeful that you, as readers, are both stimulated and informed by their contributions as you

approach the many complex challenges you must meet as you go about applying the science of educational measurement in the service of students, teachers, and the general community, whether as practitioners, educators, policy makers, or journalists.

ADDENDUM

Since the drafting of Chapter 1 of this volume, Donald J. Trump was inaugurated as the 47th President of the United States on January 20, 2025. According to Time Magazine, “the first 100 days of his second term have been among the most destabilizing in American history, a blitz of power grabs, strategic shifts, and direct attacks that have left opponents, global counterparts, and even many supporters stunned” (Cortellessa, 2025, para. 4).

Trump’s actions should not be a surprise to anyone. He has set about methodically addressing his campaign promises as documented in Project 2025, which Wikipedia describes as “a political initiative to reshape the federal government of the United States and consolidate executive power in favor of right-wing policies” (“Project 2025,” 2025, para. 1). One of those promises resulted in the creation of the Department of Government Efficiency (DOGE; The White House, 2025a), which was operational by the end of January 2025. Elon Musk, reputed to be the richest man in the world, was appointed by Donald Trump to lead DOGE, with the goal of cutting federal expenses by at least 30 percent. At the time we are writing this addendum, no federal agency has gone untouched. However, we will focus here only on cuts to agencies and funding that are impacting education and educational research.

We want to be clear that the purpose of this addendum is not to provide an extensive review of all of the funding cuts and threats to educational research and educational institutions brought about by the Trump administration’s policies. Our purpose is to provide a few examples that will help our readers understand the significant impact

the federal government is currently having on society and particularly on educational research.

One of the early cabinet appointments that Donald Trump made was the appointment of Linda McMahon as Secretary of Education (U.S. Department of Education, n.d.). Trump signed an executive order directing McMahon to “take all necessary steps to facilitate the closure of the Department of Education and return authority over education to the States and local communities” (The White House, 2025b, Sec. 2).

On March 11, 2025, McMahon announced a reduction in force of the Department that resulted in nearly 50% of the department’s work force being placed on administrative leave (U.S. Department of Education, 2025). At the time we are writing this addendum, the Institute of Education Sciences (IES), the research arm of the Department of Education, has seen budget and contract cuts that amount to hundreds of millions of dollars. Staff laid off at IES include the teams that administer tests such as the National Assessment of Educational Progress (NAEP), which is considered a gold standard of assessments and is the only national test that compares the performance of students across all 50 states, and the Programme for International Student Assessment (PISA), which measures the performance of U.S. students to allow comparisons to those around the world (Goldstein & Mervosh, 2025, para. 12).

The cuts to educational research supported by the federal government through the Department of Education have resulted in large numbers of researchers no longer able to complete their research or to find work in their field. In addition to cuts in federal funding that deal directly with education, large amounts of funding have been withdrawn from colleges, universities, and institutions carrying out research in a variety of areas. Withdrawal of research funds is causing universities to rescind admissions offers and to freeze hiring. The Trump administration has tied government funding to the need for universities to aggressively curb antisemitism and to be more open to conservative ideas. In March of 2025, the Trump administration cancelled \$400 million in grants and contracts to Columbia University alleging that the school had failed to fight antisemitism (Otterman & Stack, 2025).

On May 20th, 2025, The Harvard Crimson reported that the U.S. Department of Health and Human Services cut “an additional \$60 million in multi-year grants to Harvard over allegations of campus antisemitism and racial discrimination . . . the Trump administration’s third funding cut to Harvard in the last three months” (Patel & Yoon, 2025, para 1). This cut came in addition to the \$450 million cut announced the previous week and the \$2.2 billion cut announced in April by eight federal agencies. The university has sued the Trump administration over two of the funding cuts (Patel & Yoon, 2025).

In addition, very recently, the department of Homeland Security has revoked Harvard’s ability to enroll international students—which currently make up more than 25% of its enrollment—under the F-1 visa program (Diaz, 2025, p. 15). Secretary Kristi Noem said that Harvard was being targeted because they tolerate

“anti-American, pro-terrorist agitators” on campus (Mangan, 2025, para. 2). A temporary restraining order allowing international students to remain enrolled at Harvard pending a court hearing was issued. The university has filed a lawsuit challenging the ban on enrollment of international students (Mangan, 2025).

As well as making cuts in funding to colleges and universities, the Trump administration threatened to “withhold federal funding from public schools unless state education officials verified the elimination of all programs that it said unfairly promoted diversity, equity, and inclusion” (Bender, 2025, para. 1). In the same article, Bender also pointed out that “government-downsizing efforts led by Elon Musk . . . has said that it canceled 70 grants in the Education Department for D.E.I. [diversity, equity, and inclusion] training programs worth \$373 million” (para. 15).

We hope the few examples that we have provided will give our readers a sense of the political climate that is impacting educational researchers and educational institutions in the U.S. today. What we have not been able to describe adequately here is the fear in the educational research community and in U.S. colleges and universities that academic freedom, as we have known it, may be eroding. These fears are related to what is perceived to be punishment of both students and faculty members involved in protests that unfolded in the spring of 2024 over the Israeli-Palestinian conflict. Many protests were construed as antisemitic and have led directly to some of the losses in funding that we have described above. Students and faculty at universities who have participated in these protests have also suffered personal damage (Hartocollis, 2024).

Given the fast pace at which the Trump administration’s actions have unfolded, what we have written here is most assuredly obsolete, and may have been only days after we wrote it. For example, Elon Musk has left his quasi-governmental role, and there is strain between him and the president (Pager & Schleifer, 2025). As mentioned previously, our intent was not to provide an exact history of what has transpired in the first half of 2025, but to give a sense of the rapid changes and the resulting challenges posed in our field. It is unclear what the future of educational research, the institutions that support it, and public education may be in the U.S. We hope, however, that some good will come of the challenges we are witnessing now and that educational research and research institutions will emerge stronger as a result of the many stresses that are being placed on them.

NOTES

1. John Pitoniak, the uncle of Mary Pitoniak, was one of at least 84 veterans, most of them elderly, who died at the Holyoke Soldiers' Home after an outbreak of COVID-19 in March 2020. The Commonwealth of Massachusetts acknowledged in the settlement the "deliberate indifference" shown by administrators who combined infected or symptomatic veterans in a unit with those who did not have symptoms (Levenson, 2022).
2. According to Gloria Ladson-Billings, renowned theorist, author, and teacher, "critical race theory is a theoretical tool that began in legal studies, in law schools, in an attempt to explain racial inequity. It serves the same function in education. How do

you explain the inequity of achievement, the racial inequity of achievement in our schools?” (Anderson, 2022, Transcript section, para. 8).

3. #BlackLivesMatter was founded in 2013 in response to the acquittal of Trayvon Martin’s murderer. Black Lives Matter Global Network Foundation, Inc., is a global organization in the United States, the United Kingdom, and Canada whose mission is to eradicate White supremacy and build local power to intervene in violence inflicted on Black communities by the state and vigilantes (*Black Lives Matter: About*, 2024).
4. George Perry Floyd Jr. (October 14, 1973–May 25, 2020) was a Black American man who was murdered by a White police officer in Minneapolis, Minnesota, during an arrest made after a store clerk suspected Floyd may have used a counterfeit \$20 bill (“Murder of George Floyd,” 2024).
5. A movement of mostly young people dedicated to end the era of fossil fuels and support unions and Black, Brown, and working-class communities.
6. A cultural movement that advocates slowing down the pace of human life.
7. The periods are defined by the “growth model pilot program of 2005” (<https://www2.ed.gov/rschstat/eval/disadv/growth-model-pilot/index.html>), the “waiver” period beginning in 2011 (Congressional Research Service), and the Every Student Succeeds Act of 2015 (<https://www.everystudentsucceedsact.org>).
8. In Operation Varsity Blues, parents allegedly paid an admissions consultant between \$200,000 and \$6.5 million to guarantee their children’s admission to several different colleges and universities through a variety of means.

The History of Educational Measurement

Brian E. Clauser

NBME (Retired)

Jerome C. Clauser

American Board of Internal Medicine

Amanda L. Clauser

NBME

The history of educational measurement is not a simple history of evolving theory leading to the current state of the art. It is, in fact, multiple separate but related histories. There is a history of test theory and a related history defined by the key figures in a range of fields. Some of these figures, such as Charles Spearman, made critical contributions to test theory; others, such as Walter Bingham and Lewis Terman, influenced testing practice but are likely to go unmentioned in a discussion of test theory. Gustav Fechner studied psychophysics, Alfred Binet studied child development (and mesmerism), and Spearman explored the nature of intelligence; together, they provide a significant part of the foundation on which educational measurement has developed. Other important contributors, such as Truman Kelley, appear to have been singularly focused on the development of methodology.

In addition to these parallel histories built around theory and important contributors to the field, there is a history of evolving technology. Computers have become so widespread in test administration that someone new to the field might overlook the impact that the optical scanner had on testing practice during the second half of the 20th century. In addition to the obvious impact that technology has had on the scoring and administration of tests, computational power has profoundly impacted psychometric theory and practice. In the days when *computers* were individuals using slide rules or mechanical calculators, even a correlation coefficient might have required hours—or days—of work. Pearson (1907), Spearman (1904a), and Kuder and Richardson (1937) all put substantial effort into developing computationally simple approaches to approximating correlation (or reliability) coefficients. The increase in computational power since the 1930s has made such approximations seem quaint and has brought with it applications of Bayesian statistics, hierarchical models, and machine learning that have made educational measurement into something that would be almost unrecognizable to early practitioners.

There has also been an evolution in the application of testing. Spearman was interested in correlations across tests within populations as a means of understanding the nature of intelligence (Spearman, 1904a). Much early large-scale testing—in the military and industry—focused on personnel selection. In this context, tests evaluated individual differences. This same perspective accompanied the introduction of large-scale testing programs in schools, including not only achievement tests, which remain common, but also group IQ tests. Admissions tests follow a similar model; more recently, considerable emphasis has been given to national and international assessments for which individual scores may not even be calculated.

Finally, there is also a history related to the social trends and pressures that have provided the context in which educational measurement has evolved. The Darwinian revolution of the second half of the 19th century led to the eugenics movement, which had widespread support until the Second World War. Much of educational measurement in the early 1900s became inextricably tied to that movement. Similarly, it does not seem like unjustified speculation to suggest that the emphasis that Cronbach (1971, 1989b) and Messick (1975, 1989) placed on fairness and consequences as part of test validity

can be accounted for (at least in part) by the social context created by the civil rights movement and the war on poverty. These social pressures have also included an ebb and flow of the presence of the antitesting movement.

In considering the history of educational measurement, a similar challenge is raised by the question of where to begin. The use of examinations to select individuals for government positions in China began more than 3,000 years ago. In 1115 BCE, candidates were tested in the “six arts”: music, archery, horsemanship, writing, arithmetic, and rites and ceremonies of public and private life. During the Han dynasty—approximately 2,000 years ago—written examinations were introduced in the “five studies”: civil law, military affairs, agriculture, revenue, and geography. After the 7th century, national civil service tests were introduced for use across the empire. These tests emphasized the ability to remember and interpret the Confucian classics. They used both written and oral formats (Zhang & Luo, 2020). Modeled at least in part on these Chinese tests, in 1833 a testing program was introduced for selecting individuals for the British Indian civil service. Testing at universities as part of the process of granting degrees has also been an established practice for centuries (DuBois, 1970).

The breadth and depth of this history makes it clear that a comprehensive history is well beyond the scope of this chapter. Instead, we have identified specific parts of that history which we believe are relevant for understanding the current state of educational measurement. In selecting the parts we chose to stress, we considered several competing priorities. Most people find origin stories interesting. We hope that the events and individuals we discuss create a compelling story that will motivate some readers to explore this history in more detail. In this regard, we hope our chapter will provide a basis for basic historical literacy related to the field of educational measurement. In addition, we have attempted to provide context for understanding some of the major developments in both the theory and the practice of educational measurement. We are more likely to use measurement theories appropriately if we know the context in which they were developed. The reliability coefficient has become a ubiquitous part of test theory and practice, but our reliance on this coefficient may well have as much to do with the history of the field as it does with the usefulness of the coefficient (Cronbach & Shavelson, 2004). Additionally, viewing measurement and testing in the context of an early history that is closely tied to intelligence testing and eugenics is likely to help us understand the skepticism of and resistance to testing that have been present since the 1920s.

It is likely too much to hope that understanding the role that the misuse of measurement has played in supporting injustice will ensure that measurement is not misused in the future, but such an understanding is likely to help us remember that we need to ask not only what we *can* do with our technology, but also what we *should* (and should not) do.

With these considerations in mind, we have divided this chapter into eight sections, each with a different focus. The first section provides a discussion of some of the early foundations of educational measurement, including the contributions of Charles Spearman, Gustav Fechner, and Alfred Binet. To understand how Spearman’s contributions

came into being, we begin with the intellectual culture of the middle of the 19th century that led Francis Galton to study heredity and how Galton's use of correlation in that study provided the statistical tool that Spearman would subsequently apply to test scores. Fechner is important because his work on psychophysics represents what is likely the first scientific effort to measure psychological phenomena. Similarly, Binet introduced not only the intelligence test, but also, along with Theodore Simon, the idea that plots of performance against an independent variable (in this case, age rather than proficiency) can be used in test development.

The second section examines the rise of intelligence testing in the United States. We begin with the work of Henry Goddard and Lewis Terman in the first quarter of the 20th century. Their early work positioned them to be leaders in the development of the army testing program during World War I. That program provided a significant impetus for the rise of testing in the United States. The rise of intelligence testing in turn provided impetus for the eugenics movement in the United States.

The third section provides an overview of the impact that U.S. government programs have had on shaping the practice of educational measurement. This includes the related military research carried out during and after World War I. It also includes legislation that has funded education and both mandated and defined the scope of educational assessment.

The fourth through sixth sections trace the development of three critical aspects of test theory: classical test theory, scaling, and item response theory (IRT). The fourth section follows the development of classical test theory, picking up where the first section left off. This includes the work of Kelley, G. Frederic Kuder, and Marion Richardson, as well as Lee Cronbach's work on coefficient alpha, concluding with a discussion of the development of generalizability theory.

The fifth section builds on the discussion that was begun in the first section, which introduced the development of scaling through the contributions of Fechner and Binet. This section continues the story, following it through to the work of Edward Thorndike and Louis Thurstone, who together laid a kind of theoretical foundation for IRT. The sixth section discusses the independent but parallel development of IRT and Rasch measurement.

The seventh section again shifts from measurement theory to practice, examining the history of the use of large-scale tests both for selection and for accountability. We begin with the tests that Horace Mann introduced to evaluate the performance of the Boston school system in the first half of the 19th century. We then show how this type of test evolved to produce assessments like the College Board examinations and truly large-scale assessments, including the SAT (formerly Scholastic Aptitude Test) and the National Assessment of Educational Progress (NAEP).

The eighth and final section in this chapter shows how the five editions of *Educational Measurement* both document and have been a part of the history of educational measurement.

EARLY FOUNDATIONS OF EDUCATIONAL MEASUREMENT

As we noted in the introduction, educational measurement has a long history. Written standardized tests for selection of government officials were administered in China 3,000 years ago. Written tests have been used at universities for hundreds of years—the competitive mathematics test administered at Cambridge has been in place since the 18th century. Tests for the British Indian civil service began in 1833. These early tests for selection and graduation laid a foundation for the developments that followed. They used standardized conditions of administration and emphasized fairness and accuracy in scoring, but as DuBois (1970) noted, testing during this period lacked the theoretical framework and statistical techniques that have become the hallmark of educational measurement. Those conceptualizations had their roots in England, Germany, and France in work that spanned the period from 1860 through 1910.

England can appropriately be viewed as the birthplace of correlational psychology, and much of what we refer to as classical test theory has its beginning in the work of Charles Spearman (1863–1945), the best known of the early proponents of correlational psychology. Germany was the birthplace of experimental psychology. Gustav Fechner developed psychophysics procedures at the University of Leipzig and, in the process, provided what was likely the first scientific measure of psychological phenomena. Finally, in France, Alfred Binet developed an intelligence test with the practical goal of identifying children in need of special schooling.

Developments in England

In Harold Gulliksen's 1950 text, he summarized the history of classical test theory in a single sentence: "Nearly all the basic formulas that are particularly useful in test theory are found in Spearman's early papers" (p. 1). In a very real sense, Spearman created the foundation for what we know as mathematical test theory, so we begin this history by describing the historical context that brought Spearman's formulas into being.

The chain of events that led to Spearman's work began nearly half a century earlier and halfway around the globe. In 1858, Alfred Russel Wallace (1823–1913) was working in the Malay Archipelago. Wallace supported himself by collecting natural history specimens to be sold in England; he was also collecting evidence in an effort to answer the question of how species come into being. That year, he wrote a paper titled *On the Tendency of Varieties to Depart Indefinitely From the Original Type* (Wallace, 1858). That paper provided an elegant summary of Charles Darwin's—unpublished—theory of natural selection. Wallace mailed his manuscript to Darwin (1809–1882) with the request that if he thought it was of merit, he should forward it to the eminent geologist Charles Lyell. At the point at which Darwin received the letter, he had spent much of the previous 2 decades working (largely in secret) on the same theory and collecting material for a planned multivolume work on the topic.

The events that followed the arrival of Wallace's letter are well known. Darwin shared Wallace's paper with Lyell and Joseph Hooker, two men who were both preeminent members of the British scientific community and Darwin's closest friends. They arranged to have Wallace's paper published with two short pieces by Darwin (Brooks, 1984). All of this has importance to the history of test theory because it made Darwin realize that he could no longer delay publication of a more complete statement of his theory. In just over a year, the first edition of *On the Origin of Species* was published (Darwin, 1859). That book profoundly impacted the history of science; it also profoundly impacted Darwin's first cousin, Francis Galton.

Francis Galton

Francis Galton (1822–1911) was the quintessential Victorian polymath. He studied meteorology, created some of the first weather maps, and discovered the phenomenon of the anticyclone. He investigated the use of fingerprints for identification and wrote three books that were instrumental in the adoption of fingerprint technology (Galton, 1892, 1893, 1895). He explored a part of Africa previously unknown to Europeans (Galton, 1853). He wrote extensively on eugenics (Galton, 1909); in fact, he coined the term. But of all the seemingly limitless areas that Galton explored, his greatest contributions came from his study of heredity motivated by his reading of Darwin's *Origin*.

Galton had begun his intellectual life by studying medicine at King's College London. He had pursued medicine at the urging of his father; he also studied mathematics at Cambridge. After his father's death, Galton used his inherited wealth to mount an expedition to Africa. When he returned, he published a book on his travels (Galton, 1853) and was awarded a medal by the Royal Geographical Society. But as Stephen Stigler (1986) wrote, "Darwin's theories opened an intellectual continent" (p. 267) for Galton to explore far greater than Africa; Galton spent decades mapping that intellectual continent. This exploration of heredity led him to identify the phenomenon of regression to the mean and develop the powerful analytic tool represented by *correlation*.

Galton began his work on inheritance by documenting the extent to which exceptional talent was shared across generations in the same family. In *Hereditary Genius* (1869), he recorded instance after instance in which notable individuals (in the arts, science, and jurisprudence) have notable relatives in the same field. He used this evidence to argue that intellectual and personality characteristics can be inherited in the same way that physical characteristics are passed from parent to child. From a contemporary perspective, the book appears simplistic; Galton too quickly discounted the impact of environmental factors and personal advantage as explanations for his results. Within the context of the times, the work must have been more impressive. Darwin appears to have overlooked these alternative explanations when he wrote to Galton (Darwin, 1869, first paragraph):

I have only read about 50 pages of your Book (to the Judges) but I must exhale myself, else something will go wrong in my inside. I do not think I ever in all my life read anything more interesting & original. And how well & clearly you put every point!

Galton was an astute observer; he also carried out organized experiments to understand inheritance. In 1875, he experimented on pea plants. (Gregor Mendel's work had been published 9 years earlier in an obscure journal [Mendel, 1866], but remained unknown to the broader European scientific community.) Galton described the experiment in his autobiography (Galton, 1908).

The following question had been much in my mind. How is it possible for a population to remain alike in its features, as a whole, during many successive generations, if the average produce of each couple resemble their parents? . . . I was very desirous of ascertaining the facts of the case. After much consideration and many inquiries, I determined . . . on experimenting with sweet peas, which were suggested to me both by Sir Joseph Hooker and by Mr. Darwin. . . . I procured a large number of seeds from the same bin, and selected seven weights. I persuaded friends living in various parts of the country, each to plant a set for me. . . . The result clearly proved *Regression*; the mean Filial deviation was only one-third that of the parental one, and the experiments all concurred. The formula that expresses the descent from one generation of a people to the next, showed that the generations would be identical if this kind of *Regression* was allowed for. (pp. 300–302)

Galton followed the sweet pea experiments with efforts to collect data on humans. He solicited help from friends to collect physical measurements on parents and children and on siblings. He also opened the anthropometric laboratory at the International Health Exhibition in London. This allowed him to collect a range of measures on individuals who visited the exhibition (Galton, 1884).

These data collection efforts allowed Galton to refine his understanding of regression, and in 1886 he contributed two papers on familial relations to the Royal Society (Galton, 1886a, 1886b). These focused his attention on tables representing the relation between deviations in measures such as stature of the adult child and the same measures for parents. Galton realized that a relation existed between the measures, but he was at a loss to quantify it. Again, he described the event in his autobiography: "At length, one morning, while waiting at a roadside station near Ramsgate for a train, and poring over the diagram in my notebook, it struck me that the lines of equal frequency ran in concentric ellipses" (Galton, 1908). He returned to London and visited the Royal Institution in search of information on conic sections. At the Royal Institution, a chance encounter with the physicist James Dewar led to the suggestion that Dewar's brother-in-law, the mathematician J. Hamilton Dickson, might be able to help. Dickson viewed it as a simple problem and his solution was presented as an appendix to Galton's resulting paper.

Two years later, Galton (1888) introduced the correlation coefficient. At that time, the term and general concept of correlation were well established. As Galton stated,

“co-relation or correlation of structure” is a phrase much used in biology, and not least in that branch of it which deals with heredity . . . ; but I am not aware of any previous attempt to define it clearly, to trace its mode of action in detail, or to show how to measure its degree. (p. 135)

The 1888 paper built on his earlier work on regression. Again, using anthropological data, he showed how a coefficient could be produced by placing the measures of the correlated attributes on the same scale. This coefficient had the advantage that:

(1) $y = rX$ for all values of y ; (2) that r is the same, whichever of the two values is taken as the subject; (3) that r is always less than 1; (4) that r measures the closeness of co-relation. (p. 145)

Galton had succeeded not only in making an important contribution to the understanding of heredity, but also in providing the mathematical tools to explore a wide range of phenomena. Although we have found no references to indicate that Galton was aware of Spearman's use of the correlation coefficient, if he was aware of Spearman's work, he likely would not have been surprised. In the introductory chapter of *Natural Inheritance*, Galton (1889) commented that it would be worth the reader's time to understand the methodology he used in his study of heredity because of its wide application:

It familiarizes us with the measurement of variability, and with the curious laws of chance that apply to a vast diversity of social subjects. This part of the inquiry may be said to run along a road on a high level, that affords wide views in unexpected directions, and from which easy descents may be made to totally different goals to those we have now to reach. (p. 3)

Galton's great contribution to statistical science—and the history of educational measurement—was the phenomenon of regression to the mean and the powerful analytic tool correlation. There is, of course, some controversy about attributing the discovery of correlation to Galton, but at a minimum, he deserves credit for pointing out the broad usefulness of the procedure in the social and biological sciences. His own words written in another context describe his role in the history of correlation well: “It is a most common experience that what one inventor knew to be original, and believed to be new, had been invented independently by others many times before, but had never become established” (Galton, 1889, p. 33).

In addition to making direct contributions to the development of various fields of science, Galton impacted scientific development through the influence he had on the next generation of thinkers. One individual strongly influenced by Galton was Francis Edgeworth; Edgeworth made important contributions to the development of the correlation coefficient and wrote what may be the first discussion of the impact of measurement error on test scores; we will discuss his work in detail in a subsequent section. Another important follower of Galton was Karl Pearson.

Karl Pearson

Galton's concept of correlation is critical to classical test theory, but the specifics of the coefficient Galton created have long since been replaced by the more mathematically tractable form presented by Karl Pearson. (Galton's approach was based on median and interquartile distance rather than mean and variance.) Although Pearson spent relatively little time studying psychological measurement, his development of the product moment correlation coefficient and his relationships with Galton and Spearman make him a critical part of this history nonetheless.

Like Galton, Pearson (1857–1936) studied mathematics at Cambridge. Unlike Galton, who suffered a breakdown attempting to earn an honors degree, Pearson excelled in those studies, ranking third “wrangler” in the competitive examination taken by all Cambridge undergraduates studying math(s).¹ Pearson was an incredibly productive researcher and author: The annotated bibliography of his works contains 648 entries (Morant & Welch, 1939). Those hundreds of publications included important contributions to statistics; he is responsible for the chi squared test (Pearson, 1900) and for the product moment correlation coefficient (Pearson, 1896). Pearson presented the correlation coefficient in the following form,

$$R = S(xy)/(n\sigma_1\sigma_2) \quad (1)$$

crediting others with developing this equation; he used the bulk of his 1896 paper to argue for the advantages of this formula.²

Pearson devoted much of his professional life to advancing Galton's ideas. With Galton's support, he founded and edited the journal *Biometrika* to advance the statistical study of evolutionary biology. After Galton's death, Pearson held the Galton chair in eugenics, created with an endowment from Galton.

Pearson's admiration for Galton is clear in the following quotation from a speech Pearson delivered at a dinner in his own honor in 1934:

“Road on a high level,” “wide views in unexpected directions,” “easy descents to totally different goals”—here was a field for an adventurous roamer! I felt like a buccaneer of Drake's days. . . . I interpreted that sentence of Galton to mean that there was a category broader than causation, namely correlation, of which causation was only the limit, and that his new conception of correlation brought psychology, anthropology, medicine and sociology in large parts into the field of mathematical treatment. It was Galton who first freed me from the prejudice that sound mathematics could only be applied to natural phenomena under a category of causation. Here for the first time was a possibility—I will not say a certainty of reaching knowledge—as valid as physical knowledge was then thought to be—in the field of living forms and above all in the field of human conduct. (Pearson, 1934, pp. 22–23)

This speech also provides a vivid reminder of another part of Galton's legacy that Pearson embraced:

Buccaneer expeditions into many fields followed; fights took place on many seas, but whether we had right or wrong, whether we lost or won, we did produce some effect. The climax culminated in Galton's preaching eugenics, and his foundation of the Eugenics Professorship. Did I say "culmination"? No, that lies rather in the future, perhaps with Reichskanzler Hitler and his proposals to regenerate the German people. In Germany a vast experiment is in hand, and some of you may live to see its results. (Pearson, 1934, p. 23)³

Correlational Psychology in 1900

Eight years after Pearson published his paper on the product moment correlation coefficient, Spearman began publishing the papers that Gulliksen referred to as containing the formulas that are particularly useful in test theory. The content of those papers warrants special attention, but before examining that content, it is appropriate to consider the state of correlational psychology immediately before the publication of Spearman's papers. Spearman's methodological contributions to educational measurement were enormous, but he was not the first to apply correlational methods to psychology.

The first of these earlier papers we consider was written by William Bagley. Bagley (1901) tested schoolchildren using a range of what might be called physical and mental tests. In general, he found no relationship (or inverse relationships) between these measures. He specifically noted, "There seems to be little direct relation between mental ability as represented by reaction times, and mental ability as represented by class standings" (Bagley, 1901, p. 205). Although Bagley's paper has the title *On the Correlation of Mental and Motor Ability in School Children*, his approach to "correlation" was simplistic even in the context of the times. He examined the relationships between his measures by dividing the first measure into quintiles and averaging the values within each quintile. He then averaged the corresponding values of the second variable for the students in those same quintiles. The five pairs of numbers were then examined directly or plotted to determine whether any relationship existed.

Two additional papers from *Psychological Review* also provide examples of the prior application of correlation in psychology. Clark Wissler's Columbia University dissertation was published in 1901. S. Lovie and Lovie (2010) suggested that this was likely the first use of the product moment correlation coefficient published in a psychology journal. Wissler's paper was an early example of the now-proud tradition of using undergraduates in psychology research. Starting with the hypothesis that different measures of intelligence would be correlated, he reported on numerous measures of physical and mental proficiency, including reaction time, accuracy in marking out As in text, speed in marking out As in text, accuracy in drawing a line, length and breadth of head, and class standing in numerous subjects. Contrary to Wissler's hypothesis, the strength of these relationships was modest except for that between class standing in different subjects. Wissler recognized that "failure to

correlate” may be “due to want of precision in the tests” (Wissler, 1901; p. 29) but gave no serious consideration to how reliability might be calculated or used to adjust the correlation.

The second of the two papers (Aikens et al., 1902) also presents relations between measures of proficiency. The research shows a remarkable lack of statistical sophistication. The “correlations” that are presented have no clear relationship to the Pearson product moment approach. Instead, they used what might be described as a make-shift approximation. Again, the results show generally modest relations between the measured proficiencies, and again, the paper lacks any consideration of how to evaluate the impact of systematic or random effects that might impact the correlation of interest.

Charles Spearman

As a young man, Spearman had an interest in Indian philosophy and joined the army with the hope of being stationed in India. In his 1930 autobiographical chapter, Spearman described the nearly 15 years he spent in the army as wasted, although it did give him the opportunity to complete a 2-year “staff college.” Not long after completing these studies, he resigned his commission and moved to Leipzig to study psychology with Wilhelm Wundt. His studies were interrupted when he was recalled to the army at the outbreak of the Boer War, but eventually he returned to Leipzig, completed his doctorate, and subsequently became a professor at University College London (P. Lovie & Lovie, 1996; S. Lovie & Lovie, 2010; Spearman, 1930).

Spearman’s work focused on understanding the nature of intelligence. Although his most enduring contribution to science may be the methodological tools he developed for correlational psychology and test theory, these tools were developed to support empirical evaluation of the nature of intelligence and specifically to explore the theory that there is a general factor that underlies all measures of intelligence. Differences in reliability across tests impacted the observed correlations between test scores. Much of Spearman’s methodological work was focused on accounting for this effect.

We began this discussion of the developments that took place in England with Gulliksen’s reference to Spearman’s early papers (Gulliksen, 1950). The first of these papers was “The Proof and Measurement of Association Between Two Things” (Spearman, 1904b). This was followed later in the same year by “‘General Intelligence’ Objectively Determined and Measured” (Spearman, 1904a). Both were published while Spearman was still working on his dissertation in Leipzig. Interestingly, these papers were unrelated to his dissertation work, which focused on spatial localization, a topic more in line with Wundt’s program of research (Jensen, 1998; Tinker, 1932). The first paper introduced variations on the rank-order correlation coefficient and argued for the advantages of correlation based on ranks rather than measures. It also presented Yule’s (1897) formula for partial correlation, which Spearman stated he derived using

an independent approach. Most importantly, the paper introduced the formula for estimating true score correlation (p. 98)⁴:

$$r_{pq} = \frac{r_{p'q'}}{\sqrt{r_{p'p'} \cdot r_{q'q'}}}. \quad (2)$$

In this equation, r_{pq} represents the true score correlation between variables p and q , $r_{p'q'}$ is the observed correlation between p and q , and the denominator on the right side of the equation represents the square root of the product of the reliabilities for p' and q' .

In discussing the importance of correction that this formula produced, Spearman quoted a paper in which Pearson had concluded that “the mental characteristics in man are inherited in precisely the same manner as the physical” (Spearman, 1904b, pp. 97–98). Spearman pointed out that if the observed correlations between relatives are similar (which Pearson reported), the actual relationship must be substantially stronger for the psychological characteristics because they are measured less precisely. This criticism started a feud between the two University College London professors that continued for nearly a quarter of a century.

Pearson’s immediate response to Spearman’s criticism was to republish the lecture Spearman cited, adding an addendum responding to the criticism (Pearson, 1904). The addendum attacked Spearman’s correction for attenuation because it was capable of producing results that exceed unity and called on Spearman to provide algebraic proofs of the formulas. Spearman responded to Pearson’s criticism in 1907 with a “Demonstration of Formulae for True Measurement of Correlation.” That same year, Pearson published a paper on methods for estimating correlation and again attacked Spearman’s work. In Pearson’s 39-page report (Pearson, 1907), Spearman’s name appears more than 20 times. This creates the impression that the real motivation behind the publication may have had more to do with attacking Spearman than with advancing the practice of correlational science.

The last of Spearman’s papers to make a major contribution to test theory, “Correlation Calculated From Faulty Data,” was published in 1910. It again responded to Pearson’s criticisms and, more importantly, presented the Spearman–Brown formula,

$$r_{x[p],x[p]} = \frac{p \cdot r_{x[q],x[q]}}{q + (p - q)r_{x[q],x[q]}}. \quad (3)$$

In this formulation presented by Spearman (1910, p. 281), $r_{x[q],x[q]}$ represents the reliability of a test with $2qi$ items (with i being any number), and $r_{x[p],x[p]}$ represents the reliability when the test comprises $2pi$ items.⁵ This formula represents a seminal contribution to test theory. When the test length is doubled, the formula provides a basis for estimating split-half reliability. As we will see, this framework led to conceptualizing reliability in terms of interitem correlation and ultimately led to coefficient alpha.

Immediately following Spearman’s paper in the *British Journal of Psychology* was a paper by William Brown (1881–1952; Brown, 1910a), which presents an alternative proof for the same formula. Because of this, the names Spearman and Brown have

been linked as though they were coauthors; that is an ironic misconception. The work presented in Brown's paper comes from his then-recently completed dissertation. The dissertation was also published by the author (Brown, 1910b) and in modified form as *The Essentials of Mental Measurement* (Brown, 1911). Much of the dissertation—and the subsequent book—was an attack on Spearman. Both publications so carefully documented Pearson's criticisms of Spearman that even without Brown's acknowledgment—"Professor Pearson has very kindly read the entire thesis in proof, and made several useful suggestions" (Brown, 1910b, p. 1)—it would be clear that Pearson and not Spearman had influenced Brown's work.

Spearman's 1910 paper is a response to Pearson's criticisms, and he clearly hoped to minimize their differences, concluding, "On the whole, if we eliminate these misapprehensions and oversights, there seems to be no serious difference of opinion on all these points between Pearson and myself" (p. 288). If this was intended as an olive branch, it was one that Pearson did not accept; Pearson continued his attacks for years to come (e.g., Pearson & Moul, 1927).

That said, there is one area in which Pearson and Spearman seem to have been in agreement: They both fully supported the eugenics movement. The following quote concisely captures Spearman's views: "One can conceive the establishment of a minimum index (of general intelligence) to qualify for parliamentary vote, and above all, for the right to have offspring" (Hart & Spearman, 1912, p. 79).

Spearman's Immediate Impact on Measurement

Despite Pearson's criticism, Spearman's ideas became widely accepted, although it is difficult to make a clear statement about how fast that acceptance came about. Edward Thorndike, Wilfrid Lay, and P. R. Dean published a paper in 1909 calling the conclusions of Spearman (1904a) into question, but that same paper applied Spearman's correction for unreliability without comment. The authors appeared to accept Spearman's methodology while rejecting the idea that the available evidence supported the existence of "general intelligence."

Two years later, A. R. Abelson—also at University College London—published an extensive study on the development of a battery of tests. In this paper, Abelson used Spearman's methodology and provided what may be the first example of the use of reliability coefficients to determine the number of items to include on a test form (Abelson, 1911).

By the middle of the 1920s, numerous researchers had published empirical studies evaluating the accuracy of the Spearman–Brown formula. Using a variety of tests, the researchers compared the predicted reliabilities to actual results produced by changing the test length: Holzinger and Clayton (1925) did so using the Otis advanced mental test, Ruch et al. (1926) used spelling words, and B. D. Wood (1926) used achievement tests. The results left little doubt about the usefulness of the formula. Remmers et al. (1927) extended these findings by applying the Spearman–Brown formula to rating

scales and showing that the formula predicted the change in reliability as a function of the number of raters completing the scale.

As we will discuss in a subsequent section, the formulations provided by Spearman did much to shape thinking about reliability for the next 50 years. Numerous researchers made substantial contributions, but the general approach based on correlation coefficients and a conceptualization of reliability as split-half reliability remained intact.⁶

Psychophysics and the University of Leipzig

It would be difficult to write a history of educational measurement and not mention the University of Leipzig. The fact that Charles Spearman received his doctorate from Leipzig would be enough to ensure inclusion, but the university made a foundational contribution to what would become educational measurement well before Spearman arrived. Psychophysics can reasonably be viewed as the starting point for the empirical study of psychology. Gustav Fechner's (1801–1887) 10-year project that culminated in his *Elements of Psychophysics* (1860/1966) may reasonably represent the first effort to measure the psychological. In the process, he laid the foundations for psychological scaling. Stigler (1999) also credited Fechner's work as being the reason that psychology was the first of the social sciences to incorporate statistical theory.

Fechner was born in 1801 in Lower Lusatia, part of the Holy Roman Empire. He moved to Leipzig at the age of 16 to study medicine and stayed for the rest of his life. For the history of educational measurement, and more broadly psychology, the critical events took place in 1850 when Fechner apparently had a kind of epiphany. As Stigler (1986) stated, the stories of that epiphany are “colorful and dramatic” (p. 243). The dramatic aside, Fechner's interest not only in physics but also in philosophy and psychology led him to think about the relationship between physical energy and psychological energy; his insight was that if it is possible to measure physical energy, it must also be possible to quantify the corresponding psychological energy. Fechner took inspiration from the work of Ernst Weber (1795–1878), who was also at the University of Leipzig. Weber had done earlier work on discriminating between physical stimuli and had concluded that the magnitude of a just noticeable difference was a fixed proportion of the base stimulus (Boring, 1950). The study of just noticeable differences can take many forms. For example, a subject might be asked to lift two weights—which outwardly appear identical—and report on whether they are of equal weight or if one is heavier than the other. Obviously, if the difference in the two weights is small enough, it will generally not be perceived. As the difference increases, the probability that it will be perceived increases. Weber's law (sometimes known as the Weber–Fechner law) posits that the ratio of the difference between the two weights (ΔI) and the base weight (I) is a constant (k):

$$\frac{\Delta I}{I} = k. \quad (4)$$

Put another way, as the base weight of the objects increases, the difference in weight between the objects must increase proportionally to have the same probability of being

noticed. As we will discuss in more detail in the section on scaling, Fechner modified this relationship by basing it on the logarithm of the stimulus.

For the bulk of Fechner's work in this area, he experimented with discriminating between weights. He used apparently identical containers, one of which represented the base weight and the other of which would have an additional weight placed inside. For a given pair of weights, the relevant metric was the number of correct responses divided by the number of trials. The resulting Weber-Fechner law was a central result reported in the *Elements of Psychophysics* (Fechner, 1860/1966), but the real contributions of Fechner's work are methodological. Over time, both the accuracy and the generalizability of the law have been called into question, but the general approach Fechner used provided a model for subsequent work in psychophysics, and more importantly, Fechner introduced research design and statistical analysis into the practice of psychology.

Fechner recognized that a wide variety of factors could impact his results: which hand was used, which weight was presented first, the subject's level of fatigue. To account for these sorts of effects, he used balanced factorial designs that allowed him to not only account for the effect across repetitions of the experiment, but also directly estimate the effect of different conditions. For example, he might have a subject lift the same two weights with both the right and the left hands. Although Fechner did not use random sampling, Stigler described the *Elements of Psychophysics* (Fechner, 1860/1966) as the most comprehensive treatment of experimental design to appear before R. A. Fisher's (1935) *Design of Experiments* was published 75 years later.

In imagining Fechner's (1860/1966) experiments, it may be easy for the reader to envision a laboratory in which undergraduates queued up to participate in replications in which they lifted weights. This would be far from the reality. Much of Fechner's work was carried out with Fechner as the only subject—a subject who knew which container contained which weight.

After Fechner retired from lecturing, Wilhelm Wundt came to the University of Leipzig. Wundt continued the psychophysical program of research and established the Institute for Experimental Psychology. This would become the world's first graduate program in psychology.

Alfred Binet

In the early 1900s, when Spearman was publishing the papers that provided the foundation for test theory, Alfred Binet (1857–1911) was publishing a series of papers that provided a foundation for the practice of intelligence testing. Although Binet worked as a psychologist for decades, these papers and the scale they describe are the reason his name is so widely recognized.

Binet studied law; he received his license in 1878, but was unhappy with his career choice and began reading psychology at the Bibliothèque nationale, where he became familiar with Galton's work. In 1882, he met Jean Martin Charcot and Charles Féré and began working in Charcot's laboratory observing and experimenting with the effects of hypnosis on hysteria. In 1887, Binet published a monograph with Féré entitled *Le mag-*

netisme animal. During that year, he also became a student at his father-in-law's laboratory of embryology at the College de France. At the laboratory, he spent several hours per week practicing dissection. The results of this work provided the basis for Binet's doctoral dissertation, *A Contribution to the Study of the Subintestinal Nervous System of Insects* (Wolf, 1973).

During this time, Binet acted as an outspoken supporter of Charcot's ideas about hypnosis. As the debate over these ideas became more heated, the relatively young Binet found himself in an unenviable and untenable position and eventually severed his relationship with Charcot. In search of a new institutional affiliation, Binet requested a staff position at the Laboratory of Physiology and Psychology at the Sorbonne. In 1894, he became director of the laboratory and in collaboration with the previous director founded the first French psychology journal, *L'année psychologique* (Wolf, 1973).

During the latter part of his career, Binet had several less senior collaborators; the most noteworthy of these was Theodore Simon. When Simon approached Binet, he had completed medical school studies and needed a thesis to finalize his degree. At the time, Simon was an intern at the colony for children and adolescents with intellectual disabilities at Perray-Vaucluse. Rather than accept Simon into the laboratory outright, he challenged him to return to the colony and take a series of measurements of each of the 223 boys in the institution and report descriptive statistics for each measure by age group. Several months later, Simon returned, with his analyses completed, and was accepted by Binet; the measurements formed the basis of the thesis for his medical degree.

At the same time that Simon became Binet's assistant, Binet was asked to become part of the *Societe libre pour l'etude psychologique de l'enfant*. The society was subsequently asked to form a commission on the education of children with intellectual disabilities. Part of the commission's charge was to develop a means of identifying children who would benefit from being educated outside the regular classroom. As Binet and Simon described it (1916),

In October 1904 the Minister of Public Instruction named a commission which was charged with the study of measures to be taken for insuring the benefits of instruction to defective children. . . . They decided that no child suspected of retardation should be eliminated from the ordinary school and admitted to a special class, without being subjected to a pedagogical and medical examination from which it could be certified that because of the state of his intelligence, he was unable to profit, in an average measure, from the instruction given in the ordinary schools. (p. 9)

They go on to say that such decisions about placement

have at all times too much the nature of the arbitrary, of caprice, of indifference. Such a condition is quite unfortunate because the interests of the child demand a more careful method. To be a member of a special class can never be a mark of distinction, and such as do not merit it, must be spared the record. (pp. 9–10)

As a leader of the society, Binet was appointed to a commission and spent much of the remainder of his career (and his life) working on this problem.

Between 1905 and 1911, Binet and Simon published a series of papers in *L'année psychologique* that outlined the problem and recorded the effort they made to develop an instrument to identify children with intellectual disabilities.⁷ They began by reviewing the state of the art for such diagnosis, arguing that at the time diagnosis was typically carried out by physicians who based their conclusions on physical symptoms. Binet and Simon asserted that causes such as birth trauma or hydrocephalus may result in disability, but they do not explain the extent of the intellectual deficit. They cited a number of diagnostic frameworks with categories such as *hydrocephalic idiocy*, *epileptic idiocy*, and *traumatic idiocy*. They then argued that even when previous researchers had provided diagnostic criteria based on observable manifestations of intelligence, the criteria had been too vague to be useful. For example, one system stated that “in profound idiocy ‘the attention is fugitive,’ while in imbecility, ‘the attention is fleeting’” (Binet & Simon, 1916; p. 23).

In their next paper, also in 1905 (included in Binet & Simon, 1916), Binet and Simon laid out a synthetic approach including psychological, pedagogical, and medical methods. They began their description of the psychological method by admitting the limitations on measurement when it is applied to intelligence: “The scale properly speaking does not permit the measure of intelligence, because intellectual qualities are not super-posable, and therefore cannot be measured as linear surfaces” (Binet & Simon, 1916; p. 40).

They noted that previous researchers had built their approaches on theory. By contrast, Binet and Simon made practical decisions in constructing their scale. They tried many tests and retained those that proved useful. They designed their individual tests to be administered quickly to avoid fatigue or loss of interest on the part of the child. Finally, they described what we would now refer to as standardized conditions for the tests: “The examination should take place in a quiet room”; “the child should be called in without other children”; when the child is introduced to the experimenter, “he should be reassured by the presence of someone he knows”; and so on (Binet & Simon, 1916; p. 44).

Binet and Simon then presented procedures for carrying out 30 tests. At the simple end of the continuum, the experimenter was instructed to move a lit match across the subject’s field of vision and record whether he or she followed it visually. They assessed “recognition of food” by alternately presenting a piece of chocolate and a similarly shaped piece of white wood. The most sophisticated test required the subject to define abstract terms: for example, “What difference is there between weariness and sadness?”

Binet and Simon followed this description of their procedures with a 90-page report on applications of their new method. Binet’s contribution to educational measurement may be viewed as more of a contribution to practice than to theory. That said, the presentation of the original Binet–Simon scale included methodological and conceptual breakthroughs that have been enormously important. The first of these is empirical eval-

uation of tests (items) for inclusion in the scale. Binet and Simon tried out numerous tests and retained those that discriminated between children of different ages. Although they did not have sophisticated mathematical models to guide them, their approach to evaluating test material was a precursor to the item characteristic curves that would become an essential part of IRT.⁸

The second conceptual contribution that Binet and Simon made was the idea of a norm-referenced interpretation of the scores. Although the samples that were used for the development of their original scale were small—often in the range of 8 to 15 children for a specific age group—they attempted to use children who would be described as average for their age. Admittedly, this seems quaint when compared to the approaches to norming examinations that were used later in the century, but conceptually Binet and Simon provided the starting point for this practice.

The remainder of the work on the Binet–Simon scale was published in 1908 and 1911 (see Binet & Simon, 1916). Both papers describe revisions. In the present context the details are unimportant, but there are two issues that remain salient in the context of intelligence testing. The first is the recognition that these tests are sensitive to education; they are not tests of innate intelligence. One motivation for revision was to remove (sub)tests that were particularly sensitive to education. The second issue is the extent to which scores are influenced by “social conditions.” In the 1911 paper (included in Binet & Simon, 1916), they discussed the work of other researchers who applied their methods and found that many of the children performed well above their age level. They hypothesized that the differences resulted from the fact that the second set of children were from more affluent conditions. Clearly, concern about bias in intelligence testing has a long history.

One final contribution from Binet is an early conceptualization of what we now think of as adaptive testing. Binet recognized that there was little value in administering a test that was very difficult or very easy for the child. He instructed the administrator to move quickly through tasks that were easily mastered by the child or skip them altogether if other evidence from interacting with the child made it clear that the tests would not be useful. Clearly, this practical approach that focused on maintaining the child’s attention is a far cry from the statistically sophisticated approaches that are currently available for adaptive testing, but it shows that an understanding of the value of matching item difficulty to test-taker proficiency was present from the early part of the 20th century.

Taken together, the work that went on over a century ago in England, Germany, and France did much to provide the theoretical foundation of educational measurement. In the next section, we describe how that foundation led to the widespread use of intelligence tests in the United States and how that use has impacted and continues to impact the field of educational measurement.

THE RISE OF INTELLIGENCE TESTING IN AMERICA

Clearly, the development of educational measurement in the 20th century was tightly linked to intelligence testing. Spearman’s main interest in test scores was as a means

of understanding human intelligence, and Binet's motivation was the assessment of intelligence in schoolchildren. In addition to these more obvious connections, one of the earliest efforts to systematically quantify intelligence had its methodological roots in Leipzig.

James McKeen Cattell

In 1882, James McKeen Cattell (1860–1944) won a fellowship to study philosophy at Johns Hopkins. At Hopkins, he worked in G. Stanley Hall's psychology laboratory, where he measured the time in milliseconds it took subjects to recognize letters of the Latin alphabet (Sokal, 1990). After a year at Hopkins, Cattell moved to Leipzig to work on a doctorate at Wundt's laboratory, again studying reaction time. When he left Leipzig, he moved to England to study medicine. In England he met Galton, who was actively working on collection and analysis of anthropometric data (Galton, 1884). Both the reaction time work and anthropometric measurement influenced Cattell's contribution to the history of intelligence testing. In 1891, Cattell moved to Columbia University and established a psychology laboratory; 3 years later, he began testing each student entering Columbia College. The testing program went on into the beginning of the new century. Ultimately, some of these data were analyzed by Clark Wissler (1901) using product moment correlations. The results (which again showed few relations among scores from the different tests) put an end to Cattell's program of research and substantially deterred the use of psychophysical measurements in subsequent intelligence testing (Sokal, 1990). These results ended Cattell's testing program but did nothing to undermine the perceived need for measures of intelligence. As we discussed in the previous section, in 1905 Binet and Simon began publishing work to fill that need, and it was not long before Henry Goddard started to apply Binet and Simon's methods in the United States.

Henry Goddard

Like Cattell, Henry Goddard (1866–1957) studied with G. Stanley Hall, earning his doctorate under Hall in 1899. In 1906, Edward Johnstone, superintendent of the New Jersey School for Feeble-Minded Boys and Girls in Vineland, offered to build Goddard a laboratory if he would come to Vineland to conduct research. Goddard spent the next 2 years working with the diverse population at Vineland and came to conclusions similar to those described by Binet and Simon in their 1905 paper (see Binet & Simon, 1916). Both in France and in the United States the main responsibility for such children fell to physicians, and in both countries the diagnostic classifications and criteria were all but useless.

In 1908, Goddard set out on a tour of Europe in search of more useful approaches, and while in Belgium he came across the intelligence tests developed by Binet and Simon. Goddard's experience at Vineland put him in a position to see the value of Binet's work, and when he returned to New Jersey he translated the tests and began to use them. The resulting scale agreed with the impressions of the Vineland staff

who had direct experience with the children, and Goddard rapidly became a convert. By 1910, Goddard had used the Binet–Simon method extensively. That year, at Goddard’s urging, the Classification Committee of the American Association for the Study of the Feeble-Minded adopted the method. This was a turning point for intelligence testing because it represented formal acceptance of the approach within the medical community (Zenderland, 1990, 1998).

Although Goddard’s immediate challenge at Vineland had to do with decisions around educational placement for children, his interest in *feeble-mindedness* broadened quickly. In 1911, he used the Binet–Simon test in public schools. By 1913, he had tried out the tests at Ellis Island (Zenderland, 1998). At that point, he had already published his eugenically motivated book, *The Kallikak Family* (Goddard, 1912). Kallikak was a pseudonym for a family that Goddard studied; at the time, Deborah Kallikak lived at Vineland. The book was a kind of mirror image of Galton’s *Hereditary Genius*; instead of tracing recurrent instances of genius within the same family, Goddard traced instances of mental deficiency within a single family. Interestingly, although the book highlights the cost to society of such families, Goddard also advocated for the positive results that would be produced by what he viewed as appropriate education.⁹

Goddard was not alone in his interest in the Binet–Simon scale. In 1911, Lewis Terman published an account of his application of the scale with 400 children. And before Terman published the first version of the Stanford–Binet scale there were at least four other English translations and revisions (Hilgard, 1989). In addition to having continued in use through multiple revisions, Terman’s version of the test popularized the use of the intelligence quotient (IQ).¹⁰ This work by Goddard and Terman positioned them both to make contributions when the entrance of the United States into World War I led to a new application for intelligence testing.

Robert Yerkes and Mental Testing in the Army

There can be little doubt that the large-scale use of group intelligence tests during the First World War did much to raise the profile of psychology as a profession and testing as an accepted part of American life. Several authors have called into question the extent to which the test results were used to make important decisions about recruits (e.g., Gould, 1996; Minton, 1990), but there is no question that the army testing program demonstrated the potential for large-scale testing. Although numerous individuals shaped the project, it was led by Robert Yerkes (1876–1956). When Woodrow Wilson went before Congress to ask for a declaration of war, he also asked that universal conscription be instituted to provide the necessary manpower to wage war. Yerkes, the president of the American Psychological Association (APA), saw an opportunity. It is impossible to know to what extent he saw that opportunity as a chance for psychologists to contribute to the war effort and to what extent he may have been motivated by a desire to raise the

profile of psychology as a profession—and, with it, his own standing. Any combination of these motivations may have existed.

Weeks after the declaration of war and before the draft was approved, Yerkes called a meeting of the APA's executive council in Philadelphia. At the meeting, the council approved the formation of an APA Committee on Methods of Psychological Examining of Recruits. The committee met the next month at Vineland (Samelson, 1990; Yoakum & Yerkes, 1920). The group represented a who's who of intelligence testing, including Yerkes, Goddard, Walter Bingham, and Terman. At this time, intelligence tests were typically individually administered, and the initial plans were based on this model. The committee quickly realized that an alternative was needed and within weeks they had developed a prototype for a standardized, group-administered test that could be efficiently administered and scored.

Although the prototype for the army test was put together relatively quickly, it went through various stages of revision and evaluation. After revision, 10 tests remained. These tests were administered to approximately 5,000 men in the U.S. Army and National Guard, as well as samples from "institutions for the feeble-minded," officer training schools, and colleges and universities. The papers were then sent to Columbia University to be evaluated by a group led by E. L. Thorndike "to check their validity, reliability and significance" (Yoakum & Yerkes, 1920, p. 5).

The proposal for widespread testing of recruits with what was termed the Army Alpha was accepted and a school was established for training in military psychology; by the end of the war on November 11, 1918, approximately 120 officers, 300 enlisted men, and 500 clerks were involved in the examination effort. Yoakum and Yerkes (1920) stated (with impressive precision) that 1,726,966 men were examined.

The Army Alpha

The Army Alpha represented a pivotal point in the development of educational measurement in the United States. It represents the beginning of truly large-scale testing and widespread use of intelligence tests. It also provides results that fanned the flames of the eugenics movement and led to the antitesting movement.

As we noted, the committee working on the test quickly came to the realization that a group test was needed. This decision was critically important, but it was not unprecedented. In 1913, William Pyle published *The Examination of School Children*; this was likely the first group intelligence test. It was based on simple constructed response formats (Weinland, 1973).

A second important contribution that impacted the development of Army Alpha was made by Frederick Kelly. In 1915, Kelly published *The Kansas Silent Reading Test*. He was concerned about the unreliability of teachers' marks; he had written his dissertation on the topic. Kelly also hoped to reduce the time and effort required for administration and scoring of tests. Working at the State Normal School at Emporia, Kansas, and then as dean of education at the University of Kansas, he developed an item type that allowed for selection rather than construction of responses. The following two

items qualify as icons in the field of educational measurement in that they are two of the first multiple-choice questions ever published:

Think of the thickness of the peelings of apples and oranges. Put a line around the name of the fruit having the thinner peeling.

apples oranges

Three words are given below. One of them has been left out of this sentence: I cannot _____ the girl who has the flag. Draw a line around the word which is needed in the above sentence.

red see come

Although some parts of the Army Alpha required simple constructed responses—"How many men are 30 men and 7 men?" (Yoakum & Yerkes, 1920, p. 206)—most used the multiple-choice format.

A final contribution that impacted the development of the Army Alpha was made by Arthur Otis (1886–1964). In 1917, Otis was a graduate student at Stanford University, working with Terman. Otis had developed a group intelligence test and Terman brought a copy of the unpublished manuscript to Vineland (Yoakum & Yerkes, 1920). Yerkes's committee, working at Vineland, reviewed hundreds of published tests and ultimately modeled the Army Alpha on Otis's work. Otis interrupted his graduate studies to participate in the development and administration of Army Alpha. He published his version of the test in 1918 (Otis, 1918a, 1918b). After the war, Otis finished his degree and joined the World Book Company,¹¹ which published the Otis Group Intelligence Scale in 1920 and the Otis Self-Administering Tests of Mental Ability in 1922.

Terman, Peacetime Intelligence Testing, and Controversy

Whether the Army Alpha was used for important decisions and improved the efficiency of the war effort may be in question, but there is little doubt that the demonstration of large-scale intelligence testing provided support for the intelligence testing movement in the United States. Application of testing in the army took a back seat until the United States entered the Second World War, but group tests were rapidly adopted by school systems. By 1922, there were more than 40 group intelligence tests being published and in the 1922–1923 school year more than 3 million students were tested (Weinland, 1973). This number continued to rise and large-scale use of intelligence tests continued for decades.

In addition to publishing extensively and developing tests, in 1921 Terman began what is one of the longest-running longitudinal psychological studies in history.¹² Terman identified 1,000 "gifted" children from California with the intention of following them as they grew. The study was intended to provide information about the extent to which childhood IQ scores predicted later success in education and careers. The first results were reported in 1925 (Terman et al., 1925) and the sixth report on the gifted group in later maturity was published in 1995 (Holahan et al., 1995).¹³

As a, if not *the*, leading figure in intelligence testing at the time, Terman was soon at the center of the controversy that arose around testing. In 1922, Walter Lippmann—

author and cofounder of the *New Republic*—wrote a six-part attack on intelligence testing (Lippmann, 1922a, 1922b, 1922c, 1922d, 1922e, 1922f). Much of the content of the articles was specifically targeted at Terman. Lippmann (1922b) began with an effort to ridicule testing by focusing on the apparent absurdity of using the results of the Army Alpha test to conclude that the average American adult had the intelligence of a 14-year-old. Lippmann (1922c) then raised concerns about the potential of the tests to stigmatize children. He also expressed concern that rather than motivating remediation, low scores may provide justification for failing to provide the resources needed for education (Lippmann, 1922d). He moved on to argue against the conclusion that intelligence—as measured by these tests—is inherited and largely unchanged over time (Lippmann, 1922e). Lippmann concluded by suggesting that psychologists should abandon intelligence testing and “save themselves from the reproach of having opened up a new chance for quackery in a field where quacks breed like rabbits” (Lippmann, 1922f, p. 10).

Considering that they were written for the popular press, Lippmann’s articles (1922a, 1922b, 1922c, 1922d, 1922e, 1922f) included a surprising amount of technical detail. He criticized the appropriateness of the norming group used for the Stanford–Binet (Lippmann, 1922a). He argued that the results of the Army Alpha were manipulated by the decisions made about the time limits for the individual tests and that it was impossible to conclude that the intelligence measured by the tests is inherited because so much learning occurs before the age of 4, when these tests were first administered (Lippmann, 1922b).

Terman’s response to Lippmann began mockingly:

After Mr. [William Jennings] Bryan had confounded the evolutionists, and [the flat earth advocate] Voliva the astronomers, it was only fitting that some equally fearless knight should stride forth in righteous wrath and annihilate that other group of pseudo-scientists known as “intelligence testers.” Mr. Walter Lippmann, alone and unaided, has performed just this service. That it took six rambling articles to do the job is unimportant. It is done. The world is deeply in debt to Mr. Lippmann. So are the psychologists, if they only knew it, for henceforth they should know better than to waste their lives monkeying with those silly little “puzzles” or juggling IQ’s and mental ages. (Terman, 1922, p. 116)

In responding to Terman, Lippmann moved from attacking testing to attacking Terman, with lines such as “Mr. Terman’s logical abilities are so primitive that he finds this point impossible to grasp” (Lippmann, 1923, p. 146). Lippmann’s views aside, intelligence testing and the view that intelligence was inherited continued to grow during the 1920s.

Intelligence Testing and Eugenics

Educational measurement had its foundation in the work of Galton and Spearman, both committed eugenicists. During the first 2 decades of the 20th century, the eugenics movement was becoming well established in both England and the United States. Although we are not aware of evidence to suggest that the Army Alpha was motivated by eugenics, after the war, when detailed accounts of the test were published (Yerkes, 1921; Yoakum & Yerkes, 1920), the results certainly fanned the flames of that move-

ment. Two types of results produced particular controversy. First, the very large sample of recruits allowed for examining differences across race and ethnicity. Substantial differences were apparent between Black and White recruits. Similar differences were also observed between recruits who had recently arrived in the United States from eastern and western Europe. These results could not have been more in line with the expectations of the eugenicists who believed that White western Europeans were of superior stock. Both Henry Goddard and Carl Brigham (1890–1943)—psychologists who had worked on the Army Alpha during the war—republished these results in the form of arguments for a eugenic solution. Brigham’s (1923) *A Study of American Intelligence* was particularly strident.¹⁴

Goddard and Brigham were far from the only psychologists of this era who embraced eugenics. Truman Kelley was a member of the advisory council to the Eugenics Committee of the United States of America (I. Fisher, 1923). Psychologists testified before Congress in support of restrictive immigration laws (although there is little evidence that their testimony was a significant factor in passing these already popular measures; Sokal, 1990). Yerkes and Thorndike were members of a Eugenics Record Office committee on the inheritance of mental traits (Zenderland, 1998). In 1927, eugenics had become sufficiently well accepted that the Supreme Court ruled in favor of a Virginia law allowing for compulsory sterilization of individuals with intellectual disabilities. In writing the nearly unanimous decision, Oliver Wendell Holmes stated that “three generations of imbeciles are enough.”

There can be little doubt that the decision to uphold compulsory sterilization and the restrictive immigration policies did irreparable harm and that intelligence testing and testers were closely aligned with these efforts. Nonetheless, it should be kept in mind that, at the time, these were popular positions. In addition to Oliver Wendell Holmes, the list of public figures who wrote in support of eugenics includes Winston Churchill, Margaret Sanger, and Helen Keller¹⁵—to name just a few. Views about eugenics changed dramatically after the Second World War when the Nazi plan to implement eugenics through mass extermination became public. Although intelligence testing continued, the link to heredity (and eugenics) received much less attention. It is difficult to know what the key figures in testing believed about eugenics in the second half of the 20th century; few advocated for it publicly.

Intelligence and Race

The controversy over intelligence testing came back with force in the late 1960s when Arthur Jensen began publishing on racial differences in intelligence. In 1969, *Harvard Educational Review* published a lengthy article by Jensen along with a series of invited responses from other psychologists. Jensen argued that the failure of compensatory education programs (such as Head Start) to produce lasting effects on IQ and achievement raised questions about the assumptions that supported development of these programs. In subsequent books and papers, Jensen further developed the idea of general intelligence (a view similar to Spearman’s), argued

that a substantial proportion of the variance in IQ is the result of inheritance, and stated that the observed differences in IQ scores across racial groups cannot be explained by test bias.

Jensen's work attracted considerable attention both within the scientific community and with the general public, and he was accused of being a racist. Public speaking engagements were disrupted or canceled because of threats of disruption. At one point his university hired a bodyguard for him and his mail was routinely screened for bombs (Robinson & Wainer, 2006). Over the next 25 years, numerous books were published on both sides of the controversy.

The controversy over IQ inheritance, and differences in racial and socioeconomic groups continued for over 2 decades. Jensen was not alone in advancing what was considered inflammatory research on IQ and race. He was also not alone in publishing outside academic journals in newspapers and magazines that were certain to produce a public response. Richard Herrnstein (1971) published in the *Atlantic Monthly* and Linda Gottfredson (1994) published in the *Wall Street Journal*. As with Jensen, publishing on this topic led to calls for removal from their respective universities. Gottfredson (Wainer & Robinson, 2009) lost funding for her position at Johns Hopkins shortly after she began this line of research. Gottfredson (Wainer & Robinson, 2009) and Jensen (1980) also clearly believed that they were excluded from some of the top-tier journals in their fields, not because of the quality of their research, but because of the controversial nature of their results. This may have motivated their decision to make the discussion not only public but also high profile by publishing outside the academic literature. Alternatively, it may be as Cronbach (1975) wrote:

Scholars typically welcome the widest possible attention to their views because they cherish the ideas and because they prize visibility and influence. What wonder, then, that a scholar given his once-in-a-lifetime moment in the public eye will seek to make the moment memorable? (p. 12)

Although publication in this area has continued (e.g., Gottfredson, 2018), the last high-profile contribution to the public controversy came when Herrnstein and Charles Murray (1994) published *The Bell Curve: Intelligence and Class Structure in American Life*. This book became a *New York Times* bestseller and drew immediate attack within the mainstream press (Gould, 1996). Although this resurgence of the controversy no doubt sold many books and magazines, it is unlikely that it changed many minds. It does seem likely that the controversy created an unpleasant association between testing and racism and may have done more than a little to motivate the current antitest movement.

In this section we saw how the development of the Army Alpha impacted the practice of assessment. In the next section we look more broadly at how other federal programs and legislation have impacted educational measurement.

THE INFLUENCE AND IMPACT OF U.S. GOVERNMENT INVOLVEMENT IN ASSESSMENT

As we discussed in the previous section, World War I provided a context for the introduction of large-scale standardized testing in the United States. The Army Alpha was, however, only one of the government-initiated programs that have impacted the theory and practice of testing. In this section we consider how both ongoing Department of Defense funding and federal legislation have continued to impact educational measurement.

It is not surprising that with the U.S. entrance into the Second World War the army would again turn to psychologists to help with the challenge of selection and placement created by the need to turn millions of enlisted men into a functioning army. By 1941, the idea of using tests for selection and placement in industry (and the military) was well established. There was an opportunity for psychologists to contribute to the war effort and at the same time advance the field. One of the most noteworthy individuals driving that effort was John Flanagan.

John Flanagan and the Aviation Psychology Program

Flanagan (1906–1996) had an impressive academic pedigree. As a high school science teacher, he attended summer psychology courses taught by E. L. Thorndike. He then left his teaching position in the late 1920s to study psychology at Harvard University, earning his degree under Truman Kelley. Flanagan then joined the Cooperative Test Service of the American Council on Education. During his time with the Cooperative Test Service, he produced one of the first significant expositions on test equating (Flanagan, 1939), which developed into the chapter on equating in the first edition of *Educational Measurement* (Flanagan, 1951). This chapter may well have been the first comprehensive presentation of the subject. Flanagan examined the importance of form development and comparable application of test specifications, as well as appropriate assignment of items to forms to support score comparability. He considered statistical approaches to equating as well as providing recommendations for the statistical machinery of equipercentile equating and arguing against the use of regression functions for equating because they provide an asymmetric link between test forms (Flanagan, 1951). Despite these significant contributions to the field, Flanagan is likely best known for his work on psychological testing during World War II, including development of the critical incident technique, which has been widely used in developing specifications for credentialing examinations and is still used in the early 21st century.

Like many of the other figures we have discussed, Flanagan's early work was tied to the eugenics movement. His initial experience in military research began in 1938 when he was hired by Frederick Osborn to conduct a study of the factors responsible for decisions regarding family size made by Army Air Corps officers and their wives (Flanagan,

1942). The foundation commissioning the study was concerned that Army Air Corps pilots—“considered the ‘cream of the crop’ genetically”—were having small families. The intention of the research was to identify “incentives to encourage them to have more children” (Capshew, 1999, p. 107).

This work led to Flanagan’s commission in the U.S. Army Air Corps in 1941 to lead the Aviation Psychology Program. Under his leadership, more than 150 psychologists were similarly commissioned and contributed to the program, with more than 1,400 individuals contributing throughout the war (“APF Gold Medal Awards,” 1993). The extensive work of the Aviation Psychology Program of the Army Air Forces is documented in 19 volumes describing studies in development and analysis of criterion measures, rating scales, checklists, and materials developed based on critical incident reports. The Aviation Psychology Program introduced criterion-referenced testing and test validation approaches based on performance. The validity research included comparisons of test results with data collected during training and subsequent performance in the field (Shields et al., 2001).

After working on the Osborn study, Flanagan was sponsored by the National Research Council to develop the Aviation Cadet Qualifying Examination, a test for classifying aircrew candidates. The examination was initially implemented shortly after the 1941 attack on Pearl Harbor (Staff, Psychological Branch, Office Air Surgeon, 1944). These tests were initially used for cadet selection and subsequently for placement into specific aircrew roles. The novel contribution introduced by Flanagan’s team relied on the rapid development and validation of a complicated assessment battery. The assessment sorted participants into role-specific stanines for navigator, bombardier, and pilot roles, based on a combination of performance-based assessments (e.g., finger dexterity and rudder control), personality, and knowledge/proficiency tests. Validity evidence for the predictive power of these assessments was gathered through training measures (Did the individual successfully complete training?) and measures of success or failure in combat, including ratings, awards, errors, and survival (Flanagan, 1948).

A second research project, conducted during this period under the auspices of the Army Air Forces Aviation Psychology Program, represents a rarely possible textbook example of validity research for a selection procedure. This study was designed to evaluate the procedures and measures for selecting pilots and aircrew to maximize the match between their strengths and their assigned roles. The research reports of the Army Air Forces Aviation Psychology Program (“The Experimental Study of a Thousand Applicants Sent Into Pilot Training”) described how approximately 1,050 men were assigned to pilot preflight school without consideration of their performance on the Army Air Forces qualifying examination battery. They were then enrolled in basic training and primary/advanced flying schools, with some eventually receiving ratings as qualified pilots. “Two-thirds of the men with stanine scores of 8 or 9 completed the program, while fewer than 3% of those with stanines 1 or 2 did so” (Jones, 2007, p. 604). Jones

also noted that the predictive value of the test was substantially reduced when applied to subsequent performance. The more than 20:1 ratio for completing training was reduced to less than 2:1 in a follow-up study predicting accidents associated with pilot error. And although follow-up during combat was plagued with problems arising from incomplete data, it was impossible to demonstrate that higher scores were associated with superior outcomes in combat.

Postwar Developments

The practical work that went on during the war continued to have a significant impact after the war ended. The formalization of the critical incident technique, an evidence-based test design approach used during the war to identify effective actions taken by officers, led to the development of the “critical requirements” of combat leadership for the U.S. Army Air Forces (Flanagan, 1954) and then to a set of procedures that have been broadly used in the construction of credentialing examinations. Robert Thorndike (1947, 1949) went on to devise methodologies for developing a personnel testing program based on his work in the Army Air Forces. These reports detail methods and considerations for performing job analysis, developing aptitude tests (pilot testing, validation, revision), criterion validation, developing composite scores from test batteries, and assessing reliability. Many of the individuals who participated in the Army Air Forces became leaders in the civilian research community—some, like Flanagan and Thorndike, were officers, whereas others, like William Angoff, participated as enlisted men (Jones, 2007).

Department of Defense Support for the Development of Modern Test Theory

Beginning during the Second World War and continuing through the 1990s, the Department of Defense supported a series of projects that advanced the development of what would become known as *item response theory*. The book *Measurement and Prediction* (Stouffer et al., 1950)—published after the war—includes a chapter on Paul Lazarsfeld’s (1901–1976) wartime work on latent structure analysis. That work provided a basis for the conceptual and statistical development of IRT (e.g., Bock, 1997; Lord, 1952). In the 1950s, the U.S. Air Force School of Aviation Medicine supported Allan Birnbaum’s development of the logistic form of the one-, two-, and three-parameter IRT models (Birnbaum, 1957, 1958a, 1958b). The Office of Naval Research supported the writing of Lord and Novick’s (1968) volume that became a nearly sacred text for measurement experts and made Birnbaum’s work widely available. The Office of Naval Research (along with other government agencies) also helped to move IRT from the theoretical to the practical by sponsoring a series of landmark conferences on latent trait theory and computerized adaptive testing. The conferences took place in 1975 (Clark, 1976), 1977 (Weiss, 1978), and 1979 (Weiss, 1983). These conferences represented the state of the art in what became known as IRT and the presenters represented a who’s who of researchers working in that area. The authors listed in these proceedings include Fumiko

Samejima, Frederic Lord, Bert Green, Darrell Bock, Dan Eignor, Ron Hambleton, Mark Reckase, H. Swaminathan, Linda Cook, David Thissen, and Howard Wainer. The Department of Defense also sponsored a more than 30-year-long research project that resulted in computerization of the Armed Services Vocational Aptitude Battery (ASVAB) in 1996. The foreword to a report on this effort described this accomplishment (Sands et al., 1999).

In October 1996, the Department of Defense (DoD) implemented a computerized adaptive testing (CAT) version of its enlistment test battery (the Armed Services Vocational Aptitude Battery or ASVAB) in 65 Military Entrance Processing Stations (MEPSs) across the country. DoD became the first organization to use CAT-derived scores for personnel selection when the system was placed in five MEPSs for operational testing in 1992; now DoD has become the first employer to adopt CAT for its employment system. . . . The Department is the largest single employer of American youth, testing over 350,000 applicants for entrance into the Military Services between October 1, 1994 and September 30, 1995. (p. ix)

The ASVAB project began in the 1960s. Early aspects of this work focused on statistical models for item selection, but subsequent work covered every aspect of implementation, including pool construction, exposure control, software and hardware selection, and validity studies. This effort produced important advances in computerized adaptive testing, but more generally it advanced the field with respect to both technical and practical knowledge of IRT. As important as these contributions were in the evolution of educational measurement, they may well be judged as having a minor impact when compared to the other way the federal government influenced the measurement field—through legislation to support education and assessment.

The Impact of Legislation on Educational Measurement

In response to the Soviet launch of *Sputnik* in 1957 and the perception that America was losing the space race, federal policy began to explicitly support testing of schoolchildren in science, mathematics, reading, and foreign languages through the 1958 National Defense Education Act (NDEA). This served the purposes of establishing baseline knowledge in these areas as well as providing support for rapid curriculum development and implementation in public schools (Bunch, 2021). The testing programs supported by the NDEA were designed to evaluate college readiness, specifically preparedness for postsecondary study in math, science, and foreign languages. The act also provided federal funding for these tests in the event that a state could not legally pay for them (Section 504(b)).

Approaching federal involvement in education as a matter of national defense distinguished the NDEA from previous proposed education-spending legislation, versions of which had been passed by the Senate but languished in the House. Framing support for standard educational goals (and assessments) across states as a matter of national defense was ultimately a winning strategy, although there was controversy about the

appropriate limits and uses of standardized testing in schools. Advocates for this legislation saw the potential to provide greater access to college through federally supported scholarships, loans, and selection instruments, while challengers were skeptical about the utility of standardized tests in making decisions about individual fitness for secondary education or a career path (Urban, 2010).

The programs underwritten by the NDEA continued through the 1960s and eventually were subsumed by the Elementary and Secondary Education Act (ESEA) in 1965. The ESEA was a part of Lyndon Johnson's Great Society initiative and laid the groundwork for state and school district accountability for educating disadvantaged children. The ESEA was reauthorized and/or amended regularly through 2015 (taking on names including No Child Left Behind and Every Student Succeeds Act). The ESEA also brought the federal government into the education of bilingual students and students with disabilities, provided federal money for testing and supplemental educational services for historically disadvantaged students, and established Head Start as a permanent program (Bunch, 2021; Urban, 2010).

A significant part of the motivation to increase the assessment component of this legislation was to ensure that states and localities would effectively implement the requirements for the education of disadvantaged students and students with disabilities. The assessment component was again strengthened with the passage of the 1974 amendments (Education Amendments, 1974) requiring the commissioner of education to develop program evaluation models that "specify objective criteria" and provide "comparable [data] on a statewide and nationwide basis" (Section 151; Bunch, 2021). During the 1970s and 1980s, states were supported by 10 regional technical assistance centers to develop and implement assessments in support of ESEA requirements. These centers employed hundreds of testing specialists and interacted with education officials in all 50 states to create a standardized approach to solving educational measurement problems. Between 1979 and 1981, these centers provided over 5,000 workshops and on-site consultations for more than 80,000 clients (Bunch, 2021; Stonehill & Anderson, 1982).

In addition to promoting assessment through these regional centers, the 1978 reauthorization directed the commissioner of education to assist state education agencies in developing capacity to conduct large-scale achievement testing programs to measure reading, writing, and mathematical proficiency, along with other subjects. After the election of Ronald Reagan in 1980, the ESEA was reauthorized as the Educational Consolidation and Improvement Act. This led to more local control, but somewhat surprisingly it again increased the requirements for assessment. As a result of this act, schools, districts, and states were required to administer criterion-referenced tests to demonstrate that targeted outcomes were being met.

Despite the years of legislation and associated funding, the 1983 report on the state of American education, *A Nation at Risk* (National Commission on Excellence in Education, 1983), described America's schools as failing to educate the nation's children. This led to the 1994 Improving America's Schools Act. The act led to additional assessment requirements: Assessments aligned with the content standards were to be administered

at a point between Grades 3 and 5, between Grades 6 and 9, and again between Grades 10 and 12 (Section 1111(b)(3)(D)). Standards, however, were still established at the state level and were highly variable across states.

In 2002, this trend of increasing emphasis on assessment continued with the passage of No Child Left Behind (NCLB), in place from 2002 to 2015. The act expanded testing to include Grades 3 through 8 and required testing in one grade of high school. As with every reauthorization of the ESEA since 1966, NCLB emphasized the importance of education and testing of minority populations, English language learners, and students with disabilities. NCLB created an emphasis on state standards and assessment that led to meaningful developments in federal education policy. Building on the goal of all children achieving proficiency in reading and mathematics (by the 2013–2014 academic year), NCLB introduced test-based accountability provisions such as annual improvement targets and penalties if targets were not met. NCLB accountability requirements increased policy attention on test accommodations and accessibility, as well as expectations for progress reporting for students and student subgroups.

There can be little doubt that federal legislation has done much to drive assessment of specific populations, influence test accommodations and tested content, and impact how testing is performed in education for students in kindergarten through Grade 12. The legislation described has also shaped the significant role that measurement experts have had in education and accountability efforts since the 1960s. As significant as this has been, it may be that even more psychometric innovation was driven by a different federal initiative, NAEP. We would be remiss not to mention NAEP in this section on federal involvement in assessment, but we will present the details of this program in the subsequent section on large-scale testing.

RELIABILITY THEORY AFTER SPEARMAN

In the prior two sections we focused on the historical and social developments that shaped educational measurement. In this section we return to the more theoretical aspects of the history of educational measurement and follow the development of reliability theory after Spearman's early papers. This development has two parts that are sometimes viewed as chronologically distinct but are, in fact, interwoven. The first has to do with the continued development of classical test theory; the second part resulted in generalizability theory.

The Development of Classical Test Theory

Although Spearman's work provided the foundation for classical test theory, his focus was on creating tools for correlational psychology. He was interested in efficient approaches to estimating correlations between tests and in tools for evaluating those relations. There is little evidence that his interest extended to advancing methodology

for estimating standard errors or otherwise interpreting individual test scores. This was consistent with his interest in using test scores to study intelligence rather than to evaluate individuals. Spearman was a correlational psychologist, not a psychometrician. In this respect, Spearman had a great deal in common with Galton and Pearson. All three were interested in developing correlational tools to advance their respective substantive fields: heredity, evolutionary biology, and human intelligence. The next major contributor to the development of test theory, Truman Kelley, approached testing from a different perspective: that of a methodologist. In fact, Cronbach referred to Kelley as an “obsessive algebraist and statistician . . . who had no motive save methodologic” (Lee Cronbach, personal communication, December 22, 2000).

Truman Kelley

Truman Kelley (1884–1961) earned his doctorate under E. L. Thorndike at Columbia and went on to teach at Stanford and Harvard. In 1922–1923, Kelley spent a sabbatical year with Pearson at the Galton Biometric Laboratory. Around this same time, Kelley began publishing a series of papers that would extend classical test theory beyond the formulas presented by Spearman. What may be Kelley’s single greatest contribution to classical test theory was among his first, the regression estimate of a test taker’s true score:

$$\hat{T}_x = \rho X_i + (1 - \rho)\bar{X}. \quad (5)$$

In this equation taken from Kelley (1923), the left-hand term represents the estimated true score, ρ represents the reliability of the test score, X_i is the observed score for test taker i , and $\bar{X}$ is the population mean. This equation not only represents an important use of the implicit assumptions of classical test theory, but also links test theory to a Bayesian framework by combining the observed data with a prior assumption (Levy & Mislevy, 2021).

The next year, he published a paper showing that if we have two forms of a test such that $x_1 = a + e_1$ and $x_2 = a + e_2$, where x is the observed score, a is the true score, and e is a “chance factor,”¹⁶

$$r_{12} = \frac{\sigma_a^2}{\sigma^2}. \quad (6)$$

In Kelley (1925) he showed the relationship between the reliability of a measure and the correlation between the measure and the related true score:

$$r_{1\infty} = \sqrt{r_{1I}} \quad (7)$$

or, equivalently,

$$r_{1I} = r_{1\infty}^2. \quad (8)$$

These equations will be familiar to anyone who has studied classical test theory; they represent only a sample of Kelley's contribution. In addition to numerous additional papers of this sort, Kelley published what may well be the first book devoted to the mathematical theory of test scores, *Interpretation of Educational Measurements* (1927), and substantially influenced formal presentations of test theory that followed. The extent to which Thurstone's *The Reliability and Validity of Tests* (1931) and Gulliksen's *Theory of Mental Tests* (1950) depend on Kelley's work makes it clear just how essential Kelley's contributions were to the development of educational measurement.

G. F. Kuder and M. W. Richardson

G. F. Kuder (1903–2000) and M. W. Richardson's (1896–1965) 1937 paper followed in the spirit of Kelley in showing how simple assumptions and algebraic manipulation can be used to derive practically useful results. Their paper began with a theoretical discussion of reliability and then progressed through a series of manipulations to produce what have become known as the KR20 and KR21 (the 20th and 21st equations presented in the paper). The first of these represents a generalized equation for reliability and the latter a form that the authors stated could be calculated in 2 minutes using statistics that are readily available to the test developer. Their presentation began with a rejection of the test–retest paradigm for reliability in favor of the split-half approach (highlighting the importance of the Spearman–Brown formula). They noted that split-half methods depend on the specific split used and then presented a general equation that represents the correlation between two equivalent forms of a test. If $a, b, \dots, n$ and $A, B, \dots, N$ are corresponding items in two hypothetical forms of a test, the tests are equivalent if the items in each pair (a and A , b and B , etc.) are interchangeable. Based on this assumption, they present the KR3:

$$r_{tt} = \frac{\sigma_t^2 - \sum_1^n pq + \sum_1^n r_{ii}pq}{\sigma_t^2}. \quad (9)$$

In this equation, r_{tt} is the reliability of interest, σ_t^2 is the variance of the test, p is the difficulty for a specific item, and q equals $1 - p$. They recognized that this formulation was not of practical use because r_{ii} cannot be calculated. After 16 intervening equations, they presented the KR20, derived from KR3 with the assumption that all inter-correlations are equal:

$$r_{tt} = \frac{n}{n-1} \cdot \frac{\sigma_t^2 - n\bar{p}\bar{q}}{\sigma_t^2}. \quad (10)$$

Finally, by assuming that all item difficulties are equal, they produced the KR21,

$$r_{tt} = \frac{n}{n-1} \cdot \frac{\sigma_t^2 - n\bar{p}\bar{q}}{\sigma_t^2}. \quad (11)$$

Kuder and Richardson's (1937) paper was important both practically and theoretically. For practitioners, it provided an approach to estimating the reliability of a test that was computationally simple (at the cost of making strong assumptions). In the days before computers and electronic calculators, this was of considerable value. Their paper also represented an important theoretical step forward in the understanding of reliability.

Lee Cronbach

A final critical step in the development of reliability within the framework of classical test theory was provided by Cronbach's introduction of coefficient alpha. Cronbach (1916–2001) made major contributions to assessment. In addition to his work on advancing the conceptualization of reliability theory, he published groundbreaking work on validity theory. He coauthored the seminal paper on construct validity with Paul Meehl (Cronbach & Meehl, 1955) and wrote the chapter on validity for the 1971 edition of *Educational Measurement*. As an interesting aside, Cronbach was also a member of Terman's gifted group. The gifted group was followed long after Terman's death, and in addition to being a subject in the study, Cronbach assisted with production of the final volume of the study (Holahan et al., 1995).

Cronbach's 1951 paper on alpha may be the most cited paper in the history of measurement. According to Google Scholar, it has been cited tens of thousands of times. In a sense, the coefficient alpha paper extended the presentation from Kuder and Richardson (1937). KR20 is a special case of coefficient alpha in that it applies to items scored 0/1. Cronbach showed that coefficient alpha (and, by extension, KR20) represents the mean of all possible split-half coefficients.¹⁷ It is also "the value expected when two *random* samples of items from a pool like those in the given test are correlated" (Cronbach, 1951; p. 331).

In a posthumously published paper, Cronbach reflected on coefficient alpha (Cronbach & Shavelson, 2004). He argued that although reliability coefficients were appropriate for the kind of correlational psychology that was prevalent from Spearman's time through the first half of the 20th century, more recent applications of measurement are better served with an estimate of the standard error of measurement.¹⁸ In that same paper, Cronbach advocated for procedures based on analysis using variance components rather than correlations. He was arguing that generalizability theory should supplant classical test theory as the preferred framework for conceptualizing reliability.

Generalizability Theory

Cronbach's advocacy for the framework represented by generalizability theory comes as no surprise; he spent over a decade working through the problem of reliability before he and his colleagues published *The Dependability of Behavioral Measurements* (Cronbach et al., 1963, 1972). The work created what the authors referred to as a liberalization of classical test theory.

In classical test theory, observed scores are conceptualized as comprising a true score and an undifferentiated error term. The true score is the expected score that the test taker would receive if they could complete the test an unlimited number of

times. In generalizability theory, the sampling process is conceptualized as occurring at the task (or item) level, with tasks being randomly sampled from a universe of admissible tasks. This allows for multiple facets comprising the total score variance to contribute either to the test taker's universe score (similar to the true score) or to error. The framework allows for conceptualizing the reliability of scores in which (a) separate components of the error variance are associated with the sampling of the items and the raters who evaluate the responses to those items, (b) the total score is a composite based on stratified sampling of items from different content areas or item formats, (c) the measurement is focused on scores for individual test takers or aggregates such as classrooms, and (d) relative versus absolute score interpretations are possible.¹⁹

Clearly, any history of generalizability theory will need to include the work of Cronbach and his collaborators beginning in the late 1950s and lasting very nearly until Cronbach's death, but many of the ideas reflected in generalizability theory first appeared in the late 1800s, and as with classical test theory, they were developed by numerous individuals over time. The earliest of those ideas came from the work of Francis Edgeworth (1845–1926).

Edgeworth attended Trinity College, Dublin, and Oxford University, where he studied ancient and modern languages. He was self-taught in the areas in which he made his reputation: statistics and economics. His work in economics earned him a chair at Oxford. Edgeworth was interested in bringing mathematical analysis into the social sciences. This interest led him to become one of Galton's earliest disciples (Kendall, 1968; Stigler, 1986). This interest also led him to write three papers on the statistics of examinations. Edgeworth's interest expressed in these papers was to examine "the degree of accuracy or inaccuracy which is to be ascribed to the modern method of estimating proficiency by means of numerical marks" (Edgeworth, 1888, p. 600); in other words, he was interested in the reliability of test scores.

When Edgeworth referred to the "modern method," he was speaking of a system in which essays or short-answer papers were scored by content experts. The purpose of the paper was to describe an approach for estimating the extent to which chance influenced examination scores. He began by describing something closely related to what we now think of as the true score in classical test theory (or the universe score in generalizability theory). Using Latin translation as an example, he wrote,

This central figure which is . . . assigned by the greatest number of equally competent judges, is to be regarded as the true value of the Latin prose; just as the true weight of a body is determined by taking the mean of several discrepant measurements. There is indeed this difference between the two species of measurement, that in the case of material weight we can verify the operation. We can appeal from kitchen scales to an atomic balance, and show that the mean of a great number of rough operations tends to coincide with the value determined by the more accurate method. But in intellectual ponderation we have no atomic

balance. We must be content without verification to take the mean of a number of rough measurements as the true value. (Edgeworth, 1888, p. 601)

He went on to define error in terms of variability about this true value and concluded that for aggregate scores error “will fluctuate according to the normal law” (p. 604). Having described the observed score as being composed of a true score and a normally distributed error, Edgeworth then presented a number of the essentials of generalizability theory:

1. He described the total error score as being made up of multiple facets, including what in generalizability theory would be designated as task effects, rater effects, and rater-by-task interactions.
2. He made the assumption that tests were constructed through random sampling from a defined domain—the central assumption of generalizability theory (Kane, 2002)—and commented on conditions that would violate the model.
3. He described the total error as the square root of the sum of the squared effects and noted that the impact of any effect will be reduced by the square root of the number of observations contributing to that effect.

Edgeworth used these conceptualizations to describe data collection designs that would minimize the error without increasing the total amount of rater time required.

Having considered sources of error associated with raters, Edgeworth (1888) then examined the contribution of task sampling to the error of measurement:

We have so far been endeavouring to estimate the error which is incurred in appreciating the actual work done by the candidate. We have now to evaluate the error which is committed in taking his answers as representative of his proficiency. (p. 614)

The suggestion that Edgeworth presented the basics of generalizability theory in this paper may seem like an exaggeration because generalizability theory uses the framework of analysis of variance and R. A. Fisher did not publish his ideas until decades after Edgeworth’s paper (e.g., R. A. Fisher, 1925). It is, nonetheless, obvious that this is the framework Edgeworth intended; he had already published a paper on “analysis of variance” in 1885. Stigler (1986) commented on the 1885 paper that “the solution was insightful and foreshadowed much of twentieth-century work on the analysis of variance” (p. 314).²⁰

Edgeworth’s insights into the generalizability of test scores were impressive. Whether they influenced subsequent work in this area is difficult to say. It may be that, like his contribution on analysis of variance, these papers were largely ignored—perhaps he was too far ahead of his time. We have found no references to his work in the early literature on test theory, but this is questionable evidence because extensive citation of previous work was rare at that time. For most of the half century that followed Edgeworth’s 1888 paper, the emphasis was on the development of classical test theory, which has

already been discussed. The next important contributions to reliability theory that went beyond the classical test theory paradigm were provided in 1936 by Harold Gulliksen (1903–1996) and Cyril Burt (1883–1972).

Gulliksen's (1936) contribution appeared in the first volume of *Psychometrika*. He looked at the typical approach to reliability for objectively scored items; because variability in this context is substantially associated with item sampling, he referred to it as content reliability. He then raised the question of how content reliability can be estimated for essay examinations in which the total error includes both content error and error introduced by "readers." Assuming that two separate forms of the test are available and that one of those forms is scored by two separate readers, he developed an approach to quantifying the content reliability associated with essay tasks.

Burt's (1936) contribution is framed in the context of factor analysis. In his publication, he conceptualized total score as being constructed of multiple factors, including a general factor and sources specific to raters. Using factor analytic and correlational procedures, he described how rater error can be quantified.

Cronbach et al. (1972) described the contributions by Gulliksen (1936) and Burt (1936) as being among the first to conceptualize measurement error as comprising multiple facets. But as Cronbach (1991) would later write, univariate generalizability theory "interweaves ideas from at least two dozen authors" (p. 394). These contributions include R. A. Fisher's work on analysis of variance (R. A. Fisher, 1925), as well as that of Cornfield and Tukey (1956). Burt (1955) also made a second contribution that explicitly linked estimation of reliability to analysis of variance.

These publications and numerous others set the stage for the work Cronbach and his collaborators did in the late 1950s and 1960s. In 1957, Cronbach and Gleser began work on a handbook of measurement theory. Believing that reliability had been thoroughly studied by others, they decided to begin with that section of the book. Cronbach (1991) wrote later, "We learned humility the hard way—the enterprise never got past that topic" (p. 392).

The essential features of univariate generalizability theory were largely completed by the early 1960s and published in three journal articles, each with a different first author (Cronbach et al., 1963; Gleser et al., 1965; and Rajaratnam et al., 1965). These papers incorporated analysis of variance procedures to evaluate multiple facets representing different sources of error, absolute versus relative error, and an understanding of fixed versus random facets in the design. Additional years of effort were then necessary to expand the theory to a multivariate framework. The result was *The Dependability of Behavioral Measurements* (Cronbach et al., 1972).

Their monograph represents a remarkable step forward in both the conceptualization and the estimation of measurement error. Unfortunately, although the volume captured much of the authors' best thinking on the topic, as Cronbach (1991) wrote, "the book proved indigestible" (p. 395). Cronbach et al. (1972) warned that "the reader is certain to gain far more from his third reading of most sections than from his first or second" (p. 4). Although Cronbach continued to work in this area until shortly before his death,

he published relatively little on the topic after the 1972 volume. The extent to which generalizability theory has become widespread seems to a substantial degree to be the result of subsequent authors who have developed the theory and written texts (and software) that make it more accessible. Although numerous researchers have written on the topic, far and away the greatest contribution has come from Robert Brennan. For many years, *Elements of Generalizability Theory* (Brennan, 1983) was the primary introduction that researchers had to generalizability theory. This monograph provided the basics needed for univariate generalizability analysis and prepared readers to make use of *The Dependability of Behavioral Measurements* (Cronbach et al., 1972). Brennan's more complete text and the associated software (Brennan, 2001a, 2001b) provided a detailed resource for multivariate generalizability analysis.

In concluding, we wish to make clear that we do not intend to imply that the technology for evaluating reliability and estimating measurement error is now complete. Instead, our goal has been to explain how this technology has developed during the past century. This summary is intended to describe how these concepts have evolved. Hopefully, this will lead to a better understanding of the current state of the art and will at the same time point to areas for development of both theory and practice.

SCALING

Next, we consider the development of applications of scaling for educational measurement. Unlike the other sections of this chapter, for which the content is likely to be self-evident given the section heading, the term scaling may warrant a definition, or at least a description. This is not because it is an obscure term, but because a focus on scaling has been in and out of vogue over the decades, and ideas about the requirements for a defensible scale have varied as well. In 1954, Lord wrote that “‘scaling’ appears to be virtually indistinguishable in meaning from ‘measurement,’ which may be defined as the assignment of numerals to objects (including people), according to some rule, in order to represent their properties” (p. 375). Lord went on to state, “If a method of scaling rests upon a verifiable hypothesis as to the existence of some specified self-consistency in the data, then the data may or may not be found to scale” (p. 375). Lord's first statement sets a low bar for scaling and, by extension, for measurement. The second implies that if the user establishes a higher bar by way of the intended interpretation of the scores, it may be necessary to demonstrate that the data—and, by extension, the phenomenon represented by those data—support that interpretation. Lord's statement suggests that scaling has occurred even when it is strictly categorical; scales need not be continuous, nor do they need to represent ratio or even interval measurements.²¹

The first two editions of *Educational Measurement* included chapters on the nature of measurement. Consistent with much theory and practice at the time, this chapter did not appear in the third and fourth editions. More recently, the limited attention that has been given to the theoretical requirements of measurement (and scaling) has become a source of some controversy. Michell (1999) has written extensively and crit-

ically on this topic. McGrane and Maul (2020) described the failure to demonstrate that the latent traits reflected in IRT models have characteristics that support the use of the associated scales as a “scientifically dire situation” (p. 8). Recently, several authors have attempted to resolve this controversy by placing scaling procedures in perspective. Briggs (2021) provided a historical perspective incorporating the contributions of Fechner, Galton, Thurstone, and Stanley Stevens. Mari et al. (2021), in their volume *Measurement Across the Sciences*, tried to define the requirements of measurement in psychology from a broader scientific perspective and specifically by bringing in the perspectives of metrology. David Torres Irribarra’s (2021) volume *A Pragmatic Perspective of Measurement* provides yet another view of the controversy bringing both philosophical pragmatism and common-sense pragmatism to the discussion.

For this brief summary of the history of scaling, we focus on developments in practice. We recognize that separating developments in the taxonomy of scaling procedures (see Stevens, 1946, 1951; Torgerson, 1958) and the conceptualization of the nature of measurement more broadly from developments in the practice of scaling is somewhat artificial, but these theoretical issues are presented in detail in Briggs et al. (this volume). To outline the development of scaling, we return to Galton and Fechner, but this time we focus on their efforts to build measures. We then examine how these early efforts at scale development impacted the development of the IRT models that have become ubiquitous. (See Moses, this volume, for a presentation of current approaches to scaling.)

Ernst Weber and Gustav Fechner

In 1860, Gustav Fechner provided an initial formalization of psychological scaling with the publication of *Elements of Psychophysics* (1860/1966). As we described previously, Fechner’s magnum opus was the culmination of a decade of work conducting experiments on individuals’ responses to physical stimuli and extending the work of Ernst Weber. Weber had spent his career examining psychological responses to physical stimuli and had found that when asked to detect differences in physical stimuli, subjects were sensitive to relative changes in proportion, not absolute changes in magnitude. Fechner generalized this work by recognizing that the sensory intensity of a stimulus is the product of the log of the level of physical stimulus multiplied by some constant K (Sensation = $K \log$ Stimulus).²² This finding, later described as Fechner’s law, indicates that there is a logarithmic relationship between a physical stimulus and the associated perception. That is, if you need to double the stimulus to increase the perceived difference from 1 to 2, you must double it again to increase the perceived difference from 2 to 3 (Briggs, 2021).

Although Weber had primarily concerned himself with comparing the magnitude of these proportions across different sensory stimuli, Fechner recognized that these psychological attributes could be expressed on their own scale separate from the scale of the stimulus itself. Fechner noticed in his experiments that subjects sometimes disagreed as to which stimulus was the strongest. He hypothesized that these disagreements were attributable to random error in the assessment of the stimuli. He further hypothesized that these errors in measurement were normally distributed with a mean of zero.

Therefore, subjects disagreed as to which stimuli were more intense because the psychological comparison on the stimuli follow two random variables, each following a normal distribution (Fechner, 1860/1966).

In his experiments, Fechner compared two physical stimuli across many subjects and calculated the proportion of time that the treatment stimulus was judged to be greater than the control stimulus. Then, assuming that the standard deviations of these responses were the same for all pairs and stimuli, Fechner set these equal to 1 and used the inverse of the cumulative density function to compute an estimate of the mean difference in psychological response for those stimuli. After repeating this across multiple pairings of stimuli, Fechner was able to establish a scale for the measurement of sensory intensity.

Fechner's work was important in shaping thinking about the nature of scaling and measurement in psychology—and, by extension, educational measurement—because it established an early precedent that such measurement should follow the framework used in the physical sciences. This goes well beyond Lord's "assignment of numerals to objects . . . according to some rule" (Lord, 1954, p. 375).

Francis Galton

Although Fechner's work is notable as the first attempt to scale psychological stimuli, his work focused on the scaling of stimuli, not subjects. The first significant advance in scaling subjects was achieved through the work of Francis Galton. Although, as we have discussed, Galton is better recognized for his research on inheritance and his discovery of correlation, his work in scaling unobservable human characteristics provided an important foundation for the scaling of mental tests that is still in use in the early 21st century.

Inspired by the work of Adolphe Quetelet, Galton had become fascinated with the normal distribution and its ubiquity in nature (Briggs, 2021; Gillham, 2001). Galton recognized that the distribution of some physical traits, for example, height, was the product of many small, random events in the inheritances of each individual. He believed that unobservable mental traits were equally a product of this random path of inheritances and reasoned that they too should follow a normal distribution. This revelation regarding the shape of the distribution allowed Galton to translate the measure of any individual into its percentile—a word Galton coined—allowing individuals to be placed relative to one another along a statistical scale (Galton, 1875).

Galton referred to this approach to scaling as "relative" and recognized that although it allowed human qualities to be quantified, it lacked an objective reference point. In an effort to ameliorate this limitation, Galton developed scale anchor descriptors to indicate the performance that would be expected at particular percentiles. Furthermore, Galton recognized that relative assessments could be every bit as useful as absolute measurement in the myriad situations where individuals are assessed relative to a peer group, saying that "a blurred vision would be above all price to an individual man in a nation of blind men, though it would hardly enable him to earn his bread elsewhere"

(Galton (1889), p. 36). This relative approach to scaling individuals was valuable for the study of inheritance; by the turn of the 20th century, it was about to make its way into educational measurement. Again, we see physical measurement as the model for psychological measurement.

E. L. Thorndike

The next important contribution to scaling—and the first that was consciously intended to advance the field of educational measurement—was made by E. L. Thorndike (1874–1949). In the early 20th century, secondary education was becoming widespread in the United States. Schools all over the nation needed teachers, and increasingly, large urban universities were adding departments of education to address this need. Columbia University was at the center of this trend, and in 1899 Thorndike became an assistant professor at Columbia Teachers College (Cherry, 2023). Thorndike believed that science was the only sure foundation for social progress and was unhappy with the level of scientific rigor applied to education at that time (Clifford, n.d.). He admired the work of Galton and Pearson and wished to apply the scientific method to the study of education. To this end, he introduced the first course in educational measurement in 1902 and published a textbook, *Educational Psychology*, in 1913.

During his 40 years at Columbia, Thorndike worked on the design and development of many exams for a wide array of purposes (including his evaluation of the Army Alpha described previously). Trained in psychology, Thorndike had limited formal training in mathematics and statistics. Nonetheless, he built on the work of Galton when developing a scaling technique that placed students across grades on a common scale. To accomplish this, Thorndike began by calculating the proportion of test takers answering each question correctly for each grade. Items were then expressed as a deviation from the grade mean in terms of standard deviation units. The mean difference between common items administered in adjacent grade levels was then calculated and used to adjust grade means to place all grades on a common scale (Thorndike, 1919). Although this represented a significant advancement in educational scaling in 1905, this method assumed that the distribution of abilities across grades differed by position but not by dispersion (Engelhard, 1984; Thurstone, 1927). Twenty-five years later, this limitation would be addressed by Thurstone.

L. L. Thurstone

The year that Gustav Fechner passed away in Leipzig, L. L. Thurstone (1887–1955) was born in Chicago, Illinois. While at Cornell studying engineering, Thurstone's interest in education and psychology grew, along with his frustration with the poor quality of teaching in the college of engineering. In 1914, Thurstone abandoned engineering and matriculated at the University of Chicago to pursue his doctorate in psychology (D. A. Wood, 1962). During his graduate training, he accepted an assistantship at the newly created Division of Applied Psychology at the Carnegie Institute of Technology. During the next 9 years at Carnegie, Thurstone was at the forefront of the development

of psychological tests on a wide variety of cognitive functions. In 1924, he returned to the psychology department at the University of Chicago, where he taught a course on test theory.

At this point in his career, Thurstone began to scrutinize the scaling approaches that were common in mental assessments at the time, like those used by Thorndike and others. Thurstone recognized that earlier approaches to educational scaling assumed that dispersion was constant across grade. Thurstone believed this assumption was dubious and in 1924 he articulated a method of scaling that accounts for differences in both group means and dispersion (Thurstone, 1927). Thurstone's absolute scaling approach begins similarly to Thorndike's approach. For each test question, the difficulty is calculated for students in that grade and those difficulty values are rescaled to be expressed as deviations from the group mean in standard deviation units. Unlike Thorndike, however, in the absolute scaling approach, Thurstone calculated that standard deviation of the difficulty for common items in adjacent grades. The ratio of these standard deviations could then be used to rescale one grade onto the scale of the other grade while accounting for the differences in dispersion. This process could be repeated across adjacent grades to create a single scale that spanned several grade levels.

In 1925, Thurstone extended this scaling work to consider placing test takers along these educational scales. To unify the scales for test takers and items, Thurstone placed each test question on the test-taker ability distribution so that the percentage of test takers answering the question correctly was equal to the percentage of test takers to the right of that point in the distribution. This allowed item difficulties to be expressed as the place along the test takers' ability distribution at which 50% of test takers would answer the item correctly. He then represented these item difficulties in terms of standard deviation units, such that items at the mean ability were scaled to zero while more difficult and easier items were expressed as positive and negative normal deviates, respectively. Thurstone went on to graph the empirical probability of a correct response across grade for items at different difficulties and showed that the difficulty distributions are S-shaped, with slopes that vary by item. He stipulated,

A refined statistical method for ascertaining the age at par [item difficulty] for each test question would be to fit an equation to the curve for each test question and then to ascertain the point at which the curve intersects the 50% level. (Thurstone, 1925, p. 446)

Thurstone did not develop that refined statistical method. As we will see in the next section, that development would result in the creation of IRT.

The specific examples of scaling that we provided in this section represent major steps in the development of scaling procedures in educational measurement. Each of these procedures goes well beyond Lord's simple assignment of numerals based on a rule; each assumes "some specified self-consistency in the data" (Lord, 1954, p. 375) that contributes

to the interpretation of the measurements. As the works cited earlier in this section make clear (Briggs, 2022; Irribarra, 2021; Mari et al., 2021; McGrane & Maul, 2020), the defensibility of these types of interpretations remains controversial. The historical perspective provided in this section does not resolve that controversy, but it does provide a context for understanding it. The practical application of these efforts to construct self-consistent scales resulted in IRT—which we consider in the next section—but as we discuss in that section, it did not eliminate the controversy over the requirements for scaling.

ITEM RESPONSE THEORY

The history of IRT is complex. Part of that complexity comes from the fact that IRT as we know it in the early 21st century developed independently—at about the same time—in both the United States and Denmark. In Denmark, that work was the effort of Georg Rasch. In the United States, numerous researchers made individual contributions that supported the ultimate development of IRT.

The Foundations of IRT

Development of the One-, Two-, and Three-Parameter Logistic Models

The lineage of IRT connects it both to the work on classical test theory described earlier in this chapter and to the work on scaling described in the previous section. In 1934, the United States was in the grips of the Great Depression, and the Roosevelt administration was committed to putting Americans back to work through programs like the Works Progress Administration. During this time, Thurstone was teaching psychology at the University of Chicago when the government offered him a new research assistant, Ledyard Tucker (1910–2004; Carlson & von Davier, 2017). Like Thurstone, Tucker had an undergraduate degree in electrical engineering; Thurstone quickly recognized Tucker's talents and encouraged him to continue his education in psychology. After more than a decade collaborating with Thurstone, Tucker earned his doctorate in 1946 and took a position at the College Entrance Examination Board (College Board; Dorans, 2004).

During his brief time at the College Board, Tucker defined the mathematical form for what we now refer to as an item characteristic curve (ICC). Unlike Thurstone, who had calculated nonparametric ICCs using observed data, Tucker used the integral of the normal curve—the normal ogive—to relate test-taker ability to performance (Tucker, 1946). This work made it possible to calculate the probability that a test taker at any ability level would answer a particular item correctly.

Although Tucker described the mathematical form for the ICC, he did not devote much attention to the underlying latent trait, instead relying on the language of true score theory to describe test-taker ability. This next critical step was based on the work of Paul Lazarsfeld (1901–1976), who in his 1950 publication laid the conceptual foundation for the *latent trait*, in what psychometricians soon would call latent trait theory.

Lazarsfeld studied mathematics in Vienna. With the rise of Hitler, he left Austria for the United States and eventually moved to Columbia University, where he became the associate director of the university's Bureau of Applied Social Research ("Dr. Paul Lazarsfeld Dies," 1976). Although Lazarsfeld is known in sociology for his work on voting and the media, his contributions to test theory stem from his development of latent structure analysis. Latent structure analysis posits that there is an unobserved, *latent* cause for a subject's observed responses. By assuming that responses to individual items are independent, Lazarsfeld was able to study the joint occurrences of item response patterns to make inferences about the trait that underlies this behavior (Lazarsfeld, 1950). Although, the majority of Lazarsfeld's work concerned attitude measures, not educational assessments, the reconceptualization of observed data as being the product of a latent trait as opposed to the trait itself was a critical development.

Bert Green (1928–2019) recognized the applicability of Lazarsfeld's latent structure analysis to educational measurement. In the early 1950s, Green set to work analyzing test-taker response data using latent structure and latent class models. He extended Lazarsfeld's work by developing a general procedure for latent structure and latent class models (Green, 1951a, 1951b) and demonstrating the interrelationship between factor analysis and latent structure analysis. Through this work, Green directly connected latent structure analysis models to what would become IRT. The final steps in the introduction of a statistically rigorous theory of item response patterns was then provided by Lord (1952) and Birnbaum (1957, 1958a, 1958b).

In 1944, Frederic Lord (1912–2000) joined the graduate record office of the Carnegie Foundation, the forerunner to Educational Testing Service (now known as ETS). In 1949, he became the director of statistical analysis at the newly formed Educational Testing Service (Carlson & von Davier, 2017). He completed his dissertation in March 1951, and in 1952 the work was published as a psychometric monograph. The monograph presented the one- and two-parameter IRT models based on the normal ogive. Nearly 30 years later he published the first volume that focused on IRT: *Applications of Item Response Theory to Practical Testing Problems* (Lord, 1980). With these two publications—and the numerous journal papers published between them—he may have done more than anyone else to advance the development of IRT.

Lord was a pragmatist who allowed the data to dictate the development of the model. In this vein, Lord was a developer and advocate of the two- and three-parameter IRT models.²³ In his work in the early 1950s, Lord coined several key terms, including ICC and test characteristic curve. He also described many foundational concepts of IRT, including local independence, item invariance, and standard errors conditional on test-taker proficiency (Carlson & von Davier, 2017; Lord, 1952). Lord continued to develop these concepts throughout his career.

Lord deserves considerable credit for development of the two- and three-parameter IRT models based on normal ogive, but it was Allan Birnbaum (1923–1976) who

reconceived Lord's work using the more mathematically tractable logistic models that are common in the early 21st century. In the late 1950s, Birnbaum was introduced to educational measurement when Columbia Teachers College invited him to help support a contract with the U.S. Air Force School of Aviation Medicine on test-taker classification (Barnard & Godambe, 1982). As we have already noted, in earlier work by Tucker, Green, and Lord, ICCs were described using a normal ogive model. Inspired by the work of David Haley (1952) and Joseph Berkson (van der Linden & Hambleton, 1997), Birnbaum believed the logistic form was more appropriate for IRT because of the existence of a sufficient statistic (Barnard & Godambe, 1982). To this end, in the late 1950s Birnbaum published several research reports for the U.S. Air Force on the applicability of the logistic model to IRT. Lord later invited Birnbaum to summarize this work in four chapters in *Statistical Theories of Mental Test Scores* (Birnbaum, 1968). In those chapters, Birnbaum provided the now-familiar logistic forms of the one-, two-, and three-parameter IRT models and introduced the scaling constant D to make the logistic form nearly identical to the earlier normal ogive formulation. Birnbaum also produced a practical method for item parameter estimation and later introduced the use of prior distributions into ability estimation (Birnbaum, 1967).

Birnbaum's contributions can reasonably be viewed as completing the foundations of IRT. As we have mentioned, related work also went on in Denmark. Whereas the models described in the previous paragraphs built on the insights of numerous researchers, the work in Denmark was carried out almost entirely by one man, Georg Rasch.

Development of the Rasch Model

Rasch (1901–1980) was born in Svendborg, Denmark. He studied mathematics at the University of Copenhagen and in 1930 earned his doctorate with the intention of pursuing a teaching position at the university. When Rasch struggled to obtain a professorship in mathematics (during the worldwide depression), he turned his attention to statistical analysis and was able to earn a scholarship to study with the Nobel Prize–winning econometrician Ragnar Frisch and later with R. A. Fisher. He returned to Denmark in 1936 and was invited to teach statistics in the psychology department at the University of Copenhagen (Anderson & Olsen, 2001). It was during this time that he became increasingly interested in the problems of educational scaling. During the next 2 decades, Rasch worked as a statistical consultant, frequently on psychological and educational assessments. In 1952, while analyzing data for a Danish military exam, Rasch began work on the model for which he has become known.

Unlike Lord, who was a pragmatist, Rasch came to believe that it was critical to define the requirements necessary for objective measurement. By the time he published his monograph *Probabilistic Models for Some Intelligence and Attainment Tests* (Rasch, 1960/1980), he had developed the principles that have become associated with Rasch measurement: the requirements of sufficient statistics and specific objectivity. It is noteworthy that Rasch's *Probabilistic*

Models did not explicitly include the model widely associated with Rasch today—that is, the model equivalent to the one-parameter IRT model. The equivalent model presented in that volume lacked the logistic transformation. He began by defining the probability of a correct response as the ratio of the test takers' proficiency and the item difficulty.

If we put $\xi/\delta = \zeta$, the problem is to choose a function of ζ which only takes values between 0 and 1. And as we find both very easy and very difficult problems and both very able and very unable persons, ζ must cover all values from zero to infinity.

The simplest function I know of, which increases from 0 to 1 as ζ goes from 0 to ∞ , is $\frac{\zeta}{1 + \zeta}$. If we insert $\zeta = \frac{\xi}{\delta}$ we get $\frac{\frac{\xi}{\delta}}{1 + \frac{\xi}{\delta}} = \frac{\xi}{\xi + \delta}$. (Rasch, 1960/1980; p. 74–75)

If we reparameterize by changing ξ to e^{θ} and δ to e^b , then the model becomes the typical Rasch model or the one-parameter logistic IRT model.

Several authors noted this relationship at approximately the same time. Birnbaum (1968, p. 402) noted that Rasch's model had this characteristic in the context of his more general presentation of the one-, two-, and three-parameter logistic models. Similarly, Wright (1968) included a footnote commenting that Rasch's model could be reformulated in logistic form.²⁴ It is unclear which of these authors has priority in identifying this relationship.²⁵

After Rasch's (1960/1980) monograph, he went on to publish several additional papers on the model. Rasch's Berkeley Symposium paper from 1961 provides a general case for *specific objectivity*, and Rasch (1966) discussed other issues, including conditional independence. Throughout his work, Rasch discussed models that included logistic transformations, so it is a curiosity that he never introduced the now-common formulation of the logistic Rasch model for dichotomous items, $P(\theta) = (1 + e^{\theta - b})^{-1}$. Mark Reckase (personal communication, June 2, 2022) noted that it could be argued that Equation 4.2 in Rasch (1961) is the general case of all the models currently referred to as Rasch models and the simple logistic model is a special case of that equation. It may be that Rasch simply believed that it was more natural to use proficiency and difficulty scales with a lower bound of zero.

Although this reparameterized Rasch model for dichotomous items is equivalent to the one-parameter logistic IRT model, separate terms are often used to describe them to highlight the philosophical distinction between Rasch's approach and that represented by Lord's work.²⁶ Given the attention that has been placed on these philosophical distinctions, the reader might get the impression that Rasch developed his model based on principled a priori assumptions about the requirements for measurement; Rasch's own description of the development of his model does not support that interpretation. Regarding his early work on "reading capability," Rasch stated, "When I got the data I made the guess that it might be a good idea to try the multiplicative Poisson model. It turned out to fit the data quite well" (1960/1980, p. xiii). The con-

cept of *specific objectivity*, which has become a hallmark of Rasch measurement, seems to have been discovered after the fact, rather than motivating the development of the model. Later in life, Rasch made it clear that he only appreciated this characteristic of the model after discussing his work with his former mentor, Ragnar Frisch. Rasch visited Frisch in 1959 and described the work he had been doing in educational measurement. On seeing Rasch's formulation, Frisch expressed particular interest in the idea that the person and item parameters could be separated. This separability is what Rasch came to refer to as specific objectivity. Rasch went on to say, "What Frisch's astonishment had done was to point out to me that the possibility of separating two sets of parameters must be a fundamental property of a very important class of models" (1960/1980, p. xviii).

Rasch Versus Multiparameter IRT

This philosophical fault line that separated IRT and Rasch measurement became a growing fissure in the field of educational measurement from the late 1960s into the 1990s, often producing heated interactions at professional conferences. One such interaction was the 1992 debate between Benjamin Wright (1926–2015) and Ronald Hambleton (1943–2022) at the American Educational Research Association's annual meeting in San Francisco. To provide a sense of the division that existed in the field, we describe that debate in some detail.

Wright and Hambleton met in a packed ballroom to participate in an invited session titled "Which Models Work Best." Wright opened the debate: "I make measures for a living. Measures have a specific definition." He went on to suggest—wrongly—that the Rasch model was developed nearly a decade before multiparameter IRT. He proceeded to criticize multiparameter IRT for its "promiscuity" and willingness to "swallow whatever junk happens to come [its] way." Throughout his remarks, he repeatedly returned to the metaphor of a ruler that fails to provide objective measurement, saying, "no scientist, engineer, businessman or cook, who depends on measures . . . can work with that kind of ruler." He closed his remarks by attacking multiparameter IRT for being data centered, saying that the "Rasch model is theory-centered: data must fit, else get better data."

The younger Hambleton took a more genteel and structured approach in his response. He countered Wright's remarks on the antecedence of Rasch's work, noting that Lord's early work was published in 1952, well before Rasch's work was published in 1960. He went on to stress that the model must fit the data, saying that when "Rasch's work became known in 1960, . . . Lord had already rejected that model due to its inferior fit to his data." He discussed the virtues of modeling item discrimination and guessing, noting the 80-year history of modeling discrimination and the improvements to model fit that these parameters afforded. Hambleton devoted significant time to reflecting on the practicality of implementation, noting that the software is sufficient and improving and that many testing programs are having success with multiparameter IRT. Finally, he closed by calling for pragmatism and making it clear that there is a place for many different models, including Rasch's, saying, "Rasch has an important role only when it

fits data well, and sample sizes are modest with no need for highly precise estimates” (Hambleton, 1992; Huang, 2015; Wright, 1992).

Neither Wright nor Hambleton was declared the winner, but with the benefits of hindsight we can see that the winner of the larger debate within the field would likely not have satisfied either side. There can be little doubt that among organizations using IRT for operational purposes the one-parameter models are the most popular. So, in a sense, Wright’s model was victorious. Importantly, however, Wright’s philosophy was not. Operational testing organizations are not choosing a Rasch model because it reflects their philosophical view of objective measurement; instead, they are acceding to Hambleton’s calls for pragmatism. The one-parameter model is popular because it accommodates modest sample sizes and is easy to implement for practitioners. In that way, it is safe to say that Hambleton’s philosophy won out, even if his preferred model did not.

Although Wright and Hambleton famously disagreed about the appropriate philosophical lens through which to view these models, they shared quite a bit in common. Both men made substantial contributions to the popularization of IRT. Both men wrote articles and influential books on their vision of IRT, and both were influential professors—Wright at the University of Chicago and Hambleton at the University of Massachusetts Amherst—who trained a generation of psychometricians in the use of IRT.

IRT Extensions

Almost as soon as the foundations of IRT were completed, researchers began developing extensions to both Rasch and multiparameter IRT to accommodate a wide variety of response data. This process was so productive with extensions building on extensions that van der Linden and Hambleton’s (1997) *Handbook of Modern Item Response Theory* presents no fewer than 27 models, including everything from polytomous extensions of the logistic models, to multidimensional extensions, to models incorporating response time.

One of the earliest IRT extensions is the result of work by Fumiko Samejima. Inspired by Lord’s early work in 1952, Samejima became interested in IRT and began considering the possibility of polytomous extensions. After graduating in 1965, Samejima took several positions in North America, first as a visiting research psychologist at ETS, where she met Lord. After a number of other short-term university positions, in 1973 she accepted a position at the University of Tennessee, Knoxville. Samejima published work describing both normal ogive and logistic versions of what she called the *graded response model* (Samejima, 1969, 1972). Her approach was to model the probability that a test taker of a given proficiency would score at or above a given level on a polytomously scored task (Barnhart, 2013).

The next major extension to IRT models was the *nominal response model* developed by Darrell Bock (1927–2021) in 1972. After graduating from the University of Chicago, Bock worked at the University of North Carolina at Chapel Hill, where he was briefly a colleague of Fumiko Samejima, before returning to teach at the University of Chicago in the same department as Ben Wright. Bock’s nominal response model was

conceptually similar to Samejima's heterogeneous graded response model but allowed for unordered categories. As a result, it was useful for the sort of unordered data that result from some psychological assessments as well as analyzing distractor patterns within educational assessments (Wainer & Robinson, 2006). David Thissen and Lynne Steinberg (1984) extended this latter use with their multiple-choice model. The multiple-choice model extends the nominal response model to support a guessing parameter to further support distractor analysis in education assessments.

The first polytomous extension from the Rasch perspective was provided by David Andrich (1978). After completing his undergraduate education in Australia, Andrich came to the United States to attend graduate school at the University of Chicago. Although Andrich worked with both Ben Wright and Darrell Bock, there is no doubt that he approached his work from a Rasch perspective. In fact, in 1977, Andrich spent 6 months working directly with Georg Rasch at the Danish Institute for Educational Research. Andrich's *rating scale model* estimates the probability that a person with a given ability would achieve each of the possible score points (Webster, 1998). The model, in addition to assuming that the slopes of the items are fixed, assumes that the threshold structure is consistent across all items on the exam. That is, the offsets between each score point and the nominal item difficulty are consistent across all items. Although this assumption may be difficult to satisfy for educational assessment, Andrich was primarily interested in Likert-type data, where the assumption may be more likely to be satisfied. In 1982, Geoff Masters, a fellow Australian and graduate of the University of Chicago, extended the rating scale model to make it more appropriate for educational assessments with the partial credit model. The partial credit model allowed the threshold structure of polytomous items to vary across the exam. This makes it possible for the difference between two specific score points to vary by item. As the name suggests, this can be applied in an educational context to provide some credit for a response that demonstrates partial mastery.

In 1992, the partial credit model was extended again by Eiji Muraki. Muraki, like Andrich and Masters, attended the University of Chicago for graduate school. Unlike Andrich and Masters, Muraki was advised by Darrell Bock and brought a multiparameter perspective to his extension of the partial credit model. In 1992, while studying at Chicago, Muraki published the *generalized partial credit model* that allowed the slope of the items to vary across the exam (Muraki, 1992). At roughly the same time, Wendy Yen, while working at CTB, independently developed the same model (Yen & Fitzpatrick, 2006). Although it was parameterized differently, Yen's two-parameter partial credit model and the generalized partial credit model are mathematically equivalent. This work produced independently by Muraki and Yen transformed the Rasch derived partial credit model to make it compatible with assessments that use a multiparameter IRT model.

Computerized Adaptive Testing

One prominent application of IRT is in the area of multistage and computerized adaptive testing, or what Lord originally referred to as “tailored testing.” Broadly speaking, these approaches route test takers to different items based on proficiency estimates that are produced iteratively as the test is administered. These approaches had been explored in a classical test theory context in the 1950s and 1960s with Angoff and Huddleston’s (1958) work on two-stage testing and Cleary et al.’s (1968) work on a variety of “programmed” testing methods, but these ideas needed an IRT framework to be practical. By the late 1960s, Lord had built on his earlier work on IRT to lay the theoretical foundation for adaptive testing and developed IRT-based methods of delivering both multistage tests with a router test and item-level computerized adaptive tests (Carlson & von Davier, 2017; Lord, 1968). By the early 1970s, Lord had gone further to address many of the practical challenges of adaptive testing, before the technology to deliver these tests was broadly available (Lord, 1970, 1971a, 1971b, 1971c, 1971d; Wainer, 2000).

Since the earliest conceptualizations of computerized adaptive testing there has been ongoing research on the best method for selecting items to be administered to each test taker in a manner that maximizes score precision while respecting nonstatistical constraints on item selection. One of the most popular solutions to this problem known as the *weighted deviation method* was introduced by Lord’s longtime collaborator, Martha Stocking (1942–2006). Lord hired Stocking in 1967 as a research scientist at ETS after she completed her master’s degree in statistics at Rutgers University (Bennett & von Davier, 2017; “Martha L. Stocking Swanson,” 2006). Although her most famous and broadly applied contribution is undoubtedly the *Stocking–Lord equating method* (Stocking & Lord, 1983), Stocking was also prolific in the area of computerized adaptive testing, where she published several important articles and reports on practical considerations in controlling items exposure within an adaptive framework (Stocking et al., 1991a, 1991b; Stocking & Lewis, 1998, 2000; Stocking & Swanson, 1993, 1998).

An alternative approach to selecting items within a computerized adaptive test, while respecting content constraints, was proposed by Howard Wainer in 1987 (Wainer & Kiely, 1987). Wainer was hired in 1980 as a principal research scientist at ETS, where he remained for 21 years (Robinson, 2005). While there, as a colleague of both Lord and Stocking, he developed the testlet-based approach to selecting items within an adaptive test. In the testlet-based approach, rather than selecting individual items, small groups of items, or *testlets*, are administered as a set. These predefined groups of items can be selected and reviewed by content experts to ensure they meet all blueprint constraints before the exam is administered. Although this provides greater control over test content, it provides less adaptability than approaches that select one item at a time (van der Linden, 2000).

A third approach to item selection within computerized adaptive tests was developed by Wim van der Liden (2000). This approach, known as a *shadow test*, attempted to

allow for selecting items one at a time, while ensuring that the complete form adheres to all the underlying content constraints. In a shadow test, after each item is administered, the selection algorithm selects an entire form for that test taker that includes all previously administered items and meets all blueprint constraints. The selection algorithm then selects the item from this shadow test that provides the most information given the test taker's current ability estimate. Given an appropriate item pool, this approach ensures that the test taker will receive an exam that meets the blueprint constraints and is tailored to their ability.

The foundational theory, model extensions, and practical developments including improved estimation procedures (see Bock, 1997; Luecht & Hambleton, 2021; and Thissen & Steinberg, 2020) provided a basis that has allowed IRT to become largely ubiquitous in educational measurement. The third and fourth editions of *Educational Measurement* included major chapters on the topic. The applications are now so diverse and widespread that the current edition recognizes that the topic can no longer be covered in a single chapter.

In the prior three sections we focused on theoretical and technical developments that have shaped the current practice of educational measurement. In the next section we return to a focus on the practice of assessment.

LARGE-SCALE TESTING

In the second section, we described how intelligence testing grew from its foundations in the work of Galton, Spearman, and the eugenics movement. Intelligence testing represents a critical part of the history of the practice of testing, but it is only one part of that history. There is an even longer history of standardized tests being used for selection, graduation, and the evaluation of individuals and schools. Over time, these efforts developed into large-scale testing programs. Much of this testing is targeted at achievement rather than intelligence.

The Chinese began using written examinations for civil service selection more than 3,000 years ago when candidates were tested in the “six arts”: music, archery, horsemanship, writing, arithmetic, and ceremonies of public life. Two thousand years ago, written tests were introduced in the “five studies”: civil law, military affairs, agriculture, revenue, and geography of the empire. Later tests emphasized remembering and interpreting the writings of Confucius. Even for these early examinations there was an understanding that standardization was critical (DuBois, 1970).

The practice—and history—of Chinese testing was known in England and influenced testing practice there. In 1833, standardized testing was instituted for the British Indian civil service. Over time, similar practices were adopted in the United States. In the 1860s, a bill was presented in Congress to institute a similar civil service system, but that bill was never enacted. Civil service testing was eventually adopted in the United States, but that adoption occurred in a piecemeal fashion. The various efforts impacted specific departments in the government and came and went over time as funding was

approved or ran out. A permanent civil service commission was finally established in 1883.

Although university-based tests can hardly be viewed as large-scale assessments, to provide context we note that examinations have played an important role in that context as well. Although oral examinations may have been part of Western education since the founding of the first universities, written tests also have a long tradition. The written examination that Karl Pearson completed to achieve the rank of third wrangler at Cambridge, the Mathematical Tripos, dates to the 18th century. By the late 19th century, written examinations were common in universities.

Horace Mann and Testing in Public Schools

Given the price of paper, it is not surprising that the adoption of written testing in grammar schools lagged behind that in universities. In the United States, grammar school students were typically assessed based on oral recitation in the first half of the 19th century. The drive to create standardized written student assessment in the United States was motivated by the desire to move beyond judgments about students to evaluation of the performance of schools. By early-21st-century standards, the suggestion that standardized testing within a single city should qualify as *large-scale testing* may seem quaint, but nonetheless large-scale testing in the United States appears to have its foundations in the tests administered in the Boston public schools at the instigation of Horace Mann (1798–1859).

Mann is an icon of American education; he fought for universal nonsectarian education, and in recognition of that effort, schools across the country are named in his honor. He had essentially no experience as a teacher and yet he had exceptionally strong opinions about teaching. Most important in the context of this chapter, Mann saw that written tests were not only useful to evaluate individuals; the tests could also be used to evaluate schools—and, by extension, school administrators.

Prior to the launch of these tests in 1845, Boston's schools were evaluated by local visiting committees. The individual schools were run by masters with little additional oversight. The visiting committees routinely found the schools to be performing well based on idiosyncratic and subjective criteria. Understandably, the masters wished to be left alone to run their schools as they thought best (Reese, 2013). By contrast, Mann and his allies believed standardized testing would bring a measure of quality control to a bureaucratically managed and centralized education system. They also believed that through this mechanism they could establish performance standards and systematize education, teacher evaluation, and pedagogy.

In late spring 1845, after months of controversy between Mann and the Boston masters, the first large-scale written examinations were administered to students in Boston. As Mann and his allies planned, the examination results were used both to understand student learning and to challenge the authority of the masters. School accountability testing arguably grew from Boston's 1845 examinations, and Mann's reform work in Boston started a trend toward standardized testing throughout the United States,

including most notably the New York Regents Examinations. The early Regents examinations were introduced in 1865 following the model of Boston's written examinations. The initial examinations were used for high school admissions and to provide an annual measure of student achievement (Phelps, 2007).

The Regents examinations were the vanguard of competitive testing in U.S. schools. As school enrollment increased through the late 1800s, testing expanded beyond classroom assessments to include standardized assessments for grade promotion, high school admission, and high school graduation. Leading educators of the time supported increasingly consolidated schools and standardized curricula as well as standardized examinations, which were thought to spur excellence in teachers and students while preparing students for challenges outside school settings (Reese, 2013).

The written examinations introduced by Mann and the New York Regents established the use of standardized written examinations for both selection and accountability in the United States. Intelligence testing then went on to influence standardized selection and accountability tests after World War I. This progression and interaction will be apparent when we discuss the evolution of the SAT. However, there is an independent strand in the history of testing that warrants attention; that strand represents the continued use of tests to assess achievement, both for accountability and to evaluate the progress of individual students. J. M. Rice is a noteworthy part of that strand.

Joseph Mayer Rice

Joseph Mayer Rice (1857–1934) remains relatively unknown, although his work laid the groundwork for research by better known leaders in educational research, including E. L. Thorndike and Terman (Graham, 1966). He trained and practiced as a pediatrician and, at some point, became interested in pedagogy. This interest motivated his travels in Europe to learn about the developing field of psychology and contemporary theories of pedagogy. After returning to the United States, he developed and implemented tests of spelling, mathematics, and language to evaluate the impact of the pedagogical methods used across schools in cities around the country. He published the results from these studies in the popular magazine *The Forum* (Rice, 1897a, 1897b); many of his original articles were included in his best-known work, *Scientific Management in Education* (Rice, 1913).²⁷

Rice succeeded in collecting large data sets to support his critique of the less-than-progressive educational practices that were prevalent at the time. His first study focused on spelling. In describing this work, Rice reported, "During this time three different tests were made; the number of children examined reaching nearly 33,000" (1897a, p. 164). The primary motivation of this data collection was to explore the relation between the amount of time used to drill spelling in the classroom and the outcomes measured by Rice's tests. Rice's contemporary, E. L. Thorndike, criticized Rice for being too quick to jump to speculative conclusions in interpreting his results (E. L. Thorndike, 1903). Nonetheless, it is reasonable to consider this data collection to be the beginning of the science of educational research. Stanley (1966) suggested that this was likely "the first

full-scale ‘experiment’ ever done in schools and published” (p. 135). It is similarly not difficult to find evidence to support the conclusion that Rice was a self-promoter who brought muckraking to the field of education (Graham, 1966).

School-Based Achievement Testing

In a previous section we discussed the rise of intelligence testing following World War I. At that same time, the use of achievement tests also grew dramatically. Students were often tested with both intelligence and achievement tests in an effort to evaluate whether their performance was in line with their potential.²⁸ The other SAT—the Stanford Achievement Test—was developed by Kelley, Ruch, and Terman in 1922. An advertisement for the test in Kelley (1927, end of volume) somewhat ironically describes the test as follows:

This new battery of achievement tests is designed to measure very thoroughly the knowledge and ability of pupils in school subjects in grades two through eight. It covers all the ground necessary to cover for ordinary purposes of educational testing.

The score in any subject is immediately comparable with the score in any other subject, and valid composite scores for any number of subjects taken together are readily obtainable. Age norms as well as grade norms make possible the derivation of a satisfactory educational quotient.

The battery included tests of arithmetic, reading, spelling, science information, and history and literature. A century after its introduction, the test—now in its 10th revision—is still in use.

In 1927, the Stanford Achievement Test was far from the only large-scale test available. Kelley (1927) listed 4 elementary school achievement batteries, as well as 12 elementary intelligence tests, 15 elementary reading tests, and 10 elementary spelling tests. Clearly, the decade after the First World War was a period of substantial growth for standardized testing.

Over time, other achievement tests were introduced. Perhaps the best known was the Iowa Test of Basic Skills, which continues to the present day as part of the Iowa Assessments. These tests supported a substantial testing industry, including for-profit corporations such as CTB/McGraw-Hill, Riverside, and the World Book Company. These large-scale achievement tests also provided motivation for improving testing procedures. Perhaps most notably, E. F. Lindquist—who was a major force behind the Iowa testing program—introduced the first optical scanner to score multiple-choice items.

So far, this section has focused on achievement tests. These tests were intended as accountability measures for schools, to assess individual progress, and as a means of evaluating the efficiency of differing pedagogical approaches. We now consider two tests used for college admissions: One had its origins in intelligence testing and the other in achievement testing.

The SAT

The group that developed and administered the Army Alpha test included luminaries of the science of intelligence testing such as Yerkes, Terman, Goddard, and Otis. The group also included Carl Brigham (1890–1943). The Army Alpha test was used to measure the “verbal ability, numerical ability, ability to follow directions, and knowledge of information” of military recruits. As we have seen, Army Alpha helped to launch the now-ubiquitous multiple-choice question; it also introduced intelligence testing on a large scale. Perhaps less well known is the fact that it was a steppingstone to the creation of the Scholastic Aptitude Test, the precursor to the current SAT. The connection between the two tests is straightforward; after the war, Brigham adapted the Army Alpha test to create the original SAT.

Established in 1900, the College Entrance Examination Board represented member colleges in the interest of developing uniform assessments (essays at the time) aligned with the curricula of schools that supplied graduates to elite institutions of higher education (Lemann, 2004). Previously, individual schools were responsible for developing their own admissions essays, and the College Board examinations introduced uniformity into the administration process, the tested content, and the scoring. The College Board essay tests were first administered in 1901 (Fuess, 1950). Though the goal of these examinations was standardization, College Board member schools expressed concerns in the 1920s about the subjectivity in scoring and the narrowing effect the exams had on high school curricula (Bennett, 2017).

These concerns led to the development of alternative assessment approaches, including multiple-choice achievement and aptitude tests, leading to the development and adoption of Brigham’s Scholastic Aptitude Test²⁹ in 1926 (Lemann, 2004).

Led by James Bryant Conant, then-president of Harvard University, in collaboration with Brigham and Henry Chauncey (then–assistant dean of admissions, Harvard University), the test was first employed to identify scholarship students based on their intellect, not their educational background. Harvard began using the test in 1934 to identify scholarship students, eventually requiring it of all applicants beginning in 1941. It became a requirement of College Board member schools in 1942.

The first version of the SAT, in use from 1926 to 1930, comprised nine subtests containing 315 multiple-choice questions; it was administered under highly speeded conditions, allowing 97 minutes for the full administration. The more familiar two-section format, testing verbal and mathematical aptitude, was introduced in 1930 (Lawrence et al., 2004).

As discussed earlier, intelligence testing rose to prominence during this same period. By 1932, a vast majority of large school systems in the United States were using intelligence testing to guide ability grouping (Haney, 1984). Despite the similarities in general appearance between intelligence tests and contemporaneous versions of the SAT, there is a marked tension between intelligence testing and the SAT. Throughout much of its existence, the developers of the SAT have argued that instead of measuring intelligence, versions of the SAT have been designed to measure aptitude and reasoning.

Currently, the College Board claims that its questions focus on skills that matter for college success.

ACT (Formerly American College Testing)

Although the SAT was the first large-scale college admissions test, it is no longer the largest. In response to the increasing number of college applicants following World War II and the federal initiatives of the Great Society to increase access to higher education, there was a high demand for standardized tools to support college admissions decisions. The SAT was commonly used in the northeastern states, but elsewhere in the country, states developed their own admissions tools, which increased the complexity of college application, particularly for out-of-state students (ACT, 2009). The American College Testing Program, also known as the ACT Test and ACT,³⁰ was an attempt to meet this need. The program had its roots in the Iowa Academic Meet, the first Iowa testing program for high school students.

The Iowa Academic Meet, or the “Brain Derby,” was developed in 1929 by E. F. Lindquist (editor of the first edition of *Educational Measurement*) under the direction of Professor Thomas Kirby (Holmgren, 2009). The Iowa Meet, in its early form, was used to identify outstanding scholars while raising the standards of instruction across Iowa high schools by testing every student (Lindquist, 1976, as referenced by Croft & Beard, 2021). This grew into the Iowa Assessments (previously known as the Iowa Testing Programs). Iowa Assessments were administered to students in Iowa beginning in 1935 and around the country beginning in the 1940s.

The ACT, cofounded by Lindquist and Ted McCarrell of the University of Iowa, was introduced in 1959 and was designed to assess a student’s general educational development. It incorporated multiple-choice questions that had previously appeared on the Iowa Test of Educational Development, allowing for rapid development (Croft & Beard, 2021). The original ACT had four sections—English, mathematics, social studies, and science—and was delivered in 3 hours (Croft & Beard, 2021; see ACT, 2009, for further details).

The ACT was originally tied to the assessment of knowledge, in contrast to the SAT’s focus on aptitude. Although this historical distinction exists, it would appear to be of little practical importance given the high correlation that exists between the tests—typically reported to be approximately .90—and the existence of widely used concordance tables that allow the scores to be used interchangeably (College Board & ACT, 2018; Perez, 2002).

In the previous pages, we considered tests designed for accountability, tests designed as a metric of individual student achievement, and tests for selection. So far, the tests we have discussed have one thing in common: They produce an interpretable score for each test taker. We conclude this section by considering a test explicitly designed so that individual scores cannot be produced.

NAEP

In 1867, Congress established a Department of Education. Among the purposes of the department was “collecting such statistics and facts as shall show the condition and progress of education in the several States and Territories” (An Act to Establish a Department of Education, 1867, Sec. 1). In essence, the department was to produce a national assessment of educational progress. This did not happen; the Department of Education was reduced to an office and then made part of the Department of the Interior.

Nearly 100 years later, the idea of a national assessment of educational progress was revived. (See also Ho & Polikoff, this volume, for a review of the history and current use of NAEP for accountability purposes.) In 1964, the test was funded by the Carnegie Corporation. The Education Commission of the States subsequently took over administration with funding from the Carnegie Corporation and then with increasing funding from the U.S. Office of Education. Congress took over all funding for NAEP in 1972 and moved NAEP to the National Institute of Education in 1978.

From the outset there was an effort to make NAEP an outstanding example of measurement science. The office of education—and later the Department of Education—contracted and consulted with the most respected organizations in the country, including ETS, the American Council on Education, American College Testing (ACT), Human Resources Research Organization, and the American Institutes for Research. This led to innovation and the application of state-of-the-art methodology.

Ralph Tyler (1902–1994), a contributor to the first edition of *Educational Measurement*, was an early advisor on the project. It was Tyler’s recommendation to base the national assessment on a systematic sampling strategy rather than a more exhaustive program of testing. Sampling reduced cost, but also ruled out the possibility of producing scores for individuals, which was prohibited by the legislation.

In 1983, the sophistication of the NAEP administration again took a major step forward. ETS was awarded a contract by the Department of Education to design and conduct the examination. ETS proposed numerous changes (Messick et al., 1983). They included a more sophisticated sampling design as well as the introduction of IRT to support test construction and to carry out linking across test forms and across years.

As we noted previously, NAEP has been an example of excellence and innovation in assessment science since the 1960s. In the IRT chapter from the fourth edition of *Educational Measurement*, Yen and Fitzpatrick (2006) described NAEP as “the most famous example of a matrix-sampled test.” They go on to say that “NAEP is also notable for the use of IRT in combination with advances in missing data technology and hierarchical analyses to estimate population characteristics without estimating individual examinee scores” (p. 145). NAEP was referenced in five separate chapters in the 1989 edition of *Educational Measurement* and in eight separate chapters of the fourth edition (Brennan, 2006).³¹

As this section suggests, much of the development of large-scale testing has happened in the United States, but in recent decades these tests have become important around the globe. For example, in China, the National College Entrance Examination, which determines eligibility for postsecondary education, is taken by approximately 10 million students each year. Because of the impact this test can have on future career opportunities, students spend years preparing for it (Larmer, 2014). High school graduation and university selection tests are also an established part of education in many other countries (see Clauser & Margolis, 2023). Beginning in the 1990s, three large-scale achievement tests have also been administered internationally in multiple languages: these include the Trends in International Mathematics and Science Study (TIMSS, first administered in 1996), the Programme for International Student Assessment (PISA, first administered in 2000), and the Progress in International Reading Literacy Study (PIRLS, first administered in 2001). These international tests are discussed in detail in Chapter 20 of this volume by Braun and Kirsch.

THE HISTORY OF EDUCATIONAL MEASUREMENT AS REFLECTED IN FIVE EDITIONS OF *EDUCATIONAL MEASUREMENT*

The multiple editions of *Educational Measurement* now span more than 7 decades (Brennan, 2006; Lindquist, 1951; Linn, 1989; R. L. Thorndike, 1971), and in this final section we consider how these volumes fit into the history of *Educational Measurement*. Since the first edition was published, it has been a highly regarded standard reference. The volumes can fairly be seen as representing the state of the art for educational measurement, but in general they do not represent the cutting edge (for example, the 1971 edition included only passing mention of the relatively new technology represented by IRT, although it had been thoroughly described by Birnbaum in Lord and Novick's 1968 text and by Rasch in 1960).

Although there are lead authors responsible for the chapters in each of the volumes, the works have been intentionally collaborative. The Lindquist volume lists collaborators along with the lead authors on the title page of each chapter. Subsequent volumes all highlight the reviewers for each chapter. Although there is sometimes disagreement within the field about some of the views expressed, the resulting chapters are at least intended to make a consensus statement about their specific topics. As such, changes across chapters from one edition to the next provide a useful view of how the field has evolved. In reviewing the third edition, Cronbach (1989b) commented on the increased length of each subsequent volume, the topics covered, and the level of mathematical sophistication required of the reader. In addition to these changes across editions, we also consider how the authors have changed over 70 years.

A synoptic view of the four earlier volumes provides considerable insight. Each of the volumes has a section on measurement theory. In the third and fourth editions, this is broadened to include "theory and principles." In the first two editions, this section is

placed after the more practical sections on test development and administration. In the subsequent editions, theory is (literally) given priority by being placed at the beginning of the volume. This seems to reflect a change in the intended audience of the volumes; it may also reflect a change in the field, with higher expectations that practitioners have advanced training. In a sense, these subsequent volumes demonstrate that the place of the measurement profession was now established.

One interesting way to look across the editions is to consider how the content has changed in subsequent chapters on the same topic. Examining the parallel chapters provides a detailed outline of historical changes in thinking within the field. For example, the chapters on validity allow the reader to see how the concept grew from validity as correlation and prediction (in Cureton's 1951 chapter) to include construct validity (as described by Cronbach, 1971). Messick (1989) then broadened the view of construct validity and gave particular attention to consequences and Kane (2006) formalized the idea of validity as a structured argument in support of the inferences we make based on test scores. Green (2008) pointed out that in the fourth edition correlation and prediction are almost absent from the presentation of validity.

Kolen (2021), in discussing the history of equating, made a similar case for the historical value of the early editions of *Educational Measurement*. He described Flanagan's (1951) chapter as the first comprehensive description of equating and discussed how Angoff (1971)—writing in the second edition—reconsidered some of the basic assumptions of equating (e.g., the idea that equating should be sample invariant). As is the case with validity theory, changes in practice continue to be documented in the subsequent editions as equal percentile and IRT-based approaches receive more attention.

In addition to considering how similar content has evolved across parallel chapters in the editions of *Educational Measurement*, it is interesting to note how the content has changed across volumes. In all five editions the section on theory includes chapters on validity, reliability, and equating. The first two editions also included chapters related to theory, which were dropped from subsequent editions. Both the first and the second editions included chapters on approaches for considering multiple measurements (i.e., batteries and profiles). As less attention has been given to intelligence testing, these sections appear to have been considered less relevant. These two early editions also included chapters on the *nature of measurement*; this topic was not included in the third or fourth editions but has a reprise in the current edition.

Not surprisingly, the section on theory and principles in subsequent editions also includes chapters that were not included in the first two volumes. Three chapters in the Linn (1989) edition clearly reflect trends in the field that have received considerable attention since the second edition was published: IRT, cognitive psychology, and bias in testing. As Cronbach (1989a) pointed out, although by 1971 there had already been a long presentation of IRT by Birnbaum and a book on computer-assisted testing, there is almost no mention of IRT in the second edition. The attention given to this area since the 1970s is reflected by the chapters included in the third and fourth editions.

Similarly, the controversy over racial differences in IQ scores, concern for equity and fairness, and the increased attention given to consequences as an integral part of test validity led to a very significant focus on test bias. This is reflected in the chapter on bias in the third edition. Finally, chapters on cognitive psychology in the third and fourth editions reflect the extent to which measurement experts searched for a theory-based foundation for assessment practice.

In addition to considering the content of the editions, it is interesting to consider how the contributors have changed over time. In the first three editions, the majority of the authors were affiliated with universities (57%, 61%, and 69%, respectively). In the two most recent editions, fewer than 50% of the authors had university affiliations; most were associated with nonprofit organizations. Relatively few of the contributors to any of the editions have come from for-profit testing companies.

The authors who have made contributions to *Educational Measurement* have also changed in another important way over time. The list of authors in the first two editions included only one woman.³² The percentage of women contributing to the volumes has substantially increased with the subsequent editions. Across the four earlier editions, the percentage of women authors was 4, 0, 27, and 35, respectively. In the current edition more than 40% of the authors are women.

SOME FINAL THOUGHTS

In this chapter we have described some of the critical themes and events in the history of educational measurement. We believe that understanding the history of our field is important. To use a phrase that Howard Wainer (2005, p. 118) attributed to Aristotle, “We understand best those things we see grow from their very beginnings.” If we wish to understand the field of educational measurement, we would be well served by understanding how it developed. That history tells us something of what has been accomplished since the time of Francis Galton. It is easy to view the development of correlation by Galton and Pearson; the adoption of those methods for correlational psychology by Spearman; the extension of Spearman’s formulas by Kelley, Kuder and Richardson, and Cronbach; and finally the development of generalizability theory as an inevitable evolution. The history as presented in this chapter documents that evolution, but it also makes clear that there was nothing inevitable about it. The dominant approach to understanding reliability could instead have been based on Edgeworth’s generalizability-like framework—which was published before Galton’s introduction of the correlation coefficient. The evolution of test theory, like Darwinian evolution, has not been a progression toward some abstract perfection; it simply reflects the relative usefulness of different approaches given the environment in which they exist. Spearman’s work supported an exploration of the nature of intelligence, and that exploration was well suited to an environment shaped by the widely popular eugenics movement.

These beginnings have had a lasting impact on both the theory and the practice of testing. As we discussed in the second section, the Army Alpha test brought to prominence large-scale intelligence testing using multiple-choice questions. The focus on intelligence testing had a major impact on testing practice—up to and including early versions of the SAT, which were modeled after the Army Alpha test; the general format represented by these tests (if not the content) has remained dominant for over a century.

The early prevalence of intelligence testing also created a close link between testing theory and practice and the eugenics movement. This link helps to explain why the public may not trust experts who suggest that they can benefit society by measuring minds. The eugenics movement caused horrific suffering both in Europe and in the United States. Many of the great thinkers in statistics and educational measurement were closely aligned with that movement. Names like Galton, Pearson, Spearman, Fisher, Goddard, and Kelley represent a very partial list of eugenicists associated with educational measurement.

In understanding the context that has produced the practice of testing in the 21st century, it is also important to remember the political forces that have shaped testing. At least as far back as the 1860s, the U.S. Congress has made political decisions about whether to support—or to withhold support from—testing. The civil service commission and the army testing program during World War I are early examples, but the testing mandates put in place to evaluate the American education system and to provide accountability (such as NAEP) have likely done even more to shape the field of educational measurement.

Another example of the importance of context arises in the sections on scaling and the development of IRT. These sections are closely linked and both remind us that beliefs about the nature of educational measurement have not only changed over time, but also varied across researchers at the same time. Fechner constructed a scale that reflected his understanding of measurement from the study of physics. Binet, by contrast, rejected the link between psychological and physical measurement, stating, “The scale properly speaking does not permit the measure of intelligence, because intellectual qualities are not super-posable, and therefore cannot be measured as linear surfaces” (Binet & Simon, 1916, p. 40). This split between pragmatism and philosophical beliefs about the nature of measurement resulted in high-profile disagreements between the adherents of multiparameter IRT and Rasch measurement. That debate continues in more recent works such as those by Mari et al. (2021) and Irribarra (2021). Understanding how these differences of opinion have persisted should help the reader to hold these disagreements in perspective.

Each of the sections in this chapter provides an example of why we believe that the theory and practice of educational measurement needs to be understood in their historical context. It is easy to read a text on classical test theory or IRT and come away with the impression that they are inevitable truths describing immutable relationships. These theories are simply tools that have proven useful in specific contexts. These tools are valuable (and the present authors have spent decades trying to mas-

ter their use), but as the questions we ask change, the tools may need to change as well. Historical context provides an understanding of how and when those changes become critical.

In the end, it is not our intention to tell the reader how to interpret the history of our field. We certainly do not have answers to the question of what lessons should be learned from that history. But we do believe that leaders in educational measurement will understand the field better when they understand how it has grown from its beginnings.

ACKNOWLEDGMENTS

One of the great challenges of writing this chapter is the great expanse represented by the history of educational measurement. It would be impossible for any set of authors to know it all. We are, therefore, humbled by the tremendous support we have received throughout the process. First, we would like to thank Linda Cook and Mary Pitoniak for entrusting us with this work, as well as for their leadership and thoughtful suggestions throughout. We would also like to thank Howard Wainer, Mark Reckase, and Kadriye Ercikan, who acted as reviewers and collaborators on the chapter, for their multiple reviews filled with many valuable suggestions. Sometimes these suggestions corrected errors, but more importantly, they led us to include historical figures and events that we may otherwise have overlooked. Their contributions have improved both the content and the form of the chapter.

NOTES

1. The first and second wranglers that same year are decidedly less well known: Andrew James Campbell Allen and George Francis Walker. Other well-known scholars who performed well in the examinations but failed to achieve first place include Alfred North Whitehead, John Venn, Bertrand Russell, Thomas Malthus, John Maynard Keynes, and R. A. Fisher.
2. Several other formulations of this equation may be more familiar to the reader, including $r_{xy} = \frac{\Sigma(xy)}{\sqrt{\Sigma x^2 \Sigma y^2}}$.
3. This statement obviously reflects Pearson's enthusiasm for eugenics, but it should be noted that it was made years before the atrocities of the Holocaust were widely known.
4. The form of the equation provided in the text is the one presented by Spearman. The reader may be more familiar with the following equivalent formulation in which x and y replace p and q , $r_{x'y'} = \frac{r_{xy}}{\sqrt{r_{xx} r_{yy}}}$.
5. The reader may be familiar with the following formulation in which r_{11} is the reliability of the original test and r_{KK} is the reliability of a test lengthened by a factor of K , $r_{KK} = \frac{K r_{11}}{1 + (K - 1) r_{11}}$.
6. Clauser (2021) provided a more detailed presentation of the material in this section.
7. These papers were originally published in 1905, 1908, and 1911. In 1916, at Goddard's instigation, they were translated and published in a single volume. In what follows, the chronology of development will be based on the original publication dates, but specific references will be to the translation.
8. Some previous authors explicitly state that Binet and Simon may have been the first psychologists to work with item characteristic curves (e.g., Hambleton & Swaminathan, 1985). This requires a broad definition of *item characteristic curve*. Binet and Simon examined the probability of a correct response as a function of age rather than as a function of estimated ability. In this context, it is also worth noting that it does not appear that Binet and Simon actually plotted their results; instead, they presented the results in tabular form. That said, several of the tables in

their paper on application of the new methods present scores as a function of age and could scarcely be more informative if they were converted to graphic form.

9. Our copy was signed by Goddard in 1949 with a note supporting such beneficial outcomes claiming that “Deborah Kallikak still lives, not in story but in fact. She is now 58 years old in good health and enjoying life . . . across the street from the Vineland Training School where she was living when this book was written.”
10. The idea of forming a quotient by dividing mental age by chronological age was originally recommended by the German psychologist William Stern, but the widespread use and its transfer to a three-digit scale—with 100 representing a 1:1 ratio of mental age to chronological age—is the result of Terman’s work.
11. Not to be mistaken for the publishers of the *World Book Encyclopedia*.
12. The Terman study may be the longest running psychological study. The Fels study ran longer—from 1929 to 2018—however, this study was primarily focused on physiological measurements.
13. In addition to Terman’s effort to follow individuals into adulthood to examine how their exceptional IQs impacted their lives, he apparently thought it was possible to estimate the IQs of historical figures; he published a paper in which he estimated Francis Galton’s childhood IQ by evaluating his childhood mental age based on records of his childhood behavior. He concluded that his IQ must have been around 200 (Terman, 1917).
14. Brigham subsequently changed his mind about the usefulness of intelligence tests for making racial comparisons. In Brigham (1930), he made this change of opinion clear, stating in reference to *A Study of American Intelligence*, “This review has summarized some of the more recent test findings which show that comparative studies of various national and racial groups may not be made with existing tests, and which show, in particular, that one of the most pretentious of these comparative racial studies—the writer’s own—was without foundation” (p. 165).
15. Even Helen Keller supported the eugenics movement. In 1915, she wrote a letter to *New Republic* supporting a doctor who withheld treatment from a severely disabled baby. In that letter she advocated the formation of juries of physicians to make such decisions, stating, “A mental defective . . . is almost sure to be a potential criminal. The evidence before a jury of physicians considering the case of an idiot would be exact and scientific. . . . They would act only in cases of true idiocy, where there could be no hope of mental development.” She went on to say, “Conservatives ask too much perfection of these new methods and institutions, although they know how far the old ones have fallen short of what they were expected to accomplish. We can only wait and hope for better results as the average of human intelligence, trustworthiness and justice arises.”
16. Readers may be more familiar with this formulation in which the subscript t

signifies true score and the subscript x signifies total score: $r_{12} = \frac{\sigma_t^2}{\sigma_x^2}$.

17. It is worth noting that a paper by Cyril Hoyt (1941) published in *Psychometrika* a decade earlier (and cited by Cronbach) also demonstrated that the KR20 represented the mean of all possible split-half estimates. Hoyt's paper also provided a link to generalizability theory by producing the estimate based on analysis of variance.
18. The suggestion that error of measurement might be a more useful metric than a reliability coefficient did not originate with Cronbach. Otis and Knollin (1921) and Kelley (1921) both made this argument. As we noted, the histories of the classical test theory and generalizability theory perspectives are intertwined.
19. This is a simplified description of generalizability theory. For a more complete description, see Cronbach et al. (1972) or Brennan (2001a). Brennan (2021) specifically presented aspects of the history of generalizability theory.
20. In addition to this, Edgeworth also published two papers on correlation years before Pearson's paper and he coined the term *coefficient of correlation*.
21. In the second edition of *Educational Measurement*, William Angoff wrote a chapter titled "Scales, Norms, and Equivalent Scores" (Angoff, 1971). Angoff viewed scaling as the process of defining the scale on which scores are to be reported.
22. This relationship would have been familiar to Fechner through his research on electricity. Georg Ohm had written that the loss of current would be a logarithmic function of the length of the wire: $V = m \text{ Log } (1 + x)$.
23. Lord also proposed the less well-known four-parameter IRT model.
24. In this context, it is worth noting that Lord was substantially focused on models that were applicable to multiple-choice questions. Rasch's interests were more general. Rasch (1960/1980) presented a model for reading accuracy, a model for reading speed, and a model for intelligence tests. In reviewing Rasch's book for *Psychometrika*, Sitgreaves (1963) noted that the first two of these models are more fully developed than the third.
25. Wright (1968) was based on a paper presented at ETS in 1967, but Wright did not actually discuss the model in that paper—it is included as a footnote, which may have been added later.
26. Thissen and Steinberg (2020) attributed the use of the term one-parameter model to Wainer.
27. The research reported in this volume began with his study of spelling in 1895. Work on mathematics and language followed in 1901 and 1903, respectively.
28. Kelley (1927) considered this an inappropriate practice. He commented, "On the average, in the neighborhood of .90 of the capacity measured by an all-round achievement battery score,—reading arithmetic, science, history, etc.—and the capacity measured by a general intelligence test is one and the same. If a comprehensive educational achievement test and a general intelligence test each give 'fairly reliable' total scores, each would need to be more than ten times as

long to yield equally reliable measures of the difference between the educational achievement and intelligence scores” (pp. 21–22). It may be that the intentions behind these approaches to testing differ more than the results.

29. SAT was originally an initialism representing Scholastic Aptitude Test. The name was subsequently changed to Scholastic Assessment Test and is now officially SAT.
30. Similar to the SAT, ACT originally was an initialism for American College Testing. ACT is now the official name of the test.
31. For more information on the evolution of NAEP, see Jones and Olkin (2004).

The Sociocultural Context of Educational Assessment

Kadriye Ercikan

ETS

Guillermo Solano-Flores

Stanford University

In this chapter, we argue for and demonstrate the critical importance of considering assessment as an activity that both reflects and influences the sociocultural contexts in which it is developed and enacted. Our main goal is to highlight the nature of this bidirectional relationship for measurement professionals, researchers, decision-makers, and practitioners. We provide guidance for research and practice that contribute to promoting valid and equitable design, interpretation, and uses of assessment while taking this bidirectional relationship into account. Contexts determined by conditions such as legislation, educational policy and practices, technological advances, social inequities, and unexpected events such as the COVID-19 pandemic affect assessment practices and individuals' participation in assessment (e.g., Tong, 2022). In turn, assessment impacts education policy, teaching practices, and the learning, career, and life opportunities of individuals. There has been a great deal of attention paid to this bidirectional complex relationship recently by scholars emphasizing different aspects of the relationship (Bennett, 2023; Hughes, 2023; Randall, 2021; Russell, 2023; Walker et al., 2023). One of the key goals of our chapter is to promote dialog among stakeholders with varying perspectives on social justice and sociocultural issues given the multiplicity of stances and real-world goals of stakeholders.

This sociocultural perspective on the complex bidirectional relationship between assessment and the sociocultural context is summarized in Figure 3.1. The figure is far from being exhaustive and is intended to illustrate the variety of elements involved in the relationship. In representing this relationship, we embrace a sociocultural perspective (Wertsch, 1985) according to which cognition takes place through social interaction (National Academies of Sciences, Engineering, and Medicine [NASEM], 2018b; Rogoff & Lave, 1984; Vygotsky, 1978): Knowledge is constructed through social mediation; individuals make sense of experience according to implicit or explicit conventions about what is accepted or deemed reasonable in their societies. Different epistemologies result from different cultural influences that shape how individuals make sense of experience and how they view and solve problems (Greenfield, 1997).

We also pay attention to language and its associated communicative roles in institutional and social life as both a cultural product and a key mediator of the ways in which knowledge is represented and information is understood (Gelman & Roberts, 2017). Because languages encode cultural experience accumulated over time, each language has a unique set of resources and conventions that shape the way in which ideas are expressed.

Three notions derived from this perspective guide our reasoning about the bidirectional relationship of assessment and sociocultural contexts (Ercikan & Solano-Flores, 2016). The first notion is that culture and language influence how individuals engage with tests, how they process information presented in tests, and how they formulate solutions and generate responses.

The second notion is that, because tests and testing are cultural products (Cole, 1999), they are a reflection of the societies in which they originate and are even an agent of social reproduction. The content of tests is a reflection of the kinds of knowledge, reasoning,

**FIGURE 3.1**

The Bidirectional Relationship Between Sociocultural Context and Assessment

and skills valued in a society (Hughes, 2023; Teltemann & Klieme, 2016). Also, the ways in which tests are worded and the ways in which they represent information are aligned with implicit and explicit social conventions for representing information based on multiple assumptions about what is understandable to the test taker (Solano-Flores et al., 2013). Tests tend to be written in a standard, formal variety of the language in which they are administered and are aligned with immediate performance of tasks and their demands presented in artificial events. This type of language usage is not common among certain test takers—and especially so for test takers from a nonnative language background in the language of a test (Solano-Flores, 2006).

The third notion is that assessment has different meaning and roles for different cultures (e.g., Gebril, 2016; Kennedy, 2016) and contexts. Views of tests and testing and the consequences that tests and performance on tests have on people's lives vary across

societies. This creates differences across societies in the ways in which individuals prepare for taking tests, how they interpret test items and their demands, the level of effort they put into responding to tests, and the pace with which they solve problems during a test.

Even though much of the discussion is relevant to both large-scale assessment and classroom assessment, we focus intentionally only on large-scale assessment, given the importance of addressing the wider range of stakeholders, contexts, and formalized processes involved in the bidirectional relationship between sociocultural context and assessment. Discussions of classroom assessment and its relationship with large-scale assessment systems can be found in Ruiz-Primo and Furtak (2024) and in Brookhart and DePascale (this volume).

LIMITATIONS IN CURRENT PRACTICES

Despite recognition of the complex relationships between assessment and society, the nature of social contexts may not always be given sufficient consideration in current large-scale assessment practices. In this section, we discuss challenges and limitations in four areas of research and practice: assessment interpretation and use, assessment design and development, the operationalization of culture and language, and approaches to fairness research.

Assessment Interpretation and Use

A key implication of the sociocultural perspective is that test score interpretation needs to be grounded in the sociocultural contexts of the participating individuals and the assessment itself. For example, differences in performance on tests largely reflect social and cultural group differences that are confounded with the actual targeted constructs. In some assessments, the targeted construct is identified in vague terms such as *verbal ability*, which implies a more general reading ability than what is targeted by the assessment. For example, the assessment may in fact target reading ability to carry out a set of reasoning tasks in specific contexts that involve text. Since the context of the application of reasoning is not specific, the assessed reading ability may be perceived as “general, abstract reading ability.” The exclusion of the context from the construct definition obscures the critical need for inclusion of the context for applying the targeted skills and abilities. It also masks the need for the type of evidence required for the intended interpretation and use of the assessment, which is likely to interact with sociocultural factors. A wealth of literature and data document the considerable score gaps on large-scale assessments between groups defined by factors such as socioeconomic status, race/ethnicity, disability, and proficiency in the language of tests (e.g., Bohrnstedt et al., 2015; Gilmour et al., 2019; NASEM, 2018a). In the United States, compared to their middle-class and high-income counterparts, low-income students, Black and Latino students, and English learners (ELs; students whose first language is not the language in which they receive instruction and are tested) attend schools with fewer resources, tend to be taught by less qualified teachers, and are less likely to be

exposed to a curriculum that contains all the content assessed (Darling-Hammond, 2000; NASEM, 2017). While assessment programs are intended to serve the goal of producing insights about educational outcomes, they cannot inform policy and practice effectively without taking these important aspects of sociocultural contexts into account.

Recognizing that sociocultural contexts shape the validity and interpretation of test results is not new (see Becker, 2003; Ercikan, 1998; Ercikan & Roth, 2011). However, the focus has been primarily on examining the extent to which tests and the scores they produce can be assumed to have the same meaning when they are administered in different versions or to individuals from different groups (see Berman et al., 2020). In these comparisons, psychometric approaches such as the analysis of differential item functioning (DIF; Camilli, 2013; Hambleton et al., 2005) are frequently invoked as evidence of the ability of assessment systems to ensure fairness by identifying test items that are biased against a given group. Yet a critical perspective of empirical evidence reveals that such approaches are not sensitive to cultural, linguistic, and economic heterogeneity *within* each of the groups compared, despite evidence that cultural and linguistic heterogeneity is an important source of bias and measurement error (see Ercikan & Por, 2020; Oliveri et al., 2013; Solano-Flores & Li, 2009).

The need for critically examining the influence of sociocultural contexts on student performance is also evident in our efforts to examine response processes. The analysis of cognitive activity during test taking has been part of the arsenal of techniques for test development and test validation since the early 1980s (e.g., Chi et al., 1981; Hamilton et al., 1997; Kukea Shultz & Englert, 2021; Leighton, 2013; Pepper et al., 2018; Ruiz-Primo et al., 2001). Yet rarely has examination of evidence of cognitive activity taken into consideration the social nature of knowing and learning or the role that the sociocultural context plays in learning (see Gee, 2008; National Research Council [NRC], 2001). A sociocultural perspective should allow examination of student performance on tests in terms of how individuals think, feel, act, and interact (see Moss et al., 2008; Nasir, de Royston, et al., 2020; NRC, 2000; Solano-Flores & Nelson-Barber, 2001). Cultural factors, threats to validity due to limited language proficiency in the language of tests, and differential predictive validity of tests across individuals from different cultural groups (see van de Vijver, 2016) occupy a prominent role among the factors that deserve our attention.

Assessment Design and Development

In practice, past approaches to addressing culture and language in assessment development have largely focused on the presentation-related features of items that are known to create unnecessary linguistic complexity (e.g., Abedi, 2006) and on the inclusion of assessment developers and reviewers who represent the student target population and who are assumed to be sensitive to its characteristics and assessment needs (Welch, 2006; Zieky, 2016). Although they are valuable, these approaches may be limited in their ability to address the complex influences of the sociocultural context and language in testing. As mentioned, inevitably, tests are created not only based on

explicit prescriptions of the content that students should know but also under implicit assumptions about both the shared cultural experiences that make tests accessible and the students' familiarity with the response demands of tests as they are administered. Often, as a result, the linguistic features of tests, the contextual information they provide with the intent to make items meaningful, and the forms in which they represent information may reflect the experience and culture of those who create the tests more than the test takers' experiences. These concerns are particularly serious given that there is evidence that students rely on out-of-school, firsthand, everyday life experiences to make sense of the content of items and the contextual information they provide (Hamilton et al., 1997; Solano-Flores & Li, 2009).

Currently accepted practice in assessment design and development is not guided by clear criteria to systematically address the ways of knowing of different populations and sociocultural contexts (see Faulkner-Bond, 2020; Randall, 2021). Researchers have expressed concerns about how constructs are represented and the fact that the wording of test items and the contextual information they provide exclude certain segments of the student populations (e.g., Durán, 2011; Randall, 2021). However, very scant research (e.g., Banks, 2006; Martiniello, 2008) has examined the characteristics of test items according to variables relevant to test takers who are familiar with relevant cultural contexts and studied how those characteristics are associated with differences in student performance. Recent evidence on the development of assessments for Indigenous populations in Hawaii (Kukea Shultz & Englert, 2021) indicates that working intensively and directly with members of local communities allows development of meaningful test items. While this kind of work may not necessarily be feasible for large-scale assessment programs and heterogeneous populations, this evidence speaks to the importance of including samples of students from different cultural, linguistic, and socioeconomic groups in the process of test development as critical to ensuring fair assessment (for example, including them in cognitive interviews and focal groups intended to contribute information that allows examination of inferred cognitive processes elicited by pilot items).

The exclusion or limited inclusion of ELs in the process of assessment development is a special concern in the United States because ELs constitute the population that is most likely to be affected by challenges imposed by the linguistic features of test items. While these students are part of the population tested in large-scale assessment programs, in which tests are administered in English, they are typically not adequately represented in pilot studies to determine how the wording of items may pose challenges for understanding the items as intended and responding to them. Underlying this practice may be the erroneous conception that ELs do not have the communication skills needed to participate in responding to draft versions or participating in cognitive interviews or focus groups. In actuality, despite their classification as ELs, the majority of these students have at least a minimum level of English proficiency and ought to participate in the pilot stages of the development of tests to provide valuable information on the ways in which the wording and format of items can affect their ability to understand them (see Kachchaf, 2011; Winter et al., 2006; Young et al., 2014).

Evidence of cultural relevance and appropriateness of assessment tasks for students from different cultural backgrounds and identities is even rarer and more limited (Randall, 2023). A key, simple way of examining cultural and linguistic appropriateness of items consists of conducting cognitive labs with individuals from different backgrounds to probe their interpretations of test items and the variety of ways in which they respond to them. Unfortunately, in practice, these activities do not involve adequate samples of students from different cultural, linguistic, and socioeconomic groups. At best, broad categories of linguistic or ethnic groups are used under the implicit assumption of population homogeneity—a serious limitation, given the fact that cultural and linguistic minority groups tend to be highly heterogeneous (Ercikan & Roth, 2009; Sireci & Faulkner-Bond, 2015). Missing this opportunity for examining the degree to which test items align with students' cultural experiences and language can compromise measurement and the interpretation of assessment results.

Operationalization of Culture and Language

An important challenge in addressing cultural and linguistic issues in assessment is the difficulty of developing actionable principles that are sensitive to the characteristics of the populations included. There are comprehensive guidelines for developing tests for diverse populations offered by both scholars (e.g., Taylor, 2022) and professional organizations (see American Educational Research Association [AERA] et al., 2014; International Test Commission [ITC], 2017). In addition, most assessment programs have item-writing guidelines intended to address culture and language (e.g., ETS, 2022). Large-scale assessment programs include stages in the process of assessment development in which external reviewers examine items to identify potential sources of bias or difficulty in the wording of the items or the contexts they use.

Unfortunately, while these actions may produce valuable information on how the characteristics of items need to be adjusted, the information provided by adult reviewers may not be comparable to the information obtained from students with whom the items could be tried out. There is evidence that the features of items reviewers identify as potentially challenging for proper interpretation by their students are not necessarily the same features that pose a challenge to those students (Solano-Flores & Trumbull, 2003). The absence of proper conceptual and ideological frameworks imposes a limit to the ability of test reviewers to detect and address limitations concerning issues of culture and race (Randall, 2023).

Regarding the testing of ELs, for example, it is not uncommon to find recommendations for item writers that focus on principles for the use of linguistic features such as word length, negation, conditional clauses, and passive voice (e.g., Abedi, 2006, 2016). While these recommendations may be well informed by empirical research, they are limited in their ability to minimize unnecessary linguistic complexity because they are not item specific. Analyses of test takers' interpretations of items always reveal unanticipated challenges. Indeed, it is extremely difficult to predict what may become an issue in the development of an item. Not only does each item have a unique combination of

linguistic and contextual features (in addition to the content it is intended to assess), but also each test taker has a unique combination of skills and cultural experiences that influence how they make sense of items. Because of this variation and its unpredictability, actions oriented to addressing the cultural and linguistic aspects of tests need to be taken for each item and need to be empirically supported.

Limitations in addressing cultural diversity largely stem from the predominance of implicit deterministic views underlying assessment practice and policy and the role of schools in educating students with limited understanding of their backgrounds. It is a surprising fact that, while probability is at the core of the reasoning in the field of psychometrics, assessment systems' procedures reflect deterministic, rather than probabilistic, views of culture and language (Solano-Flores, 2014). At the core of these deterministic views is the treatment of populations as homogeneous. An example of these deterministic views can be seen in approaches for examining bias based on the analysis of DIF. These approaches implicitly assume homogeneity in both the focal and the reference samples, which may lead to a high proportion of undetected biased items (Ercikan et al., 2014). A second example of this deterministic view is the use of small numbers of general ordered categories to characterize EL students' proficiency in English. The limited number of categories and their oversimplification fail to communicate the complexity of a given student's reading, writing, and conversation skills in an EL student's second language and the interaction of these skills with each other in authentic situated communication (see Hsieh et al., 2023; Linquanti et al., 2016). A third example is observed in translation procedures used in international large-scale assessment comparisons, which are silent about linguistic variation within the users of the same language and within the same given country (e.g., Yu & Ebbs, 2012).

The limitations discussed point to the complexity and uncertainty involved in defining and operationalizing culture, language, disability, and any other form of diversity into a narrow set of categories. They also speak to the need for treating tests as boundary objects. Star and Griesemer (1989) proposed the notion of *boundary objects* in identifying common elements in complex interactions. This notion is defined as "an analytic concept of those scientific objects which both inhabit several intersecting social worlds . . . and satisfy the informational requirements of each of them" (p. 393). The notion of boundary objects is useful in conceptualizing aspects of tests that are flexible enough to adapt to local individual student backgrounds and needs, yet have elements that are common enough across students and contexts to support consistent meaning. The balance of commonality and uniqueness in tests to account for the complex interaction between student, context, and assessment is central to supporting consistency of meaning and claims.

FAIRNESS RESEARCH

Differential item functioning (DIF) methodology has constituted a key approach to examining fairness in assessments. Sociocultural perspectives challenge the assumption of within-group homogeneity in the statistical analyses used for detecting DIF. This is

especially important in the case of second-language learners, ethnically diverse groups, and students with disabilities—groups that can be tremendously heterogeneous. There is evidence that as the heterogeneity of focal group samples on sociodemographic variables increases, the detection of biased items decreases (Oliveri et al., 2014). This finding indicates that the violation of the homogeneity assumption has significant implications for fairness and bias analyses (Oliveri et al., 2014). In addition, DIF-based approaches commonly assume that measurement is comparable for the considered groups, *except* for the item being analyzed, given the reliance on performance on the assessment as the conditioning variable for comparisons. This assumption ignores the possibility that, given a set of intended interpretations and uses, a test as a whole is biased against a particular group.

There are also important limitations, which are often ignored, to the extent to which DIF-based approaches may mitigate bias. A first set of limitations stems from the fact that, while they allow detection of biased items, DIF-based approaches cannot detect the specific characteristics of items that may lead to bias. Work based on interviewing or conducting think-aloud protocols with students to elicit their interpretations of translated items has shown the complexity of disentangling sources of DIF (Ercikan, 2002; Kachchaf et al., 2016; Zenisky et al., 2004). Unless they are used in combination with cognitive interviews, verbal protocols, and other methods for probing cognitive activity, DIF-based approaches do not provide actionable directions to adjust the characteristics of differentially functioning items.

IMPLICATIONS OF A SOCIOCULTURAL PERSPECTIVE ON MEASUREMENT PRINCIPLES AND STANDARDS

From a sociocultural perspective, testing can be viewed as a multidirectional nexus among institutions, people, and purposes—all concerned with gathering, transmitting, and using information about what people know and can do. From this perspective, performance on a test can be viewed as the outcome of a complex set of interactions between an individual's knowledge and skills, personal and social background, learning experiences, and the conditions under which testing takes place. There are an infinite number of ways in which this complex interaction between sociocultural contexts and assessment can take place given the large numbers of students, stakeholders, contexts, and assessment characteristics and perspectives that might be at play. Differences in the meaning of this complex interaction create challenges to supporting claims and interpretations of assessment results that are consistent across individuals and groups, which requires finding common elements of the interaction that can support such consistency.

The field of measurement has been concerned about the properties of tests and how they are interpreted and used for different groups. Guidelines have been developed to “provide criteria for the development and evaluation of tests and testing practices and . . . the interpretation of test scores for the intended uses” (AERA et al., 2014, p. 1).

Standards such as those generated by AERA et al. (2014) and by the ITC (2017) acknowledge the importance of examining the properties of tests and the evidence that supports their interpretation and use for individuals from different groups focusing on broad demographic groups defined by race/ethnicity, gender, language, disability, etc. Central to the measurement principles communicated by these guidelines is the assumption of standardization—ensuring

that the results of measurement (the numeric values) will have an interpretation that is trustworthy and invariant (within specified limits) to the objects being measured, the instruments used to produce the numeric values, and the person who is interpreting the values. (Briggs, 2022, p. 13)

Efforts to standardize the conditions under which test takers are tested have a long history in educational measurement. Traditionally, standardization has been considered central to ensuring score comparability and fairness. It assumes that, even though some aspects of assessment may advantage some students, other aspects advantage other students, and on average, advantage or disadvantage evens out—which is referred to as *marginal inference* (Mislevy, 2018).

A sociocultural perspective challenges the notion that standardization and equivalent conditions and procedures result in uniformly *equivalent evidence* of students' knowledge, skills, and abilities in tests. There is ample evidence that standardization and equivalent conditions and procedures do not always provide *equivalent evidence* of students' knowledge, skills, and abilities. This is particularly true for minoritized student populations such as students who are schooled in a second language (Ercikan et al., 2014) and students with disabilities (Kopriva et al., 2016), or across student populations from different cultural backgrounds within countries or across countries (Ercikan et al., 2015).

As an alternative to marginal inference, *conditional inference* departs from observing everyone under the same conditions to a situation in which everyone's performance is evaluated by procedures targeting the same construct (Mislevy, 2018). Legislation requiring the inclusion of all students in large-scale tests has led to questioning whether equal testing administration conditions suffice to ensure valid, fair assessment for diverse populations (DePascale & Gong, 2020). Testing accommodations (adjustments made on the conditions on which tests are administered) are an example of a move toward flexibility in the ways in which test items are presented, the ways in which students can respond to those items, the settings used to test students, and the timing of tests, among other things (Kopriva et al., 2016; Mislevy et al., 2013; Thurlow & Kopriva, 2015). For example, a read-aloud option or assessment in a different language deviates from a standardized version with the intent to allow students to access, interact with, and provide responses to tasks in modes that are aligned with their backgrounds (Rose et al., 2012).

Unsurprisingly, validity is at the core of this tension between standardization and flexibility. On the one hand, standardization may restrict the opportunities for atypical or minoritized students to demonstrate knowledge because of limited language

proficiency, disability, cultural differences, etc. On the other hand, accommodating a wide spectrum of students' needs may be a formidable and costly task complicated by the lack of appropriate theories on testing accommodations, uncertainty about the fidelity with which accommodations are implemented, and lack of sufficient empirical evidence of the effectiveness of multiple forms of testing accommodations used by different assessment programs.

Treating observations as equivalent across students from different sociocultural backgrounds has implications for all aspects of measurement, including validity of score interpretations, assessment design and development, measurement modeling, and concepts of fairness. The view of tests as boundary objects highlights the possibility of designing tests that are flexible enough to adapt to local individual student backgrounds and needs with respect to content, presentation, and format and yet have elements that are common enough to facilitate consistent meaning, interpretation, and use (Bennett, 2023). However, there are multiple conceptual challenges that need to be addressed before such an ideal can be achieved. Among other things, existing testing practices (e.g., assessment development, design, and review) need to be revisited and important steps need to be taken to ensure that cultural, linguistic, and ability diversity are addressed and enforced with more rigor by professional organizations and testing standards (Solano-Flores, 2023).

The notion of conditional inference opens the door for developing interpretation and measurement models that allow creation of equivalent evidence of the construct from observations based on a combination of flexible and common elements of tests and facilitate equitable and consistent interpretation and use of tests. The challenges posed by a sociocultural perspective to the field of measurement are foundational and significant. This is a critical time for the field to recognize the consequences of ignoring this perspective on equity and to rectify this situation as a fundamental validity issue. In the following sections, we first discuss assessment as a social phenomenon and elaborate on the bidirectional relationship between sociocultural context and assessment. We then describe the bidirectional relation of legal context and assessment as an example of this strong bidirectional relationship. This is followed by a section on designing tests that are better grounded in their underlying sociocultural contexts using an evidence-centered design approach. We end the chapter with a discussion of the implications of sociocultural contexts on validity and fairness of interpretation and use.

ASSESSMENT AS A SOCIAL PHENOMENON

In the social and behavioral sciences, measurement is always a challenge, not only because many of the constructs of interest are latent (not visible), but also because each measurement endeavor involves a unique set of interacting factors (see Cronbach, 1975; Hedges, 1987). It is not an overstatement to say that, in educational measurement, many of those interacting factors are sociocultural in nature. Indeed, psychological attributes “are dynamically indexed to particular cultural, social, and historical conditions”

(Maul et al., 2016, p. 312). Obvious examples of this social, cultural, and historical relativism are the challenges encountered when attempts have been made to measure the quality of family functioning in international contexts (Puffer et al., 2021). What counts as “quality” or “functioning” varies tremendously across cultures. Therefore, how effectively the construct is operationalized based on the relationships between family members may be limited by these social, cultural, and historical contexts.

The complex relationship between assessment and society is largely due not only to the challenges of measuring psychological and social constructs—an issue that has been discussed for a long time in psychometrics literature (e.g., Green, 1981)—but also to the challenges of understanding educational measurement. Unlike measurement practices in other professions (e.g., medicine, engineering), measurement in education is particularly likely to affect the constructs being measured. For example, there is evidence and concern that what is tested tends to influence what is taught (Jenning & Bearak, 2014; Popham, 2001). Moreover, probably more than in any other discipline and profession, measurement in education is regulated or at least influenced by societies in ways that determine what is to be assessed and how constructs are to be measured. Furthermore, unlike measurement and measures relevant to other aspects of life (e.g., inflation, pollution, nutritional content, cholesterol levels), measurement in education is the one in which almost everyone has a stake, has some form of first-hand experience with, and believes to know well enough to have an authorized opinion about.

This section provides a model that represents the complex relationship of multiple aspects of assessment and multiple aspects of a society, followed by a discussion of different roles assessment plays in this relationship.

Sociocultural Influences

While it is widely recognized that social interaction provides individuals with opportunities to learn through collaboration and dialogue (NRC, 2000; Tomasello, 2009; Vygotsky, 1978), the notion is much more than a good pedagogical principle. Evidence from multiple disciplinary perspectives, including sociocultural theory, learning sciences, and neuroscience, speaks to the influence of culture and society on learning (e.g., Cole, 1999; Cole et al., 1971; Kahneman, 2003; Meltzoff et al., 2009; NASEM, 2018b; Nasir, Lee, et al., 2020; NRC, 1999, 2001; Rogoff et al., 2003; Roth & Lee, 2007). This perspective differs from cognitive views of learning focused mainly on “the way knowledge is represented, organized, and processed in the mind” (NRC, 2001, p. 3), mostly silent about society and culture.

A sociocultural perspective on learning holds that culture and society shape the mind (Wertsch, 1985). According to this sociocultural perspective, learning takes place through both informal everyday life and formal schooling experiences. The former takes place through the individual’s participation in communities of practice and plays a critical role in shaping individuals’ worldviews, identities, and the ways in which they make sense of different kinds of knowledge (Greeno, 2002; Greeno & Gresalfi, 2008;

Lave & Wenger, 1991; NASEM, 2018b). The latter are shaped, among many other factors, by structured activities, curriculum, resources, and teacher practices (Goldman & Lee, 2024; Greeno & Gresalfi, 2008; Moss et al., 2008). Altogether, these experiences both reflect and influence how individuals organize knowledge and solve problems, what kinds of knowledge are valued, and what counts as learning outcomes in a society.

Considering how culture and society shape the mind, we need also to examine the impact of social stressors on learning. For example, in the United States, individuals who self-identify as Black, Latino, Native American, gay, or transgender are more likely than mainstream individuals to have a lower quality of life, as shown by most metrics of well-being, such as physical and mental health, employment, housing, education, income, and wealth (Verschelden, 2017). Also, minoritized populations are more likely to suffer chronic illnesses such as asthma, diabetes, and heart disease. There is evidence that these chronic diseases are associated with higher school absenteeism and psychological problems among children (Chavira et al., 2004; Martinez & Ercikan, 2009; Peterson et al., 2006; Shaw & Páez, 2002).

Social stressors such as poverty, bullying, and violence are well known to lead to social withdrawal, peer conflicts, and difficulty developing adaptive behavior and healthy peer relationships (Shaw & Páez, 2002; Taras & Potts-Datema, 2005). These stressors also lead to an increased likelihood of developing anxiety and anxiety-related disorders (Adewuya & Ola, 2005; Baki et al., 2004; Chavira et al., 2004; Hommel et al., 2003)—factors that are shown by extensive research to be associated with lower performance on achievement tests and an increased incidence of learning difficulties and disabilities (Albano et al., 2003; Huberty, 2012; Leibert & Morris, 1967; Shaw & Páez, 2002; Taras & Potts-Datema, 2005; Van Ameringen et al., 2003; Wigfield & Eccles, 1990; Wine, 1971, 1980).

Research on the sociocultural context of learning demonstrates the negative effects of “scarcity” (Mullainathan & Shafir, 2013; Obradovic & Armstrong-Carter, 2021; Verschelden, 2017) on “mental bandwidth.” Goldrick-Rab et al. (2017), for example, report evidence of impact on learners when basic human needs are not met. Two thirds of community college students surveyed in the United States experienced food shortages and 13% or more reported some form of homelessness. Also, over 2% of students in public schools (over 1 million students) in the United States experienced some form of homelessness during the 2020–2021 school year (National Center for Homeless Education, 2022). Such scarcity is likely to impact well-being, attendance at school, and the opportunity to obtain the maximum benefit from available learning opportunities. These adverse social conditions can also impact students’ ability to demonstrate the knowledge, skills, and capabilities targeted by tests.

The implication of this evidence is that accountability decisions based on assessment results should not be based on assumptions that teacher practice is the sole factor involved in student achievement. Narrow interpretations of learning outcomes solely focused on teaching overlook the potential impact of poverty, racism, and social marginalization on cognitive resources (Verschelden, 2017) and the tremendous differences in the sets of opportunities to learn across different groups.

Social Complexity

The way we view the complex relationship between assessment and society is illustrated in Figure 3.2. The diagram has the limitation that it is an overly simple representation of the sociocultural context in the United States and may not entirely reflect the sociocultural contexts of other countries, which may have different but similarly intricate patterns of relationships between assessment and society. Still, it illustrates the reasoning that can be used to examine this relationship.

Three types of interacting components are distinguished: the main stages in the process of large-scale assessment (Components 1–5); the social, legal, and knowledge

FIGURE 3.2
Relationship Between Large-Scale Assessment and Society

Note. Numbers refer to the components of the relationship between assessment and society, as described in the text.

foundation of assessment as an institutionalized activity (Components 6–10); and the sociopolitical influences and practical constraints that shape the role and impact of assessment in a society (Components 11–15). Figure 3.2 represents the notion that the social and legal foundation of assessment is an institutionalized activity made explicit through formal documents (sometimes legislation) that justify, mandate, and regulate assessment activities. Also, it is supported by a body of knowledge (e.g., current knowledge in a disciplinary field) that determines the content of assessment and by a set of paradigms and methodologies that establish what is acceptable practice concerning assessment development, how assessment data are to be obtained and analyzed, and how assessment results are to be reported.

Social Nature of Assessment

Assessment is assumed to originate from the need to both understand and provide evidence. It is “intended to produce knowledge on the state of an empirical system” (Tal, 2013, p. 1159). All cultures develop measurement strategies that meet societal needs (e.g., Lipka et al., 2015; Owens & Kaleva, 2007). Often, such needs entail construing persons’ differing capabilities in terms of interpersonally well-defined attributes, operationalizing the attributes so construed, and then reasoning through this construal, comparing persons on certain attributes or determining how much of those attributes they have. Validation is the process of marshaling empirical and theoretical evidence to support this reasoning for some persons, contexts, interpretations, and uses. Assessment, as a formal, institutionalized activity, concerns sampling: The tasks or items used in a test can be viewed as samples of observations (Kane, 1982). For a test to be accurate, constructs need to be operationalized into samples of observations that are representative in content and number of the target constructs. Not surprisingly, a significant part of measurement modeling focuses on accounting for measurement error due to the nature and size of the sample of observations (i.e., the content and number of items) used in tests.

Viewing assessment as a social phenomenon (see Vera, 2015) allows examination not only of what is valued in assessment but also of how assessment results are interpreted. For example, test scores can affect an individual’s civic life in several ways. How a person (or their children) has been exposed to schools and tests and the consequences of test scores in life shape their conceptions of educational and testing issues and lead them to develop an opinion on those issues. To the layperson, the causes and implications of a drop in the scores in their children’s school district may be easier to understand (correctly or not) and to act on (effectively or not) than an increase in the average temperature on Earth. The effect of inaccuracy in interpretations of test scores and test score trends are not particular to the general public: Even education officers may advance inconsistent explanations of the decline of national scores in an international test (Morsy et al., 2018)—which may be a reflection of the challenges of examining the role of noninstructional, social factors as sources of measurement error and the perception of tests as instruments that produce precise measures.

Theories of social reproduction (e.g., Bourdieu, 1977; Collins, 2009) provide a lens for examining the complex relationship of assessment and society. As cultural products, tests reflect the thinking, values, and cognitive styles of the persons and institutions that create and use them (Cole, 1999). Institutions and systems in charge of testing infuse their view of the constructs measured and become an important influence on what knowledge is valued and how that knowledge is to be demonstrated. This process can lead assessment systems to prioritize cultures, varieties of language, learning styles, and situations that are aligned with the mainstream culture. This happens even when the number of persons adhering to such practices is no longer a majority, putting individuals who are not from mainstream cultures or in political power (e.g., those who are from lower socioeconomic backgrounds and minoritized economic, racial, ethnic, and linguistic groups) at a disadvantage.

The influence of costs and the technology available for assessment development, administration, and scoring should not be underestimated. For example, large-scale assessments greatly rely on multiple-choice items and make limited use of constructed-response formats because of cost-effectiveness. The former are machine scorable; the latter typically involve human judgment and, therefore, time-consuming activities such as the development of scoring rubrics and the training of scorers (e.g., see Bejar, 2017a; Downing, 2006; General Accounting Office, 1993; Koretz & Hamilton, 2006; Phelps, 2000). While it can be argued that recent advances in artificial intelligence make automated scoring of open-ended responses possible, these possibilities have costs associated with the development of scoring engines and come with the risk of underrepresentation of constructs. Similar limitations are associated with the development of test items using ChatGPT and other generative artificial intelligence technologies and the use of games and simulations as surrogates of hands-on tasks. As a result, cost and development time are important factors in the types of items used and construct representation in large-scale assessment.

Perceptions of Assessment as "Scientific"

In addition to contributing to scientific defensibility, measurement arguments are used to support policies and decisions that affect individuals, institutions, and societies. Student promotion or retention, accountability, school sanctions, and even the ranking of countries are based on comparability and accuracy assumptions (Koretz, 2008). Understanding the sociocultural context in which assessment instruments originate and the operating motivations for their use (and misuse) are central to evaluating these assumptions and moving assessment forward.

How quantitative assessment outcomes influence society by informing decisions about individuals, groups, or institutions is determined not only by the scientific defensibility of these outcomes and the processes that generate them, but also by the views of different segments of the society that utilize quantitative data. According to this reasoning, the effect of tests and assessment on society is shaped not only by the quality of data but also by societal perceptions of what counts as scientific and what makes quantitative data scientific.

Indiscriminately ascribing scientific rigor to quantitative data may contribute to or be associated with different aspects of the complex relationship between assessment and society. One of these aspects may be the lack of a critical interpretation of test scores, which stems from the fact that quantitative information is deemed unconditionally accurate and scientific (Mlodinow, 2008). An example of misuse resulting from this lack of critical perspective concerns international tests.

The view that quantitative data are unquestionably scientific has contributed to the development of polarized perspectives of educational research according to which the qualitative is deemed subjective and the quantitative is deemed objective (Ercikan & Roth, 2006). While psychometrics is concerned with the measurement of psychological, unobservable qualities, efforts to examine the validity of interpretation and use of methods of inquiry on mental process are based on subjects' verbal reports. Perhaps as a reflection of this misalignment, cognitive validation—validation based on the use of think-aloud reports and cognitive interviews to probe how tests elicit the reasoning targeted by tests—was not adopted as a method of validation until the 1990s (Glaser, 1991; Messick, 1995). Still, while there is a wealth of literature on the value of cognitive processes in examining the kind of reasoning elicited by test items (e.g., Ercikan et al., 2010; Ercikan & Pellegrino, 2017; Ericsson & Simon, 1993; Leighton & Gierl, 2011; Ruiz-Primo et al., 2001), methods for cognitive validation using qualitative methods are underused or underreported. It must be acknowledged, however, that thanks to recent developments in information technology, artificial intelligence, and natural language processing, it is possible to obtain quantitative information on test response processes relevant to examining cognitive validity. For example, now it is possible to track eye movements during reading (e.g., Oranje et al., 2017), process verbal responses (e.g., Leighton, 2017), analyze thousands of written essays (e.g., Alvero et al., 2021), and code student responses (e.g., Ercikan & McCaffrey, 2022; Ferrara & Qunbar, 2022) with unprecedented levels of efficiency. Yet while such advances pave the way for research examining the multifaceted nature of constructs, they also put pressure on continually updating of our views of validity (Mislevy, 2018). Rapid adoption of innovative sources of data in assessment without proper support of empirical evidence on validity and fairness may compromise score meaning interpretation (see Bejar, 2017b; Dorsey & Michaels, 2022).

This disappointing scenario is aggravated by the limited scope of the work that examines cognitive activity in assessment. As mentioned before, efforts to examine cognitive validity typically fail to consider the sociocultural context in which cognitive activity takes place. Yet there is evidence that speaks to the importance of examining sociocultural activity as part of the process of test validation. For example, poverty may influence the reasonings used by students when they engage in solving mathematics items that involve addition, multiplication, and rounding (Solano-Flores & Nelson-Barber, 2001). The cultural dimension of thinking and learning is yet to be systematically and routinely incorporated in research and practice in educational measurement.

Unlike the legal and knowledge foundations of assessment, the sociopolitical and practical components that influence the process of assessment are not necessarily explicit and are not formally established. Moreover, being of a dynamic nature subject to negotiation among stakeholders with different objectives and values, these sociopolitical and practical components may be difficult to predict or control. For example, at a given time, beliefs and expectations held by a particular segment of society may lead to inappropriate interpretations of assessment outcomes. Or, under a given political climate, information from tests may be overemphasized or neglected, or the impact of tests on policy may be mediated by political forces.

ASSESSMENT AND SOCIETY: A BIDIRECTIONAL RELATIONSHIP

The purposes and content of assessment, how assessment is conducted, and how assessment results are used and interpreted involve many decisions made by policy makers, test developers, testing agencies, and test users. We argue in the following that each of these choices about assessment both influence and are influenced by sociocultural context.

Societal Needs

The use of assessment with the intent to meet societal needs is far from new. An oft-cited example comes from 14th-century imperial China when, as part of government personnel selection practices, civil and military examinations were used to make hiring and promotion decisions based on rankings on tests (see Brown, 2022; Clauser et al., this volume). However, whether this system of examinations promoted social mobility strictly based on performance is subject to discussion because the emperor had the final word in the selection process of candidates for public service (Elman, 2013). More recent examples of early uses of testing include screening tests for developmentally delayed children in France by Binet in the 20th century (Binet & Simon, 1907) and the adoption of Binet's intelligence test as the Stanford–Binet test in the United States by Louis Terman and colleagues for selecting individuals into the military according to a set of minimal competencies (Gould, 1981). Both instruments involved the classification of individuals. In Binet's tests, in France, the assessment focused on separating children whose development was delayed (as compared to the general population) to provide them with certain services and/or institutionalize them. To measure their abilities, individuals were assessed using basic, everyday life tasks. Views of society and gender influenced the actions taken when the same test was adopted in the United States to meet a very different purpose—selecting men to serve in the military. The concrete life tasks of the test were deemed to be favoring women and therefore “biased,” and decisions were made to include tasks intended to assess abstract reasoning, a construct considered more consistent with expectations for men serving in the military (Gould, 1981). Ironically, while the changes were intended to ensure validity, given the goal

of selecting male army recruits, they may have contributed to promoting narrow and sexist views of intelligence.

A more recent example of how societal needs drive assessment is observed in education reform movements. One motivation for school reform is the need to improve education to create a competitive workforce and reduce disparities in achievement between genders and between ethnic/racial groups. Another motivation is the need to inform decisions concerning the distribution of resources among states, districts, and schools. In the United States, public recognition of discrepancies in the funding of education across districts in the country has led to education reform policies such as the Elementary and Secondary Education Act of 1965 (ESEA) and the No Child Left Behind Act of 2001 (NCLB). The stated goal was to provide equitable financial support and address inequities in educational outcomes. For example, NCLB legislation (NCLB, 2002) involved the development of academic content standards and tests and the establishment of proficiency levels with the intent to monitor and evaluate the effectiveness of education.

Sociopolitical Ideologies

The use of testing for decision-making is often driven by alignment with certain ideologies. The most problematic example of this can be seen in the eugenics movement, which used testing to provide so-called evidence to support racist political ideologies (Gould, 1981). A very different ideology, meritocracy, was grounded in social equality and equal opportunities for individuals from different cultural backgrounds and uses assessment as a key source of information for decision-making.

Among the examples of this use is the inclusion of tests like the SAT or ACT to inform decisions about admission to higher education institutions. While historically there has been a well-supported argument that tests facilitate meritocratic decision-making, more recent discussions highlight the limitations of meritocracy as a singular fairness principle that should inform decisions solely based on tests. Those who support the elimination of the SAT and ACT as part of the set of college admission requirements point to the differential performance of individuals from African American and Latino backgrounds as lowering their chances of admission into higher education, and these supporters of elimination thus hold these tests responsible for the associated inequities. In 2020, the University of California Board of Regents approved a recommendation by Janet Napolitano, then-president of the University of California system, to eliminate the requirement of the SAT and ACT in admission decisions. This recommendation involved making the use of these tests optional for 2021 and 2022 admissions and not using them for 2023 and 2024 admissions for California residents (Anderson, 2020). After the University of California's decision, other universities followed suit (Hubbler, 2023).

Ironically, while arguments in support of eliminating the SAT and ACT are predicated on the premise that these tests are biased against traditionally underserved students, little is said about the fact that the sources of information left to make

admission decisions may be biased too. Biased human judgment may have an especially deleterious impact for traditionally underserved groups in a process of admission that is not informed by any common measure of achievement. For example, applicants who have attended prestigious schools or whose social capital allows them to obtain letters of recommendation from prominent citizens might be at an advantage over other, less privileged individuals. This view is gaining growing support as several institutions started reversing their test-optional, test-free admissions policies (Huebeck, 2024).

The debate on the elimination of standardized tests for college admissions illustrates how testing practices may be shaped by social processes beyond empirically supported arguments. Multiple angles on fairness speak to the complex nature of the relationship between assessment and society and highlight the importance of the current sociopolitical ideologies in shaping the role of assessment in important societal outcomes.

Valued Outcomes

A key decision point in assessment involves choices around what is assessed and how assessments are implemented. What is assessed reflects what is deemed important and relevant for the purposes of testing and the knowledge and skills valued in the society. For example, as we have discussed, assessing abstract reasoning was deemed relevant in the early 20th century in the Stanford–Binet tests for the purpose of selecting men into the military over tasks assessing more practical skills. More recently, emphases on critical thinking, collaboration, problem-solving, and technology and engineering literacy reflect values in the society embracing these constructs as important for success in today’s socio-cultural contexts (e.g., Braun et al., 2020). The surge of interest in performance assessment as a potential tool for assessment-based education reform in the 1990s illustrates these emphases. If performance assessments are more sensitive to higher order skills than conventional, multiple-choice items, then their use in large-scale assessment programs with the purpose of accountability could drive teachers to promote problem-solving strategies and critical thinking among their students (Shavelson et al., 1990).

An example of the influence of sociocultural context and the trade-offs in assessment it motivates was seen in the implementation of NCLB, in what was assessed (primarily reading and mathematics), how students were assessed (primarily with multiple-choice items), and how performance was evaluated (mainly through comparisons against a level of proficiency). The focus on reading and mathematics is a clear example of what was prioritized and what the limitations were of the decisions made: There is a wealth of research on the importance of reading and mathematics for learning more broadly in all subjects. However, excluding science, social studies, and arts from NCLB put teaching and learning in these subjects in second place (Overbaugh & Lu, 2008; Winstead, 2011).

Concepts of Fairness

The concept of fairness has revolved around the notion that performance on tests should not be influenced by factors that are irrelevant to the constructs that tests are intended to measure. This notion has been invoked to evaluate fairness and support decisions

about the content and format of tests, the language in which they are administered, the item types included, and the administration of tests in standardized conditions. For example, the perception of multiple-choice tests as objective because their scoring does not require human judgment and standardization in the ways in which tests are administered stems from the intention of establishing fairness and creating an even playing field for test takers at a time when such conditions were considered sufficient for fairness (Mislevy, 2018). As mentioned, more recent conceptions of fairness include the establishment of conditions that optimize the opportunities made available to test takers to perform on tests, which may be different for different individuals (Mislevy, 2018; Thurlow & Kopriva, 2015). We see clear examples of these conceptions in test accommodations for students with special needs. Since the 1990s, the Americans with Disabilities Act (ADA; 1990, 2008) requires testing organizations to offer tests to persons with disabilities in a manner that allows them to demonstrate their knowledge, skills, and competencies in optimal ways. These accommodations allow item types and formats to be modified with the intent to create equal opportunities for individuals with disabilities to take tests and enhance the fairness of interpretations and uses of assessment results (Abedi & Ewers, 2013). (See also Rodriguez & Thurlow, this volume, for discussion of fairness issues related to students with disabilities and English learners.)

Changes in conceptions of fairness highlight that this fundamental concept in assessment is socially grounded. A relatively recent conception of fairness has been expanded to recognize cultural and linguistic diversity in societies around the world and the implications of such diversity on assessment and measurement (Ercikan & Lyons-Thomas, 2013; Ercikan & Oliveri, 2013; Ercikan et al., 2014; Grover & Ercikan, 2017; Solano-Flores & Li, 2013). Such diversity is officially recognized in some countries, such as Canada, with 2 official languages, and South Africa, with 11 official languages, where most tests are offered in all the official languages.

Official language policies may fall short of fairly considering the complexity of sociocultural context. For example, in South Africa, the number of languages spoken at home is much greater than the number of official languages (Setati & Adler, 2001). Furthermore, these policies do not consider the Indigenous languages. In countries with Indigenous populations such as Canada, Mexico, and the United States, teaching and assessing in Indigenous languages is difficult because of the social stigma attached to them or limitations in the number of educators who are native users of those languages (Oliveri et al., 2015; Simon et al., 2013; Solano-Flores et al., 2015). Recognition of the heterogeneity of cultural groups has led to the development of methodologies for taking such heterogeneity into account when examining fairness (Oliveri et al., 2014).

Researchers have argued that opportunity to learn—“whether or not . . . students have had the opportunity to study a particular topic or learn how to solve a particular type of problem presented by the test” (Husén, 1967, pp. 162–163, cited in Burstein et al., 1993) should be considered part of the efforts to ensure fairness and, more specifically,

the equivalence of score meaning for different groups (Kane, 2012). Opportunity to learn has clear relevance to the appropriateness of interpretations and uses of assessment results in cases in which learning outcomes are used to evaluate teachers and for accountability. In the context of COVID-19, opportunity to learn greatly varied among students from different socioeconomic backgrounds (Kane & Reardon, 2023). Factors that might have limited the opportunity of low-income students to learn remotely during the COVID-19 pandemic started with the level of access to the Internet, including digital devices, familiarity with devices and features for effective learning experiences, schools' and teachers' ability to switch to online learning in a very short period of time, and parents' ability to support online learning at home, among many other possible adverse circumstances. In this context, digital assessments reflect complex interactions between these social factors and the students' knowledge, skills, and competencies.

Taking sociocultural context into account is central to the concept of fairness in the interpretation and use of assessment results. An example of problems that can arise with inferences made from assessment results when opportunity to learn is not taken into account is provided by Shepard (1993). The example is focused on a kindergarten "readiness" test, considered an accurate measure of basic skills, a good predictor of performance in kindergarten, and "fair and valid," using narrow notions of fairness and validity based solely on psychometric criteria. Problems can arise if the test is used to admit children to kindergarten or delay admission because low scores may actually be an indicator of a home environment that does not promote the development of those basic skills (i.e., a lack of opportunity to learn). Holding children back based on test results that are mere indicators of opportunity to learn would be a clear violation of fairness defined as a consistency of score meaning and interpretation of assessment results.

Globalization

Globalization offers many examples of how social contexts provide an important impetus for assessments. The impact of globalization is enhanced through greater sharing and communication of policy and practices in online environments and through greater educational exchanges and expectations for exchangeability of educational outcomes such as professional education programs. The globalization of the labor force has contributed to pushing competitiveness among countries with regard to their educational outcomes, as captured by country rankings based on international tests. Teltemann and Klieme (2016) highlighted the challenges countries face regarding the effectiveness of their education systems as a primary reason for joining efforts in developing international tests of educational outcomes such as the Trends in International Mathematics and Science Study (TIMSS) and the Programme for International Student Assessment (PISA).

Technological Advances

A significant societal development that is transforming assessment and learning is the series of advances in information technology and computational tools for using a variety

of data types in assessment (Ercikan et al., 2020; Katz & Gorin, 2016). These technological advances make it possible to use a wide range of assessment types, including interactive tasks, adaptive testing, and open-ended or performance tasks that can be scored automatically using scoring engines. These technological advances are changing not only assessment practices, but also *which* constructs can now be assessed, including collaborative problem-solving and interactive communication. Through the administration of tests in digital environments, we have access to data on student response processes in assessing such complex constructs in ways that are not possible with paper-based tests. Response process data, also referred to as process data, are changing what is considered construct-relevant evidence and how we conceptualize validity and fairness in digitally based assessment environments (see Bennett et al., this volume). Advances in artificial intelligence and other related computer science technologies are utilized increasingly in many aspects of assessment development and scoring of performances. These include the development of test content and item generation and the scoring of text and speech as responses to assessment tasks (see Nikolic et al., 2023; Yaneva & von Davier, 2023).

Unfortunately, advances in information technology, especially the use of artificial intelligence-based algorithms, can be an agent of reproduction of social inequities (Noble, 2018). This concern is important to consider when using artificial intelligence-based algorithms to derive scores either based on responses in formal assessment contexts or using “big data” on individuals’ engagement in online environments such as news, shopping, and entertainment sites (DiCerbo, 2020; King & Mrkonich, 2016). Artificial intelligence-based algorithms use text, images, speech, and test-taker actions to develop features generated from natural language processing in the scoring algorithms. These algorithms are critically dependent on the data sources used in their creation (Baker, 2021; Manyika et al., 2019). Scores may not have equivalent validity and accuracy for all groups if data sources for these algorithms are restricted to specific cultural and language groups (Noble, 2018). For example, on an English-speaking test, the scores from the artificial intelligence-based scoring engine may be biased for students who have different accents or use nonstandard dialects (Benzeghiba et al., 2007). An automated scoring algorithm developed using data from mainstream student groups resulted in less accurate scores for certain racial and ethnic student groups (Bridgeman et al., 2009, 2012). Similar types of bias may be observed in algorithms used for scoring written responses.

An additional challenge in utilizing artificial intelligence-based scoring algorithms using assessment response data or big data is that even though patterns in text or speech or actions may have a specific relationship with the targeted construct, these relationships may vary because of differences in educational and life experiences (Ercikan et al., 2020; Guo & Ercikan, 2021). Inaccuracy in scores and bias may result if the scoring algorithm assumes a uniform relationship between patterns and the targeted construct. Therefore, taking sociocultural context into account has heightened importance when engagement in tests is evaluated using artificial intelligence-based algorithms.

Assessment Capacity

How assessment is conducted is inevitably affected by a wide variety of conditions, including assessment literacy, the availability of individuals with expertise in assessment, and technological resources that can be used to administer assessment and analyze assessment data. Such conditions are undoubtedly expected to affect the quality of assessment and the degree to which assessment can fulfill its intended role.

The context of international test comparisons such as PISA and TIMSS illustrates how certain institutional and human resources are needed for countries to benefit from their participation in these assessments (Husén, 1983). Assessment capacity—the ability of a country to produce assessment instruments with sound psychometric qualities and to develop and sustain its own assessment systems (Solano-Flores & Milbourn, 2016)—greatly influences the extent to which a nation benefits from participating in international comparisons, for example, by being able to make sound interpretations of test scores that inform its educational policy decisions. Poor countries not only tend to perform poorly in international test comparisons, but also have limited resources needed to influence the process of assessment development and take advantage of their participation in international tests as an opportunity to increase their assessment capacity. In addition, this lack of assessment capacity can limit countries' engagement in grounding assessment in their sociocultural contexts. This context of international assessments is a case in which the bidirectional relationship between sociocultural context and assessment is expressed as a vicious circle of inequity at the international level (Solano-Flores, 2019). It also shows, at an international level, a pattern of social inequities and power asymmetry that parallels the social inequities and power asymmetry observed among different racial and socioeconomic groups within a country.

Social Inequities and Test Taking

How assessment is viewed and how human capabilities are valued by society can affect the performance of individuals on tests and how assessment results are interpreted. Two contrasting examples can be used to illustrate the multiple and complex ways in which this relationship between sociocultural context and assessment is expressed. On the one hand, some argue for the motivating effects of the importance given to tests and attribution of fairness and meritocracy to assessment in, for example, East Asian student populations (see Kennedy, 2016). On the other hand, researchers have argued that stereotype threat (fear of confirming a negative stereotype on one's social or ethnic group) may have an adverse effect on the performance of racial minorities on tests (Steele et al., 2002). Structural stigma, the “societal-level conditions, cultural norms, and institutional practices that constrain the opportunities, resources, and wellbeing for *stigmatized* populations” (Hatzenbuehler & Link, 2014, p. 2) is a related concept to stereotype threat; however, it encompasses broader societal contexts that may affect learning and socioemotional and cognitive abilities when learners engage in responding to tests. Even though research has examined the potential of culture as a source of construct-irrelevant variance, mainly bias, this research has had a narrow focus on

cultural references and the linguistic features of items. There is need for more research that investigates the mechanisms through which the broad sociocultural context (which may include the context in which the assessment is conducted as well as individual students' personal contexts) may influence performance on tests and guide appropriate test use and interpretation, given the potential impact of stereotype threat and structural stigma.

Legislation

In the United States, legislation plays a key role as an enforcer of views of assessment and the functions it should have. The effect of the ADA, when it became law in 1990, illustrates the impact of legislation on assessment. The ADA “prohibits discrimination against individuals with disabilities in all areas of public life, including jobs, schools, transportation, and all public and private places that are open to the general public” (see Family Institute, 2024). Since the 1990s, assessment systems have been required to provide accommodations to students with disabilities with the intent of providing them an equal opportunity to demonstrate their knowledge and skills. These accommodations include read-aloud options, Braille versions, and extended testing time options, among others.

Another piece of legislation with impact on assessment has been Title VI of the Civil Rights Act of 1964, which is intended to address the needs and rights of speakers of other languages in public education. This act required districts and schools to provide equal opportunities and services to linguistic minority students in learning and assessment. Optimizing testing conditions for linguistic minority students as policy mandates have also been addressed in this act and have included mandatory provision of bilingual versions of tests, access to dictionaries, and efforts to minimize unnecessary linguistic complexity of the assessment tasks (Takanishi & Le Menestrel, 2017).

Impact of Assessment on Education and Society

Assessment has the potential to impact society in multiple ways. In the United States, assessment has played a central role in providing information about trends in educational outcomes and in shaping teacher practice, student learning, and policies around resource allocations. Assessments have been used as key sources of information for evaluating the effectiveness of education and for holding states and local education agencies accountable, thereby defining expectations for teaching and learning.

In international contexts, assessments of learning outcomes such as TIMSS or PISA receive both positive and negative attention in participating countries, which often leads to significant changes in policy and practice. When participating countries were surveyed about the impact of PISA on their education systems, more than half of the countries reported PISA as being “extremely influential” or “very influential” (Breakspear, 2012). Discourse and rationales for reform efforts and policy changes have used PISA or TIMSS in justifying the direction for policy changes (Feniger & Lefstein, 2014). In Canada, rationales for reform have included the alignment of within-country assessment programs with PISA and the harmonization of national indicators with the

Organisation for Economic Co-operation and Development's at-a-glance indicators (Froese-Germain, 2010).

Another impact of assessment has been the shaping of education policy and practice. We see examples of this impact in England and Germany, which have made major changes to teaching practices, teacher training, instructional materials, educational standards, and curricula based on information and insights gained through international assessments (Heyneman & Lee, 2014). The comparative emphasis in international assessments shifted the focus from ideology-based policies to evidence-based policymaking based on assessment results (Bieber et al., 2014; Grek, 2012), as well as a shift from "input oriented" to "output oriented." At the root of this comparative perspective is an assumption that education systems are comparable and policies and practices are transferable. Despite criticisms of this assumption by researchers (see Carnoy & Rothstein, 2013; Ercikan et al., 2015; Singer et al., 2018), a consequence of that perceived transference is a promotion of *convergence of education systems* toward each other and globalization of education (Drezner, 2001).

When developing an understanding of the impact of assessment on society, examination of the unintended consequences of assessment is as important as examination of the intended consequences. Intended consequences of assessment are easier to understand and are likely to be more openly invoked by decision-makers and policy makers. Obvious examples include changing education practice to improve learning, driving policy to narrow disparities in educational achievement, and making changes in professional education that may contribute to bettering health outcomes or reducing societal risks of malpractice in professions.

Unintended consequences of assessment may be more difficult to recognize, but are important to consider in improving education systems. A clear example is the impact of statewide assessments used for accountability purposes on Indigenous populations in the United States. There is evidence that the pressure to meet demands imposed by NCLB drove some teachers to neglect instruction based on firsthand, meaningful cultural experience and to instead emphasize instruction oriented to promote high performance on statewide summative assessments (Trumbull & Nelson-Barber, 2019).

Assessment of individual competencies inevitably reflects educational opportunities, practices, and resources, which are all affected by inequities in societies. When assessment results inform high-stakes decisions (e.g., the admission of individuals into higher education institutions), these uses may contribute to perpetuating educational and social inequities. Other assessment uses with potential for unintended consequences include their inclusion in high-stakes accountability decisions for rewarding or penalizing schools and teachers and for allocating resources for schools. In such scenarios, schools and teachers working in the most challenging educational contexts may be unfairly evaluated by formal accountability models that are based on value-added models or simple comparisons of performances across schools.

LEGISLATION AND ASSESSMENT IN THE UNITED STATES: A STRONG BIDIRECTIONAL RELATIONSHIP

Legislation and policy have shaped assessment and its role in education and the society in significant ways, which speaks to the strong bidirectional relation between sociocultural context and assessment. Laws have been mechanisms through which many aspects of the sociocultural context have found ways to shape education and assessment, including expectations for teaching, learning, and allocation of resources in education. In fact, assessment has been used as a key tool for implementing significant legislation since the 1980s.

Legislation has played a central role in shaping assessment in two related ways. One is when legislation dictates features, uses, and interpretation of assessments; the other is when it is intended to prevent bias and discrimination to protect individual rights.

In U.S. educational contexts, the foundations of the rules for how assessments are conducted and used are grounded in the U.S. Constitution, federal civil rights statutes, judicial decisions, and state laws. Current federal, state, and local legislation and policies use student assessment for eight distinct purposes, with the same test often serving multiple functions (NRC, 1999):

- evaluating and improving district-level educational programs;
- providing information about individual students to inform instruction;
- monitoring educational outcomes and providing information about the status of the education system;
- motivating change in education;
- informing program evaluation by using pre- and posttest results to gauge the impact of educational programs;
- holding states, local education agencies, schools, and educators accountable for student performance;
- promoting change in classroom instruction; and
- certifying student achievement as meeting a performance standard, typically used in graduation from high school or promotion to the next grade.

The legal context of assessment is particularly relevant to high-stakes testing. Practices and instruments may be challenged when there are claims of misuse or discrimination. In state tests, there are four major areas of concern: (a) testing to award diplomas; (b) potential bias against historically disadvantaged groups; (c) providing testing accommodations to individuals with disabilities; and (d) issues specifically related to performance tests.

In this section, we describe how these legal contexts shape assessment in the United States, as well as how assessment is used to make changes in education and society through legislation. We first describe key legislation that impacts assessment in the United States. We then describe how legislation is used to ensure the inclusion of two populations of students—students with disabilities and ELs—in education and assessment.

Key Legislation Impacting Assessment in the United States

Key federal pieces of legislation relevant to testing in the United States are the Family Educational Rights and Privacy Act of 1974 (FERPA), Section 504 of the Rehabilitation Act of 1973, the ADA Act of 1990 as amended in 2008, the Individuals With Disabilities Education Improvement Act of 1997 (IDEA) and its 2004 reauthorization, and the ESEA of 1965. These five laws inform key concepts in testing and address issues ranging from confidentiality and privacy to discrimination and access to educational diagnosis and overall educational accountability (Borreca et al., 2013).

FERPA is a U.S. federal law that has been in existence since 1974, and several amendments have been made since that time. It involves three issues: access to education records, opportunity to have records amended, and disclosure of information from records. FERPA regulations have been used to access and review tests or amend scores from tests when the results have been successfully challenged (Borreca et al., 2013).

Section 504 of the Rehabilitation Act of 1973 and the ADA of 1990 are intended to protect the rights of children and adults with disabilities. Section 504 is considered the first civil rights statute for persons with disabilities. It is designed to eliminate discrimination based on disability in programs and activities receiving federal funding and covers K–12 public education and higher education, including educational assessment. The ADA was signed into law in 1990 and extends law into private-sector programs and activities that do not receive federal funding. Both Section 504 and ADA relate to educational testing in three areas: evaluation procedures, determination of disability, and provision of accommodations. Evaluation refers to specific processes and tools used for evaluating targeted knowledge and skills of individuals with disabilities, so that their performance accurately reflects such knowledge and skills, by removing the confounding effect of the disabilities. For individuals with disabilities to be protected by Section 504 and the ADA, the individuals need to demonstrate that they have a physical or mental disability that substantially limits one or more major life activities.

In 1965, President Lyndon B. Johnson signed the ESEA. This legislation signaled a significant federal initiative for improving “quality and equality” in K–12 public education. The law was intended to provide substantial resources to support educational opportunities for students from lower socioeconomic backgrounds. The support for public education by the federal government was accompanied by an emphasis on accountability for schools. Initial accountability efforts focused on how schools used the resources for improving education. In the subsequent reauthorizations of ESEA, accountability evolved into outputs, primarily focusing on student learning outcomes. The 1994 reauthorization, called the Improving America’s Schools Act, highlighted a focus on accountability. The biggest shift to accountability through assessment was in the 2001 reauthorization of the ESEA legislation, the NCLB (2002). The associated regulations of NCLB were passed in 2003, and new regulations were added, some of which were rescinded. In addition to research-based instruction and parental choice, accountability was central to NCLB, which required the development of content-area standards for

reading, mathematics, and science, with annual testing of student proficiency in these areas in Grades 3 through 8 and once between Grades 10 and 12. Student performance results were used to evaluate the effectiveness of schools and teachers. NCLB mandated that results be broken down by racial and ethnic groups, for students with disabilities, for students who were poor, and for students with limited English proficiency. Two types of changes were allowed for students with disabilities and those with limited English language proficiency: accommodations (adjustments made to assessments that are not expected to alter the assessed construct) and modifications (changes in test content that are expected to affect the construct being measured). Reporting of adequate yearly progress, an estimation of change in percentage of students performing at *Proficient* or higher levels, was central to evaluating school performance.

The influence of the IDEA of 1997 and its 2004 reauthorization on the field of assessment in the United States cannot be overstated. As a result of this law, there have been significant changes in how assessments are used, developed, and administered. There may be both a positive side and a negative side to these changes. First, requiring students to be evaluated to inform special education referral decisions has contributed to giving assessment a prominent place in educational practice. Second, requiring the inclusion of students receiving special education services in state and district assessments for states to receive their funding for school-age special education has strengthened the role of assessment as a tool for state control. At the same time, it has contributed to promoting a socially shared view of inclusion as both a reachable goal and an institutional responsibility. Third, this requirement of inclusion has attracted the attention of researchers and practitioners to testing accommodations as a viable set of resources to be used by students when demonstrating their knowledge.

At the same time, it must be acknowledged that legislation prescribing inclusion in assessment is not always aligned with the actual advances in the field of educational measurement. As is the case for legislation relevant to ELs (see Solano-Flores & Hakuta, 2017), legislation intended to serve ELs appears to be driven by high expectations about the precision of the information provided by assessments and unrealistic expectations about the ways in which the information is used. Also, while school districts may be diligent in taking the actions prescribed by the law to include students with disabilities through the use of testing accommodations, there may not be empirical evidence of the effectiveness of these accommodations, or they may not be implemented with fidelity. In the end, while the ultimate intent of IDEA is to provide appropriate forms of support to students with disabilities, overreliance on assessment can sometimes drive efforts toward this goal in the opposite direction.

The Every Student Succeeds Act (ESSA; the current authorization of the ESEA) was signed in 2015 and continues to focus on assessment and accountability. Compared to NCLB, ESSA provides more flexibility in how assessment is used in accountability models. However, ESSA continues to require testing of all students in English language arts and mathematics in Grades 3–8 and once in high school. In addition, states are required to test students at least three times in science, once in Grades 3 through 5,

once in Grades 6 through 9, and once in Grades 10 through 12. The flexibility of ESSA includes the possibility of replacing the high school tests with “nationally recognized” college-readiness tests and the use of multiple interim tests in place of a single summative assessment.

Since the early 1970s, these legislative acts have had a great influence on many aspects of education, assessment, and testing. Borreca et al. (2013, p. 450) summarized the implications of these laws and regulations for testing as follows:

- Professionals who work in education at all levels must remain knowledgeable about laws and keep up to date with revisions made through amendments and reauthorizations.
- Educators must ensure that all evaluations are conducted in a manner consistent with federal laws.
- For individuals identified with a disability, educational tests must provide accurate measurement of the student’s knowledge and skills, rather than be adversely impacted by the student’s disability.
- The confidentiality of all testing records must be safeguarded, and test preparation protocols should not be destroyed.
- Tests must undergo constant scrutiny to ensure that they have adequate content-related validity evidence.

The wide range of influences of legislation included expectations for professionals, how assessments are conducted, how individuals with disabilities are assessed, how assessment information and data are stored, how assessment results are to be used, and what psychometric requirements should be met.

Legislating Inclusion of Students With Special Needs

Definition of Students With Special Needs

For the purposes of our discussion, we use the term *students with special needs* to refer to ELs (students who are not proficient in the language of testing) or to students with disabilities. While the two groups of students are very different and the legal provisions for their inclusions in tests vary, there are important commonalities that stem from the challenges posed by the groups’ heterogeneity. In the United States, legislation that mandates the inclusion in large-scale testing programs of students with special needs is intended to ensure that tests produce information on student achievement that ultimately informs policy and practice in ways that benefit all students. This legislation focuses on (a) identifying, through diagnostic testing, those individuals with given characteristics who require certain forms of support intended to ensure that they benefit from instruction and (b) ensuring that individuals already identified as having that condition are tested with supports intended to minimize the effect of that condition as a source of measurement error. This legislation generates a tension between what assessment programs, school districts, and educators are legally required to do and what is technically possible to accomplish.

An important aspect of legislation concerning inclusion is the definition of students with special needs. In accordance with Sections 300.304 through 300.311, “child with a disability” means a child evaluated as having an intellectual disability, a hearing impairment (including deafness), a speech or language impairment, a visual impairment (including blindness), a serious emotional disturbance (referred to in this part as “emotional disturbance”), an orthopedic impairment, autism, traumatic brain injury, any other health impairment, a specific learning disability, deaf-blindness, or multiple disabilities and who, by reason thereof, needs special education and related services. In the case of ELs in the legislation, the ESSA (2015) defines them as “students whose English language proficiency affects their ability to meet state academic standards.”

Testing Accommodations

Legislation for inclusion in assessment largely depends on the use of testing accommodations—adjustments to the ways in which students are tested with the intent to minimize construct-irrelevant variance due to disability or limited proficiency in the language in which tests are administered (see Abedi, 2012; Sireci et al., 2005). Requirements for accessibility are intended for tests to accurately reflect targeted attributes and abilities. In the case of students with disabilities, the examination

is selected and administered so as to best ensure that when the examination is administered to an individual with a disability that impairs sensory, manual, or speaking skills, the examination results accurately reflect the individual’s aptitude or achievement level or whatever other factor the examination purports to measure, rather than reflecting the individual’s impaired sensory manual or speaking skills, except where those skills are the factors that the examination purports to measure. (Department of Justice, 2010, § 36.309)

In the case of ELs, ESEA legislation holds schools accountable for demonstrating improvements in students’ English language proficiency each school year, as well as demonstrating improvements in achievement levels as expected of the other students. Consequently, ELs are required to take English language proficiency tests in addition to taking the same state tests (with accommodations) as the other students. Unfortunately, while these requirements are based on the premise that test accommodations are effective, most test accommodations for ELs are limited in their effectiveness for removing English proficiency as source of construct-irrelevant variance, and the fidelity with which they are implemented is rarely documented (Solano-Flores, 2022; Wolf et al., 2008). Ironically, while accommodations are intended to ensure fairness in testing, the assumption of effectiveness implicit in legislation that mandates the inclusion of ELs in large-scale assessment produces a complex set of unfair conditions for these students.

Limits of Inclusion

The inconsistency between the ways in which special populations are defined and the ways in which research, practice, and ideology construe these populations is a major

factor shaping the complex relationship between sociocultural context and assessment. For example, actions taken by practitioners may be oriented to comply with the law. However, the skills targeted by legislation may not exactly match the constructs identified by research as those that are measured with defensible accuracy. Consequently, efforts to use assessments as policy tools for making changes in schools and improving education may be limited in their effectiveness in improving education.

As with any other legislation, legislation of fairness leaves room for interpretation, which in some cases may lead to undesired outcomes. Educators and test users need to be aware of multiple issues concerning legislation for fairness because decisions about students may have long-lasting effects on students' lives. The first issue concerns the fact, previously mentioned, that legislation that establishes that students must be given diagnostic tests implicitly assumes that tests are more precise instruments than they really are (see Solano-Flores & Hakuta, 2017). Legislation is silent about the false-positive and false-negative identification of students in diagnostic tests. Because measurement error can be minimized but not eliminated, any test may erroneously identify an individual as having or not having a condition (Durán, 2008). For example, in the case of proficiency in English as a second language, one factor that contributes to this challenge is that language is a vast domain. Proficiency in a language is largely dependent on the contexts in which language is used, and these contexts may not be appropriately considered in the design of tests used to make inferences regarding language skills. Also, many tests used to measure English proficiency focus on discrete language skills (Valdés & Figueroa, 1994) and mostly on vocabulary (García et al., 2006) which are far from being sufficiently representative of the multiple aspects of language that are relevant to learning in school (Wolf et al., 2008). Historically, the development of English as a second language has been erroneously viewed as the learning of a subject (Valdés, 2004, 2018) and proficiency in English as a second language at large is often confused with proficiency in English language arts (which involves formal instruction in using language for specific academic purposes). Fortunately, the development of English development standards that are sensitive to learning in school contexts (see Gottlieb et al., 2007) has the potential to contribute to changing that trend.

The second issue has to do with the categories used for classifying students with special needs. In the field of special education, authors have expressed concern that while the disability categories established by IDEA may serve the purpose of identifying who qualifies to receive special education services, the categories are overly broad and overlapping. Concerns also exist that these categories do not carry the meaning relevant to informing decisions on the optimal ways of supporting students with disabilities and may be interpreted differently by different individuals (MacMillan & Hendrick, 1993; NRC, 1997). This mismatch poses serious challenges to both effective identification and valid, fair interpretation of assessment results.

The third issue is the fact that legislation on fairness appears to be based on unrealistic assumptions about the challenges of serving students with special needs and the capac-

ity of school systems to properly implement this legislation. For example, the ESSA authorizes states to test EL students in their first language, guided by the premise that all EL students are more able to demonstrate their knowledge in their first language than in English (Solano-Flores & Hakuta, 2017). In actuality, most EL students have been schooled in English-only programs and have been formally taught to read and write only in English (American Federation of Teachers, 2002). For the majority of EL students, testing them in their first language could be more harmful than beneficial. ESSA is also silent about the nuances of assessing different content areas in the students' first language. For example, is it possible to assess English language arts skills in a different language? As discussed previously, although they are related, English proficiency and proficiency in English language arts are very different constructs. Furthermore, this legislation appears to assume that all states and school districts have the same capacity to translate tests in ways that ensure the comparability of scores across test language versions. Yet a wealth of evidence shows that, in the absence of a strong process of test translation, translated tests may assess different constructs, or the scores produced by tests in different languages are not comparable (Gierl & Khaliq, 2001; Hambleton, 2001; Sireci, 1997; Solano-Flores, 2012; van de Vijver & Poortinga, 1997).

Altogether, lack of consideration of these issues may have a deleterious impact on the sets of opportunities made available for students to progress academically. They speak to the need for extensive training and professional development that enables education administrators and educators to make sound interpretations of legislation and its impact on instructional practices. For example, there is evidence that ELs who are native users of Spanish are less likely than ELs who are native speakers of other languages to be reclassified as English proficient (Faulkner-Bond, 2016), which suggests that there is a bias in the ways in which information from tests, in combination with other sources, is interpreted to make decisions concerning the reclassification of students as English proficient. Also, there is evidence that students from traditionally underserved groups are overrepresented in special education programs (Artiles et al., 2010), which is an indication that there is a bias against these students in the diagnostic assessment of disability. Particularly for EL students (see Abedi, 2014), this pattern also indicates that, despite the information on English proficiency from mandated tests, special education referral decisions may be influenced by erroneous perceptions of students' proficiency in English that educators may develop based on natural aspects of language (e.g., unfamiliar patterns of spelling mistakes and pronunciation) that may be confused with intellectual disability (Klingner & Harry, 2006). Clearly, legislation concerned with fairness cannot have the desired impact in the absence of serious, coordinated efforts that are oriented to promoting the proper interpretation of legislation and improved assessment-use practices.

Unfortunately, given the limitations of existing legislation on assessment and fairness and in a climate of accountability, assessment developers, school officials, administrators, and educators may reach a point where their efforts are focused more on complying with legislation on the assessment of students with special needs than on addressing each special education student's needs. Indeed, an obstacle that may hamper the ability

of assessment systems to properly provide accommodations for students with disabilities is that disability legislation (IDEA, 2004) imposes a system of disability categories that may not serve the unique set of needs of each special education student with the same effectiveness with which it serves the need for operationalizing students for legal and accountability purposes.

In sum, reflecting the concerns discussed, legislation concerning fairness in assessment does not necessarily guarantee implementation of fair assessment. Proper implementation, deep integration of the sociocultural context in assessment design and use, institutional commitment to fairness, and a critical interpretation of legislation are all critical for decision-makers and educators to meet the goals of that legislation.

Legislating Change in Schools and Classrooms: Accountability

Assessment has been used by elected officials and other policy makers as one of the most powerful tools for influencing and changing what happens in schools and classrooms. There is a great degree of evidence that this use of assessment has, in fact, met the intended purposes (Corbet & Wilson, 1991; Durán, 2008; Gándara & Baca, 2008; Herman & Golan, 1993; Milner et al., 2012). These influences include the prioritization of learning outcomes and instructional methods.

The effects of such tests have been debated and have not always been in the direction of improving learning (Mehrens, 1998; Milner et al., 2012). However, compared to other interventions, such as improving the quality of teaching or providing better quality resources, tests are considered relatively inexpensive and quicker ways of influencing what goes on in classrooms and have become the hortatory go-to strategy for policy makers.

Assessment experts and others concerned about the effects of inappropriate uses of tests have cautioned against their use for high-stakes policy goals. Several areas of concern have been highlighted, including creating greater differences in educational opportunities and resources for students from different sociocultural backgrounds, narrowing curriculum, removing local control of educational decision-making, and reducing teacher control and professional decision-making (Amrein & Berliner, 2002; Haertel, 1989; Huebert & Hauser, 1998; Jonsson & Leden, 2019). (See also Ho & Polikoff, this volume, for discussion of assessments used for accountability purposes.)

The use of assessment for such policy strategies has two key challenges. One is related to unrealistic expectations for assessment to meet the intended policy goals. The second challenge is related to the tension between the use of assessment to provide “objective” and “fair” information about learning outcomes and the limitations in creating tests for fair and valid interpretation of assessment results for diverse student populations (NRC, 1999). The unrealistic expectations for tests include their use for multiple purposes, some of which they were not designed for, and thus do not support all the purported interpretations and uses. A common challenge emerges, as a result of financial constraints and timing-related issues, when existing tests are used instead of developing tests for valued, targeted purposes. For example, problems arise when tests that are intended to provide group-level results, such as at school or classroom levels, are used

to make decisions about individual students, such as for grade retention or assigning individual school grades. These problems become expanded and compounded further when what is assessed does not correspond to the opportunities made available for students to learn in their sociocultural contexts.

There is extensive reliance on tests and test results as objective sources of information about student populations, especially highly diverse student populations. Tests have been used for classifying students into achievement levels, for assigning them to classrooms, and for tracking purposes. There are extensive current and historical examples of such uses. During the growth of mass public education between 1870 and 1890, student enrollments doubled in size because of an increase in immigration, which created a more diverse student population. Managing schools during this time required “the objective and efficient classification, or grading of pupils” (Tyack, 1974, p. 4). Tests were believed to have provided fair and objective information for making decisions about these students (Haney, 1984; Office of Technology Assessment, 1992). Researchers have highlighted the limitations of the notion of objectivity and the generalizability of claims based on assessment results for diverse student populations (Bailey & Durán, 2019; Ercikan & Roth, 2009; Ercikan & Solano-Flores, 2014; Solano-Flores, 2009). For assessments to support valid interpretations of scores for diverse populations, this diversity needs to be considered at all stages of assessment design, development, interpretation, and use (Solano-Flores & Nelson-Barber, 2001). However, “taking diversity into account” has many possible interpretations. Research and new conceptual developments are needed to establish how this is to be done in optimal, cost-effective ways.

Foundational Impact of Court Cases on Assessment

Court case rulings have historically had a foundational impact on assessment in practice. There are different types of arguments that are used in court cases for arguing for a particular use as being legally discriminatory in assessment. These include (a) presenting the intent to discriminate, (b) preserving the effect of prior illegal discrimination, and (c) causing a disproportionate adverse impact (Borreca et al., 2013; Phillips & Camara, 2006). These arguments focus on whether tests are used in a discriminatory manner for tracking, promotion, graduation, or licensure and certification.

Intentional discrimination or the intention to discriminate is forbidden under the equal protection clause of the Fourteenth Amendment. This clause forbids schools, districts, or officials from engaging in acts of intentional discrimination based on race, color, national origin, or sex (Personnel Administrator of Mass. v. Feeney, 1979; *United States v. Fordice*, 1992). Lawsuits arguing intentional discrimination have been rare and are difficult to support. These lawsuits have the burden of demonstrating not only the disproportionate adverse impact but also the intentionality of such impact. Regarding high-stakes testing, courts have almost always dismissed claims of intentional discrimination (NRC, 1999).

Lawsuits arguing that the test preserves the effects of prior discrimination are supported by the Supreme Court ruling that the Constitution forbids practices that serve to preserve or continue the effects of prior illegal school segregation (Borreca et al.,

2013). This legal claim was more common in the 1970s and 1980s because attendance at illegally segregated schools is rare to nonexistent in the early 21st century.

In arguing for disparate impact, plaintiffs need to demonstrate that some policy or practice, such as the use of a test, has disproportionate adverse impact on a particular group. This claim cannot be supported by just the difference in test scores for groups. There are two key requirements for disparate impact claims. First, the difference in performance between groups is *too large*, although it is possible to have psychometrically sound instruments that produce very large differences between groups. Criteria for deciding which differences are considered too large involve *practical significance* and *statistical significance*. Practical significance requires the demonstration of a disproportionate number of individuals from a particular group being assigned to treatments or given access to placement opportunities. The second requirement is the demonstration of lack of psychometric defensibility of the instrument or practice, as is the case with insufficient validity evidence for the proper interpretation and use of assessment results. The decisions about such claims may also depend on whether test scores are the only source of criteria in making placement or treatment decisions.

Rulings in the court cases involving due process challenges to some of the high-stakes tests constitute examples of foundational impact of assessment. The landmark *Debra P. v. Turlington* (1979) court case involved a challenge by a group of African American students who were denied a high school diploma based on a score on a statewide Florida competency test. The challenge claimed that the testing requirement was racially biased. The 1979 claim was supported by the discrepant failing rates: 2% for White students versus 20% for Black students. In this court case, the U.S. Court of Appeals made opportunity-to-learn central to fairness. It specifically ruled that if a high school graduation test covers material not taught to the students, then it is unfair and violates the Fourteenth Amendment of the U.S. Constitution. The challenge resulted in two major requirements for fairness: *adequate notice* and *curricular validity*. Adequate notice requires clear communication of the expectations for the test several years before the test is administered to allow students and their associated schools to prepare for the test. Curricular validity requires documented evidence that the students had reasonable opportunities to learn the content and skills covered by the test. The ruling highlighted the importance of connections between schools' accountability in providing opportunities to learn and denial of a high school diploma to students. Since demonstrating actual opportunity to learn at the individual student level is difficult, the U.S. Court of Appeals accepted evidence of the content being included in the curriculum and endorsement of the content by teachers as being skills they would teach (*Debra P. v. Turlington*, 1983, p. 186).

This challenge established new legal requirements for defensible high school graduation tests and other high-stakes assessment uses. First, in designing new tests for high-stakes decision purposes, the risk of not being able to meet the curricular validity requirement arises if sufficient time and resources have not been provided to schools for making the appropriate changes to curriculum and instruction. This is an important consideration when new tests are introduced for high-stakes decision-making purposes. New high-stakes

tests need to allow an adequate amount of time and dedicated resources for the required changes to align curriculum and instruction to the targeted assessment. This may require several years, depending on the level and types of changes that need to be made.

A shortcut to meeting the curricular validity requirement might be thought to be teaching to the test. However, ironically, this strategy compromises curricular validity because of the impact this practice has on learning more broadly and because it compromises the interpretation of test results as an indicator of student learning (Linn, 1983; Popham, 2001). Therefore, simply teaching to the test cannot be used to support curricular validity. There is a requirement to demonstrate that opportunity to learn, and therefore curricular validity, is established without compromising the validity of the measurement of learning.

Standards for testing, such as the *Standards for Educational and Psychological Testing* (AERA et al., 2014), play an important role in the defensibility of tests and test results and are often invoked in legal cases involving testing. They are often cited by experts, plaintiffs, and testing organizations for appropriate measurement, interpretation and use, and consequences of use issues. Central to the defensibility of tests is following professional standards in all technical matters, including, but not limited to, item development, item selection, validity, reliability, item bias review, equating, scaling, setting performance standards, test security, accommodations, test administration, scoring, and score reporting.

DESIGNING ASSESSMENTS GROUNDED IN SOCIOCULTURAL CONTEXT

This section discusses how considering the sociocultural context of assessment contributes to informing and guiding educational measurement decisions. In the following subsections, we first present a discussion of measurement as reasoning from evidence, followed by an exploration of what it would mean to situate this reasoning in the sociocultural context.

Assessment as Reasoning From Evidence Grounded in the Sociocultural Context

Our discussion in this section builds on the three interrelated core aspects of reasoning from evidence referred to as the *assessment triangle*, originally proposed by the NRC's flagship book *Knowing What Students Know* (NRC, 2001). First, we discuss the assessment triangle and then we discuss each of its components from a sociocultural perspective.

Underlying an assessment are three (implicit or explicit, formal or informal) interacting models: a *cognition model* (characteristics of the target construct), an *observation model* (features of tasks and observations expected to provide evidence of the target construct), and an *interpretation model* (rules, guidelines, and statistical models for interpreting observation as evidence of the target construct). These three models need to interact coherently to support assessment claims. Thus, their relationships can be represented as a triangle in which each vertex is intended to inform its two adjacent vertices (see Figure 3.3).

FIGURE 3.3
The Assessment Triangle

We point out the issues and dilemmas that need to be resolved if assessment is to effectively consider sociocultural context. We make a case for each aspect of the assessment triangle—cognition, observation, and interpretation—as well as the relationships among these vertices of the triangle to be grounded in the sociocultural context. Also, we highlight the importance of conditional inference discussed in the first section of the chapter in interpreting and making claims about assessment results (see Figure 3.4).

Cognition Model

The cognition model, also referred to as the *cognition and learning model* or the *student model*, concerns the construct targeted by an assessment and specifies an expected progression in learning. It includes aspects of the construct including knowledge, skills, and competencies in different stages of development and progression in a particular area of assessment.

Two challenges in developing a model need to be acknowledged as influencing the effectiveness with which it is specified. One is representational: A cognitive model postulates a structure of knowledge, for example, in terms of the sequence with which concepts are acquired and their hierarchical or reticular organization (see Nichols et al., 2017). This structure needs to be efficiently represented for proper analysis. For example, it should be able to allow examination of multiple sequences of learning—which can be many, even for seemingly small knowledge domains (e.g., Falmagne et al., 2006).

The second challenge is the difficulty of handling ontoepistemic heterogeneity—the condition that “knowing and being are inextricably tied” (Warren et al., 2020, p. 278). Individuals with different backgrounds (histories, identities, social practices) construct knowledge and make sense of experience differently (Rogoff, 1998). The differences in sociocultural contexts of learning point to possible differences in learning and cognition models, as well as in the organization of knowledge structures for individuals from different contexts (Rogoff, 1998).

FIGURE 3.4
Factors and Considerations Impacting the Cognition Model

Taking the sociocultural context into account in the cognition model requires gaining insights about what, why, and how students are learning (Donovan & Bransford, 2005; Engeström, 2001), the relationship between the learner and the context of learning, and the conditions of learning. The following are possible guiding questions for examining the equivalence of cognition models for students from different sociocultural backgrounds:

- What are the key aspects of the students' learning environments, including home and schooling environments, technology access, and integration?
- How is the intended learning expected to progress?
- How do the target learners organize aspects of the knowledge they are attaining?
- What are the factors that drive their motivation, or the lack of it?
- How are students expected to apply their knowledge in their everyday lives and at school?

These questions (represented in Figure 3.4) need to be explored through empirical research focusing on differences between students from different sociocultural back-

grounds with respect to how they think and learn, how performance at different levels of proficiency varies, and how they understand and relate to the subject matter.

The equivalence of cognition models is central to equivalence of measurement that allows comparisons of scores across individuals from different sociocultural groups (Ercikan & Por, 2020). This equivalence refers to the degree to which individuals are expected to develop and progress on the target constructs in similar ways and the extent to which the constructs are accessible to students from different backgrounds in similar ways. Differences in some components of the cognition model may require an assessment to focus on parts of the construct that, according to empirical evidence, have been shown to be equivalent across the considered groups.

Notice that the emphasis on the ways in which knowledge is acquired may vary depending on the purposes of testing because individuals may acquire knowledge in multiple ways—formal or informal, structured or unstructured—a strong reason that speaks to the limitations of assuming uniformity in learning progressions.

Observation Model

The observation model concerns observations made from student responses to tasks and the assessment situation relevant to the target construct. It includes key features of assessment tasks that might elicit evidence related to that construct. The connections between the task and the target construct are established through identifying cognitive requirements for completing the tasks and describing how these requirements are related to the target construct and construct components in the cognition model.

In addition to how students learn, a myriad of factors that constitute the sociocultural context can affect how students relate to an assessment. Examples of these factors are how familiar students are with the items' contexts (the stories and situations provided by items with the intent to make problems meaningful; Ruiz-Primo & Li, 2015), how able they are to understand the items and communicate their answers, and how effectively they function and navigate in tests administered on digital platforms (Figure 3.5). In a science assessment, student perceptions of what science items are about, what they believe they are expected to do in responding to them, and what problem solution strategies they use to solve the problems may be shaped by their sociocultural activity (Solano-Flores & Nelson-Barber, 2001). In addition to these cognition-related factors, affective factors such as how students feel about the assessment situation, how they relate to the assessment tasks, and how their motivation is affected by the assessment contexts can impact how they approach and perform on an assessment (Pennington et al., 2016; Randall, 2021; Steele & Aronson, 1995).

This complex interaction between sociocultural context, student knowledge, and assessment challenges the assumption that responses to tasks can be interpreted as *equivalent evidence* of the construct for students from different sociocultural backgrounds and has serious implications concerning comparability and the use and meaningful interpretations of scores (Sireci, 2020). A key consideration is that the same task may impose different sets of cognitive demands that are not germane to the construct

**FIGURE 3.5**

Factors and Considerations Impacting the Observation Model

being assessed on students from different sociocultural backgrounds. Another key consideration is that students from different sociocultural backgrounds should not be expected to relate to that task in the same ways.

Grounding assessment in students' sociocultural contexts requires designing variations and features of tasks in ways that allow obtaining equivalent evidence of knowledge, skills, and competencies of students from different sociocultural backgrounds. We see examples of attempts to address such variations when tasks, task situations, or evaluation procedures are adapted to individual student contexts so that the resulting evidence is more comparable across individuals in tests adapted to different languages or modified to provide accommodations for specific student needs. It is important to note that because of cultural differences in practices and expectations regarding a construct, variations in tasks and task situations may not necessarily result in adequate comparability of evidence of the targeted constructs. An example of these types of large differences can be observed in cross-cultural intelligence testing (van de Vijver, 2003). Even though it may be possible to conceive of an "intelligence" construct with comparable elements across cultures, such capabilities are applied in extremely different activities in different cultures, which precludes the creation of tasks that will result in equivalent evidence and creation of a common assessment.

Two interrelated aspects of tasks are important to consider. One is the features of tasks intended to be related to providing construct-relevant evidence. The other feature

is the format and forms of representing information (e.g., wording, illustrations, and contextual information) that are not central to the target construct yet are needed to administer the task, but add cognitive demands irrelevant to the target construct. This is the case of text with directions explaining what the test taker is expected to do in a given task. Unless reading and interpreting the directions is the target construct, these directions inevitably add cognitive demands for completing the task.

In addition to these added cognitive demands, there is evidence that students from different cultural or linguistic backgrounds interpret graphics and images in tests differently (Solano-Flores et al., 2013), have different intrinsic interests in topics that impact their performance on tests (Ercikan, 1998), and use testing time differently (Ercikan et al., 2020). These findings underscore the key role that different semiotic (representational) resources play in designing tests and minimizing construct-irrelevant variance (Solano-Flores, 2021).

Fairness issues arise when these construct-irrelevant factors make assessment tasks systematically more challenging for students from certain backgrounds. In fact, the traditional notion of fairness is tied to the extent to which construct-irrelevant variance exists on a task that might be attributable to such presentation-related features. Minimizing construct-irrelevant variance involves the recognition of variations in cultural backgrounds, identities, reading ability, familiarity with context, and digital literacy among students and making choices about the ways in which tasks are to be presented.

In designing construct-relevant aspects of tasks, taking sociocultural context into account must also include considerations of the variations in hypothesized learning progressions and knowledge structures required to perform well on tasks across student groups. Unfortunately, while some researchers have recognized the influence of culture on students' learning progressions (e.g., Wilson & Toyama, 2018), empirical research has yet to systematically examine how these progressions vary across students from different cultural or linguistic groups. If learning progressions are substantially different across students from different backgrounds, then the features of the tasks that determine difficulty levels should not be assumed to be uniform across groups of students from different sociocultural backgrounds. Equity needs to be explicitly incorporated into the task of developing learning trajectories and learning progressions (Delgado & Morton, 2012).

The goal in designing both the presentation-related and the construct-related features of tasks from a sociocultural perspective is to contribute to obtaining valuable, equivalent evidence of knowledge, skills, and competencies for students from different sociocultural backgrounds. Consistent with Figure 3.5, possible guiding questions for developing and evaluating observation models include the following:

Presentation-related features:

- Are students from different backgrounds expected to relate to assessment tasks and the assessment situation differently?
- Are variations in sociocultural context expected to lead to different cognitive processes for students from different backgrounds?

- Are familiarity and working understanding of features used in a test (e.g., text, images, computer user interface) different across students from different backgrounds?
- Do these features need to be adapted to optimize performance across students from different sociocultural backgrounds?

Construct-related features:

- Are the definitions of the target construct different for different groups?
- Is there evidence of differences in learning progressions across groups?
- Is there evidence of differences in knowledge structures across groups?

Answers to these questions require empirical evidence, which typically is not available for all constructs that assessments may target. However, even in the absence of that evidence, and with input from experts in relevant sociocultural contexts, the questions should be used to guide explorations about the optimal design of tasks.

Interpretation Model

The interpretation model describes rationales and reasoning that are applied to interpreting observations (i.e., student responses, actions, products) as evidence of the target construct. It consists of two components, the *scoring model* and the *measurement model*. The scoring model, on the one hand, describes the essential features of the student responses that are relevant to the competencies in the cognition and learning model and assigns scores (ordered or partially ordered) or categorization codes to student responses or products. The scoring model is a characterization of the evidence in the performance that is relevant to making inferences about the target constructs. An example that illustrates a scoring model is the set of rules used to score constructed-response items or essays as indicators of performance in relation to the target construct. Other examples include evaluation and scoring of patterns of actions in a simulation-based task or an interactive communication assessment based on the degree to which different sequences of actions may be indicators of the targeted constructs at different levels.

The measurement model, on the other hand, is the psychometric approach for integrating performance data into evidence across student responses and products. For example, in the simplest case, using classical test theory, dichotomous scores on the correctness of the responses given by a student to multiple items can be added to compute a total score. Other measurement models include item response theory (IRT)–based models that define a probabilistic relationship between the performance and the target construct, Bayes nets, or integrated hidden Markov models that combine evidence from both responses and process data (Scalise et al., 2022). Measurement models facilitate the interpretation of observations in relation to what they indicate about the target constructs and involve making generalizations across individuals and contexts. Central to these interpretation models are standardized procedures for collecting data through tests and surveys to allow for the application of a single interpretation model across contexts. This standardization has utmost importance in creating comparable scores

and making defensible, consistent, and fair inferences about test takers' knowledge and skills (Moss et al., 2008).

Traditional interpretation models are silent about the sociocultural contexts of assessment and learning (see Figure 3.6). Typically, the same interpretation model is applied to individuals regardless of social, cultural, and language contexts. However, there is evidence that individuals engage in activities and tasks differently in different contexts (e.g., Beach, 1999; Lave, 1988; Mehan, 1998; Schratz & Mehan, 1993). For example, Lave (1988) demonstrated that some individuals who do not perform well on mathematics problem-solving tasks in formal testing situations were able to solve similar mathematical problems in everyday situations, such as determining the best supermarket buys. Lave argues that it is not possible to separate mathematical challenges from the sociocultural contexts and specific circumstances in which they are presented. These types of variations of performance across contexts limit the possibility of making generalizable claims about individuals' abilities.

Sociocultural context may impact student engagement with tasks in complex ways. Students' responses to tasks may vary because of differences in opportunity to learn given content and variations in access to resources that support learning. For example, the meaning and interpretation of the performance of students on active items that allow or require the use of calculators in a mathematics assessment are shaped by the kind of access students have to calculators at home and school. Imagine including calculators as a resource students can use optionally with the intent to eliminate calculation as an extraneous source of variance when calculation is not part of the target construct. This resource may make certain items easier for those students who are used to using calculators, but it may make them function differentially for those who are not accustomed to using calculators at home.

As with many tests being administered on digital platforms, access to technology and familiarity with different devices may impact performance on tests in different ways. There is extensive evidence of a digital divide among students from different cultural and socioeconomic backgrounds (e.g., Ching et al., 2005; Ercikan et al., 2018). There is also evidence that students' performance may be differentially impacted by the mode in which assessment is administered (e.g., paper based versus computer based) for students from different ethnic/racial and socioeconomic backgrounds (Jewsbury et al., 2017). These examples point to limitations of uniform interpretations of performance across groups. Therefore, in these circumstances, applying the same interpretation model might lead to inappropriate interpretations of response data and, therefore, to measurement error and bias.

Taking sociocultural context into account in the interpretation model requires considering the possibility that the same scoring model may not result in equivalent evidence of the target construct and that the same measurement model may not produce scores with equivalent meaning and, therefore, cannot be interpreted in the same way across students from different sociocultural contexts. Consistent with Figure 3.6, possible questions that need to be explored to examine the degree to which the same scoring and measurement models are expected to lead to valid interpretation and use of scores include the following:

FIGURE 3.6
Factors and Considerations Impacting the Interpretation Model

Scoring model:

- How might the observations be interpreted differently in different sociocultural contexts?
- How might the presentation of items impact student performance differentially?
- How might different worldviews, knowledge structures, and learning progressions impact the nature and quality of observations?
- What types of variations in scoring models are needed for obtaining equivalent quality of evidence of the constructs from different student groups?

Measurement model:

- To what extent can the same psychometric model be used to summarize evidence across tasks for student groups from different sociocultural contexts?
- What adjustments might be needed in psychometric models for summarizing evidence of the construct with equivalent score meaning?

Effectively answering these questions requires developing scoring and psychometric models that recognize variations across different sociocultural contexts, as well as methodologies for examining the degree to which uniform interpretations of observations and accumulation of evidence are supported by response patterns. The considerations for all three models are summarized in Figure 3.7.

FIGURE 3.7
Sociocultural Considerations in the Assessment Triangle

IMPLICATIONS FOR FAIRNESS

We hope that in previous sections we have clearly argued that sociocultural context is relevant to all aspects of assessment, including how constructs are defined and developed, how performance on tasks can be designed, how measurement information can be derived, and how overall performance can be evaluated. This context is also central to the interpretation and use of assessment results, particularly to the consistency of such use and interpretation for individuals from different sociocultural contexts, which is at the core of fairness.

Two notions are central to Kane's (2006) view of fairness: (a) consistency of score meaning for groups and (b) equitable treatment of groups. *Consistency of score meaning* refers to the degree to which the same claims and inferences can be made based on test results for different groups. This notion of fairness has been the focus of much of fairness research. *Equitable treatment of groups* refers to the degree to which testing conditions are equivalent across groups. The notion of fairness as equitable treatment of groups has traditionally been addressed by standardization of testing conditions. The following sections discuss the sociocultural context and these two concepts of fairness.

Consistency of Score Meaning

To a great extent, measurement involves extracting and synthesizing evidence from students' performance on assessment tasks. A single measurement model is intended to summarize the relationship between observations and the target constructs. The measurement models used in synthesizing evidence regarding target constructs across tasks are intended to be used to make claims about all individuals. The appropriateness of the model as a method for summarizing evidence, as indicated by the fit of the model to the response patterns, is expected to vary across individuals and groups. Consistency of score meaning critically depends on the degree to which the same measurement adequately represents the relationship between response patterns and the target construct for different groups. Much of fairness research has been restricted to comparing the degree to which a given measurement model fits the response pattern data for individuals from different backgrounds—in other words, the degree to which a single measurement model can be justified for different groups.

There is evidence that speaks to the limited generalizability of models appropriate for overall groups to subgroups and individuals in the society (Ercikan & Roth, 2009). Social science research that relies on between-group score variations and marginal inference implicitly assumes generalizability of fundamental cognitive and affective processes across populations. However, there is a great degree of evidence of variations among human populations in visual perception, analytic reasoning, fairness, cooperation, and memory (Heinrich et al., 2010). Heinrich et al. (2010) highlighted that people from *Western, educated, industrialized, rich, and democratic* (WEIRD) societies are

among the most studied but are not necessarily the most typical. Findings from research that focuses on these restricted segments of societies hardly ever acknowledge the limitations that stem from the generalizability of its findings (Ercikan & Roth, 2009).

There are parallels in measurement. In North American contexts, with White, English-speaking mainstream cultures, estimation of measurement models through calibration analyses using IRT-based methodologies are heavily determined using response patterns from the mainstream culture through their higher degree of proportional representation in the calibration samples.

Measurement concepts and challenges to generalizability of measurement models are pertinent when taking sociocultural context into account. Because individuals from different sociocultural contexts and with different sets of learning experiences are likely to have differential response patterns, a single measurement model may not be equally effective in capturing the relationships between observations and the target construct for different groups.

Variations among contexts and individuals can result in differential response patterns and, therefore, in different levels of fit between the data and the model. These variations are captured by several measurement concepts. These include *person fit* (an indicator of the fit with the model summarizing relations among the tasks and the target construct for the individuals), *person-by-task interaction* (atypical response patterns for groups across tasks), and *group-by-task interaction*, also known as DIF. Researchers have highlighted the limitations of a single measurement model to *all groups* and *all individuals* (Ercikan et al., 2014; Molenaar, 1999, 2004; Molenaar et al., 2003; Oliveri et al., 2013, 2014). Borsboom et al. (2005) stated that “if a model fits in a given population, this does not entail the fit of the same model for any given element from a population, or even for the majority of elements from that population” (p. 73).

Person fit statistics allow the identification of individuals with different or atypical response patterns. Among other factors, poor person fit statistics could be indicators of confusion about the item’s content or presentation, lack of opportunities to learn the item’s cognitive requirements, and familiarity or lack thereof with the context in which the item is presented, which may impact the engagement of an individual with the item as compared to other persons. Inaccurate measurement results from estimating target competencies with a measurement model that has poor person fit. Appropriate uses of assessment results are critically dependent on the accuracy of measurement. The notion of accuracy as captured by person fit is different than reliability, which is a function of the correlation among the item responses calculated at the group level, or IRT-based measurement accuracy, based on information function values, also estimated at the group level. It is possible to have high reliability and information function values and still have poor person fit for some individuals and, therefore, low accuracy of score estimates. Typically, individuals from mainstream cultures tend to highly influence the overall estimation model. Therefore, individuals from nonmainstream cultures tend to be the most affected by poor person fit and, therefore, by inaccuracies of measurement. Different statistics developed for person fit (Meijer & Sijtsma, 2001; Rupp, 2013) are the best approaches created to address fairness for individuals.

Person-by-task interactions can be captured in generalizability theory models to identify the degree to which performance can be generalized across tasks to make claims about individuals' performances (see Cronbach et al., 1972). Large amounts of variance due to person-by-task interaction are common, which points to limitations in combining evidence of constructs across different types of tasks, such as hands-on tasks and multiple-choice questions. A sizable person-by-task interaction indicates variation of performance across both different types of tasks and individuals. It poses a limit to the use of a single model of synthesizing evidence across tasks (Shavelson et al., 1993). This interaction can be large when different constructs are measured by different tasks—in particular, by different task types. Large person-by-task interaction can also be an indication that fairness is compromised if its magnitude varies considerably across groups (Solano-Flores, 2017). This fact underscores the need to examine the technical properties of tests separately by group (e.g., the group-based variance components), which may reveal low technical properties of tests for some groups. It also speaks to the fact that generalizations based on a given test about specific individuals or about populations are tremendously dependent on the specific set of items included in the instrument and the specific conditions under which tests are administered.

Group-by-task interactions indicate systematic variations of group performance on specific tasks. These interactions are typically referred to as DIF and are central to examining consistency of score meaning for groups. These approaches play a critical role in identifying differential response patterns for *manifest* or observed groups identified as the focus of fairness research. However, a focus on sociocultural context and population heterogeneity highlights the limitations of these methodologies in examining fairness and identifying bias.

Population Heterogeneity and Fairness

IRT-based approaches to examining fairness are based on examining how differently items function across reference groups (typically, mainstream groups such as White/Caucasian or male groups) and focal groups (typically, historically underrepresented or underserved groups such as ethnic or linguistic minority groups). IRT-based DIF analysis is frequently invoked as a tool for examining bias and ensuring fairness in testing. However, DIF analysis methodologies are silent about the heterogeneity of populations. The configuration of focal groups often neglects the complexity of sociocultural contexts. This omission can lead to differential response patterns within such groups because of linguistic, cultural, and ethnic diversity (Cohen & Bolt, 2005; De Ayala et al., 2002; Ercikan, 2009).

Ignoring heterogeneity in comparison groups in DIF analyses compromises the fairness and consistency of score meaning. In DIF analyses, there are two possibilities: An item is identified as either differentially functioning or DIF free. When DIF detection involves heterogeneous group comparison groups, not all members of the focal group may be affected by DIF uniformly. Heterogeneity in response patterns may mask systematic differential response patterns between some subgroups within comparison groups and lead to false DIF-free identifications for some group comparisons. This can lead to inappropriate conclusions about item equivalence and score meaning for different groups.

The implication of heterogeneity within comparison groups is that items identified as differentially functioning and, therefore, potentially biased for the overall group (e.g., males or females) may not be functioning differentially for some of the subgroups within the larger group. Conversely, items that are identified as DIF free for the overall group may be differentially functioning for some subgroups. In essence, population heterogeneity may lead to inappropriate inferences in fairness research and consequently result in inconsistency of score meaning for some groups.

Researchers have recognized the possible limitations of DIF methodology as a result of diversity within comparison groups. Also, some researchers have highlighted heterogeneity within gender and ethnic groups and proposed examining possible interaction between these groupings (Dorans & Holland, 1993; Zhang et al., 2005). These researchers propose the creation of more homogeneous groups by crossing gender and ethnicity. While such an approach may indeed reduce heterogeneity within groups, it continues to rely on manifest grouping. Yet in the complex sociocultural context, the sources of variation in response patterns may not be easily identifiable through manifest labeling such as gender, ethnicity, socioeconomic status, or educational opportunity.

Other researchers have proposed consideration of latent groups that may be identifiable using statistical methods such as latent class modeling in fairness research. These researchers have proposed mixture model approaches for investigating differential response patterns (Bolt et al., 2001; Cohen & Bolt, 2005; De Ayala et al., 2002; Webb et al., 2008). In these models, also referred to as latent DIF models, comparisons focus on latent classes instead of manifest groupings. In mixture model approaches, the first step is to identify latent classes. Test takers are assigned to latent classes based on their item response patterns. Whereas manifest group-based DIF investigations typically focus on predetermined and potentially disadvantaged groups, this type of classification results in groupings that may have a combination of test takers from different ethnic or gender groups. One challenge with the mixture model approach to DIF is related to the interpretation of latent class membership for guiding fairness investigations.

Ercikan and Oliveri (2013) proposed an approach in which, first, heterogeneity within manifest groups is identified using latent class analysis and, second, DIF analysis for latent classes is performed. This two-step approach, which focuses on manifest groupings and addresses heterogeneity within these manifest groups, produces more accurate identifications of DIF and actionable steps following DIF investigations (Grover & Ercikan, 2017).

Equitable Treatment of Groups

Standardization has been central to the notion of fairness through the equitable treatment of groups, which assumes that even though some aspects in an assessment advantage some students, other aspects advantage others, and thus, on average, advantage/disadvantage evens out (Mislevy et al., 2013). However, as discussed before, standardization does not necessarily create equivalent testing conditions for individuals from different sociocultural backgrounds and, therefore, does not always provide equivalent evidence of students' knowledge, skills, and abilities. Individuals

with different experiences with testing (such as familiarity with testing formats and testing in technology-rich environments) and people from cultures and contexts who are not used to performing cognitive tasks in limited times or who relate to assessment tasks differentially may engage with tests differently. The extent to which testing conditions are equivalent has been investigated indirectly by comparing the performance of students from different ethnic and racial backgrounds on multiple-choice and performance tests (Ercikan et al., 1998), on paper-based and digital tests (Bennett et al., 2008), and across individuals from different sociocultural backgrounds (Ercikan et al., 2020). Despite pointing to the potential for nonequivalence of testing conditions, these approaches typically do not result in differential interpretations of scores.

Building on the notion of “marginal fairness” introduced by Hansen et al. (2005) for accessibility of tests, Mislevy et al. (2013) introduced the “conditional sense of fairness,” which

means taking certain information into account in inference rather than averaging over the ways it might vary. In assessment, it means a designer purposefully varies aspects of an assessment so that students can each access, interact with, and provide responses to tasks with minimal difficulty, and primary challenges are central to the intended construct. (Mislevy, 2018, p. 220)

This approach deviates from standardization and focuses on systematic variations of assessment and assessment conditions to provide equivalent evidence of the target construct. Examples of such deviations are observed on testing students with disabilities using accommodations of the tests (Kopriva et al., 2016; Mislevy et al., 2013; Thurlow & Kopriva, 2015) and adaptations of tests to different languages (Ercikan & Por, 2020; Solano-Flores et al., 2009).

Conditional Sense of Fairness and Measurement Models

The implementation of a conditional sense of fairness requires building conditional inference into assessment design and measurement models. Examples of conditional inference are presented by Mislevy et al. (2013), who proposed that tasks be matched to student populations. These researchers proposed integration of the universal design for learning with the evidence-centered design approach to assessment and drawing inferences from tests. The goal of this approach is to provide optimal conditions for students to demonstrate their knowledge, skills, and abilities in assessment situations. For example, students may be presented with different forms of the same task (e.g., braille versus regular text or different language versions) or they may be allowed to respond in different ways (e.g., in writing or orally).

Three sources of data are central to these inferential models: (a) student actions and products, (b) task specifics and contexts, and (c) student background data. Conditional inferences regarding student knowledge and abilities are conditional not only on student actions and products, but also on student background and task specifics (Figure 3.8). In this approach, the conditional relationship between responses, task context, and student background can be expressed in psychometric models for tests with multiple formats, such as those with accommodations presented to students with disabilities.

**FIGURE 3.8****Conditional Inference About Student Knowledge and Abilities**

Note. Adapted from “A ‘conditional’ sense of fairness in assessment,” by R. J. Mislevy, G. Haertel, B. H. Cheng, L. Rucitinger, A. DeBarger, E. Murray, and T. Vendliski, 2013, *Educational Research and Evaluation*, 19(2–3), p. 125. <https://doi.org/10.1080/13803611.2013.767614>.

Mislevy et al. (2013) discussed psychometric modeling of conditional inference when tasks are matched to students a priori. This modeling is proposed when students have varying levels of knowledge and skills that are irrelevant to the target construct yet are needed for reading, interpreting, and responding to tasks. Such a variation in construct-irrelevant skills can be observed for students with disabilities and ELs. Conditional inference is achieved by design by matching students to the appropriate task variations. This approach can be easily adopted when assessing students from diverse sociocultural contexts, provided that there are identifiable background variables of focus. These may include development of multiple versions of tasks, with different technology requirements for students with differential digital literacy or technology skills.

There are multiple complexities in identifying relevant sociocultural context factors, such as language, race/ethnicity, gender, intersectionality, and the features of tests that optimize performance for students from such backgrounds. Grounding assessments in sociocultural context requires gaining insights about aspects of sociocultural contexts that are of utmost importance to be reflected in an assessment situation, developing assessment task design strategies to reflect those aspects and optimize performance of students from all backgrounds, and developing measurement models that support making claims about diverse student populations based on such complex assessments. To do so requires a theory-based and empirically supported definition of the targeted construct as it relates to the intended interpretations and uses, the features of tasks and situations in which the construct is relevant, and the variety of necessary but construct-irrelevant features of situations that can be required to act in situations that can produce evidence of the intended construct.

FINAL NOTE

Our chapter is intended to help guide full consideration of the complex relationship of sociocultural context and assessment. Our main goal for the chapter is to raise awareness among measurement professionals, researchers, and practitioners of the importance of sociocultural context on the assessment, use, and interpretation of assessment results. We make recommendations for steps and considerations for a thoughtful approach to assessment. Such awareness is central to gauging how different contexts are affecting choices and decisions made in measurement, as well as in understanding the complex impact measurement has on different populations.

Our discussion has been grounded in the idea that social processes are central to learning and cognition and that individuals learn through social interaction, through learning from each other, and through motivating each other. In addition, sociocultural contexts influenced by adversity, poverty, and racism can have long-lasting impacts on health, well-being, learning, and achievement. From this sociocultural perspective, context shapes the mind, how knowledge is organized, how individuals approach solving problems, and how they engage with tests. Using the assessment triangle framework, we presented a set of considerations and issues to be addressed in each component of the triangle. These considerations are organized around questions intended to inform the definitions of each of the models and modify them for different sociocultural contexts.

Modifying each of these models can be challenging. We find some parallels when tests are modified to fit the needs of students with disabilities and ELs. However, these examples do not completely meet the requirements for tests in complex multicultural contexts. In the case of assessing students with disabilities and ELs, accommodations are made to the construct-irrelevant surface features of tests to optimize students' participation in the assessment. Therefore, only the observation and interpretation models are modified. In multicultural contexts, with evidence of different knowledge structures, modifications of the cognition model may also be needed. In that scenario, designing tests for variations of the cognition model will inevitably lead to variations of observation and interpretation models.

We offer two related approaches to addressing sociocultural context in assessment argumentation. One is the concept of *conditional inference*, which focuses on obtaining "equivalent evidence of the target construct" rather than standardized testing conditions for fairness of interpretations and uses of assessment results. The conditional inference approach allows for variations in observation and interpretation models. This means that variations in tasks for different sociocultural contexts are created to optimize testing conditions for different groups. It also means that responses can be interpreted differently using different scoring rubrics for extracting construct-relevant information from responses. We emphasize the recognition of population heterogeneity, moving away from the uniform treatment of groups such as language or cultural groups. This heterogeneity requires careful evaluations of the use of a single measurement model for different sociocultural contexts. Three sources of data are central to these measurement models: (a) student actions and products, (b) task specifics and contexts, and (c) student background data. Conditional

inference regarding student knowledge and abilities is conditional on student actions and products, but the student background and task specifics are relevant as well.

We believe that differences in the opportunities for learning the content assessed in tests, the cultural contexts in which students learn, and the variations among students in their ability to engage in assessment for students from different populations cannot be ignored. Validity and fairness are indissociable characteristics: One cannot address one while neglecting the other (Herman et al., 2023). Consideration of sociocultural contexts needs to occur continuously, from the conceptualization of a test and in all aspects of its development, interpretation, and use. Failure to take sociocultural context into account has significant consequences, including making inappropriate inferences about student learning, faulty decisions about individuals, unfair resource allocation and planning, and unequal distribution of opportunities to access education and careers.

Finally, this chapter should end by emphasizing the important role that organizations (e.g., local education agencies, assessment systems, test developers) play in ensuring that these ideas are applied to ensure fair and valid testing. While many of these methods and ideas have been available for decades, they are far from being consistently and systematically applied in practice. A serious commitment to fair, equitable testing necessarily entails a profound revision of assessment development procedures and a realistic allocation of the time and resources needed to properly address diversity. Clearly, the level of institutional commitment to fairness and equity is part of what defines the bidirectional relationship between sociocultural context and assessment.

ACKNOWLEDGMENTS

We thank the three reviewers, Bob Mislevy, Martha Thurlow, and Richard Duran, who reviewed and provided extensive feedback and directions in several iterations of this chapter. We are deeply grateful for their thoughtful suggestions and collegiality.

Part II

Foundational Concepts

Validity and Validation

Suzanne Lane

University of Pittsburgh (Emerita)

Scott F. Marion

National Center for the Improvement of Educational Assessment

Now, as a nation, we don't promise equal outcomes, but we were founded on the idea everybody should have an equal opportunity to succeed. No matter who you are, what you look like, where you come from, you can make it. . . . Where you start should not determine where you end up. (Obama, 2014, p. 1)

Validity frames all aspects of testing, from conceptualizing the targeted construct; to designing, developing, and implementing the test; to evaluating the consequences of test use. Fundamental to the validity of score meaning and test use are investigations of validity for different groups in the population defined by ethnicity, race, culture, language dominance, disability, and other relevant experiential, educational, social, and personal characteristics. Throughout the chapter, we typically refer to these various population groups as diverse groups. President Barack Obama's sentiment was a mandate for equal opportunity in higher education, but his words also are applicable to equal opportunity in testing, from accessing the construct to reaping any intended positive benefits of test use while minimizing any undesirable outcomes. Intentional test design that accounts for different ways of knowing and doing across diverse groups has the potential to improve the validity of score meaning and use for individuals—no matter who they are, what they look like, or where they come from.

We refer to *validity* as the extent to which theory and evidence supports or refutes proposed and actual or enacted test score interpretations, uses, and consequences and to *validation* as the process of gathering, evaluating, and synthesizing such evidence. Evaluations of validity depend on the specific uses of tests. For example, validity evidence to support or refute the use of a college-readiness test as a high school state assessment should be commensurate with this proposed purpose and not rely solely on evidence supporting the test for admissions decisions.

We adopt the argument-based approach to validity espoused by Cronbach (1988), Kane (1992, 2006, 2013), and Shepard (1993), which entails an interpretation and use argument and a validity argument, where the purpose, use, and context of testing are at the forefront of the argument-based approach. Emphasizing the need to focus on the validity of test use as well as score interpretation, Kane (2013) shifted from using the term *interpretive argument* to *interpretation/use argument*, although he emphasized use in his original framing of an interpretive argument. The interpretation and use argument (IUA) explicitly links the inferences from test performance to decisions and uses, including actions resulting from decisions. Consequences of test-based decisions and uses are therefore central to the argument-based approach to validity. The validity argument provides a comprehensive framework, including the rationales, assumptions, and backing or evidence, to support (or refute) the inferences and uses laid out in the IUA. Judgments regarding the evidence do not result in a yes/no endorsement regarding the validity of the score inference and test use; rather, they are more nuanced and suggest a degree of validity.

The *Standards for Educational and Psychological Testing* (American Educational Research Association [AERA] et al., 2014) referred to validity as the “degree to which evidence and theory support the interpretation of test scores for proposed uses of tests”

(p. 11) and to validation as a “process of constructing and evaluating arguments for and against the intended interpretation of test scores and their relevance to the proposed uses” (p. 11). We maintain that the *Standards* offers a narrow view of validity by indicating that validity refers to score interpretations “for proposed uses” instead of “and uses.” In contrast, we argue that validity refers to score decisions and test uses *including their consequences* and is not limited to the evaluation of score *interpretations* for a particular use. As an example, some tests are intended to serve as levers of educational reforms—such as raising academic standards and achievement for students, in particular, for historically underserved students—by signaling the importance of instructing students on rigorous content. The use argument for these tests as educational change agents requires a corresponding validity argument. Consequences, therefore, are central to the validity argument. Validation entails providing evidence regarding the use of tests and their intended and unintended consequences as well as evidence to support test score interpretations. The *Standards* are ambiguous regarding the use of tests and their consequences as part of the validity argument, whereas we support, and discuss in the chapter, the now long-standing position that test use and its consequences are integral to validity (Kane, 2006, 2013; Messick, 1989; Shepard, 1993).

We argue that fairness issues are validity issues because they are inherent in the validity of score meaning and test use for individuals from diverse groups. Consequently, because fairness issues are validity issues, they must be addressed in the IUA and validity argument. Fairness is at the core of all aspects of testing, from conceptualizing the targeted construct; to designing, developing, and administering the test; to evaluating the consequences of test use. Throughout this chapter, we use the argument-based approach to validity because it provides a mechanism to address validity and fairness throughout the testing process, from conceptualizing the construct to evaluating the consequences of test use.

As the title of this chapter implies, we discuss validity theory. However, we emphasize *validation*: the application of validity theory in conducting validity evaluations. We begin this chapter with the position that validity is an overarching concept that subsumes reliability/generalizability and fairness. We then review the evolution of validity as conceived by authors of the validity chapters in previous editions of *Educational Measurement* and by other validity theorists and researchers, providing a historical account of how consequences became central to validity and validation. We discuss the argument-based approach to validity espoused by Kane (2006) in the fourth edition of this text, as well as by other validity theorists and researchers, advocating its essential role for evaluating score meaning, test use, and resulting consequences. We then argue that consequences are essential to validity and the validation process and, further, discuss their importance in the IUAs and validity arguments for different testing programs, including credentialing testing programs, K–12 assessment and accountability programs, and language testing programs.

The next section addresses validity challenges when assessing individuals from diverse cultural and language groups. Our discussion supporting culturally responsive

and situated assessment practices that aim to provide more meaningful and equitable score interpretations and test uses for individuals from diverse cultural backgrounds is situated during a pivotal time of heightened recognition of the long-standing systemic inequities in our assessment and education systems. Our discussion of assessment and learning in context emphasizes the role of situated learning theory to improve the validity of test score inferences and uses. Further shifting the testing process to provide more valid score meaning and use for individuals from different cultural, social, experiential, and personal backgrounds requires partnerships among all those involved in and affected by testing. However, we recognize the challenges in designing such assessments and the need to obtain evidence to support their use.

We conclude by addressing applications of validity theory to testing programs, although throughout the chapter we emphasize applications of validity theory, including to K–12 assessment and accountability programs and to testing programs that use innovative technology. One of our main goals in this chapter is to wrestle with the tension between (a) the validity of score inferences and uses for assessments that are relevant and appropriate for all groups of individuals and (b) the large-scale assessment uses that rely on score meaning and test use that are essentially the same across groups.

VALIDITY AS AN OVERARCHING CONCEPT

Validity, reliability, comparability, and fairness are inherently interwoven, with validity as the overarching concept. In their discussion on the differing perspectives of fairness, Nisbet and Shaw (2019) concluded that validity, fairness, reliability, and comparability are “closely related and intersect at many points in most theoretical accounts” (p. 624). Moreover, as Messick (1994, p. 13) noted, “validity, reliability, comparability, and fairness need to be uniformly addressed for all assessments because they are not just measurement principles, they are social values that have meaning and force outside of measurement wherever evaluative judgments and decisions are made.” Crisp (2017) reviewed the stance of validity theorists on the relationship between comparability and validity, advancing the position that comparability issues are part of validity as they relate to the appropriateness of score interpretation and uses of test outcomes. Historically, validity and fairness of score inferences and test use require the assumption of comparability.

Comparability and Validity

The validity of large-scale assessment score interpretations and uses is influenced by the comparability of score meaning for individuals as well as for aggregated groups, such as schools, states, cultural groups, English learners, and test takers with disabilities (Berman et al., 2020; DePascale & Gong, 2020; Keng & Marion, 2020). Comparability means that test takers who have the same test score have the same level of competence with respect to the construct a test is intended to measure (AERA et al., 2014). Investigations of score comparability have traditionally focused on statistical methods

to evaluate measurement invariance, such as multigroup factor analyses and differential item functioning (DIF).

Score comparability requires the critical assumption that the construct, as defined, is appropriate for all groups in the targeted population. If this assumption is untenable, the validity and fairness of score interpretations and uses will be compromised. As we will discuss later in this chapter, to attain a more responsive assessment of contextually bounded ways of knowing and doing, comparability investigations must begin with an appraisal of the appropriateness of the conceptualization and definition of the construct for all groups in the targeted population. Teachers, and others in classroom settings, may have to contextualize tasks to accommodate different backgrounds, cultures, and dominant languages to ensure valid interpretations and uses of assessment data. Since comparability, like validity and reliability, is evaluated in the context of use, comparability requirements for classroom assessments are not as stringent as those for educational large-scale monitoring or accountability tests, as well as other large-scale tests such as licensure and certification tests. In fact, classroom assessments (and, many would argue, other educational assessments) may better serve learning if they are tailored to individuals' social and cultural histories.

Fairness as Integral to Validity

The 2014 *Standards* (AERA et al., 2014) elevated fairness to one of the three foundational chapters, along with validity and reliability, for evaluating the quality and uses of tests and test score interpretations. The *Standards* posited that fairness is a “fundamental validity issue and requires attention throughout all stages of test development and use” (AERA et al., 2014, p. 49). As with generalizability and reliability, we argue that fairness forms the core of validity arguments, although we support the need to assert fairness's own identity so that equity and social justice issues in testing are brought to the forefront. Therefore, we will use both terms—validity and fairness—throughout this chapter.

Fairness issues are fundamental to the validity of test score interpretations and test use, and they surface throughout the testing process. Theory and logical and empirical analyses provide evidence to support or refute the validity and fairness of score meaning and test use for individuals with different social, cultural, and personal histories. Messick (1980) discussed the complexities in conceptualizing and labeling a construct based on theory and evidence: “[The] choice of construct labels is influenced by theory as well as by evidence and . . . by ideologies about the nature of humanity and society which add value implications that go beyond evidential validity” (p. 1019). Others have argued that it is not necessarily the targeted construct that is being assessed, but the individual's cognitive construction of knowledge and ways of knowing that arise from one's social and cultural experiences (Hood, 1998; Mislevy, 2018; Nortvedt et al., 2020).

Fairness evaluations typically address the validity of score inferences and test use for relevant groups in the targeted population; and because score inference and test use

are fundamental to validity, fairness, too, is fundamental to validity. As expressed by L. Shepard (personal communication, May 22, 2021), “first we (historically as a field) had validity, which was implicitly validity for the dominant group. Then, in response to the civil rights era, the field addressed validity for non-dominant groups and called that new thing ‘fairness.’” The groups identified for fairness evaluations arose from equity and social justice concerns. Whether based on gender identity, culture, ethnicity, language status, or disability, group definitions must attend to the heterogeneity of the individuals within each group. For example, English learners comprise many subpopulations, with various dominant languages as well as variants within dominant languages.

From a broader perspective, Rawls (2001) saw justice as fairness “to provide an acceptable philosophical and moral basis for democratic institutions and thus to address the question of how the claims of liberty and equality are to be understood” (p. 5). He advocated that every individual is entitled to the same basic liberties and equality of opportunities, and additional resources should be provided to those who do not have equal opportunities. Fairness in testing requires all test takers to have equitable opportunity to access, and demonstrate knowledge of, the construct measured so that score meaning and test use for individuals are comparable regardless of group affiliation. Messick (1998) argued that “evidence of fairness indicates that score meaning does not differ consequentially across individuals, groups, or settings; the major concern is comparability” (p. 1). We contend that evidence of fairness also indicates comparability and equity in terms of test uses and their consequences. Cronbach (1976) promoted the importance of values in the evaluation of test use, but he also acknowledged the importance of values in shaping validity evaluations. Messick (1998) expanded on this perspective, advocating that values, beliefs, and perceptions bear on fairness evaluations of testing programs: “Fairness judgments and validity judgments *are* value judgments” (Messick, 1998, p. 26).

Camilli (2006) provided a broad perspective of fairness, advocating that an evaluation of fairness may involve “legal, ethical, philosophical, and economic reasoning” (p. 225). He argued that concerns about fairness arise from the intended and unintended consequences, primarily adverse consequences of test use, and thereby noted that “investigations of fairness are framed by test use” (Camilli, 2006, p. 251). This view agrees with Messick’s (1998) assertion that fairness is an “overarching issue in the validity of test use” (p. 12). Camilli (2006) argued that issues of fairness are “inevitably shaped by the particular social context in which they are embedded” (p. 223).

Kane (2010) embraced these notions of fairness in his discussion of the relationship between fairness and validity. Fairness and validity, he maintained, are “closely related ways of examining the same question: Are the proposed interpretations and uses of the test scores appropriate for a population over some range of contexts?” (p. 177). He posited that this question is addressed from slightly different perspectives and entails different emphases. A fairness evaluation entails examining, across diverse groups, whether score interpretations are equally plausible, decision rules are equally appropriate, and consequences are comparable (Kane, 2010). Fairness is central to the evaluation of consequences, in particular, when they lead to differential outcomes across

groups. We support this perspective on fairness. And since consequential evidence is critical to validation, as we explain later in this chapter, we contend that fairness is at the core of validity arguments.

Fairness evaluations require “responsiveness to individual characteristics and testing contexts so that test scores will yield valid interpretations for intended uses” (AERA et al., 2014, p. 50).¹ A fair test

reflects the same construct(s) for all test takers, and scores from it have the same meaning for all the individuals in the intended population; a fair test does not advantage or disadvantage some individuals because of characteristics irrelevant to the intended construct. (p. 50)

The *Standards* promotes sound perspectives on fairness and acknowledges fairness as fundamental to validity, but it falls short of explicitly addressing how fairness contributes to the validity of score decisions, test use, and the resulting consequences.

To summarize, we conceptualize fairness as a component of the validity of score interpretations and uses and the resulting consequences of test use. Fairness issues arise throughout the testing process, from the conceptualization of the construct to the consequences of test-based decisions. Fairness evaluations are critical for testing programs claiming to have indirect benefit beyond test score interpretations and score uses, such as tests used as levers to improve educational opportunities for students, especially students who have been historically underserved. Consequences can have differential effects, so this entails evaluating potential differential effects on relevant groups in the targeted population. Such differential effects may signal the systemic inequities of educational opportunities for certain groups of students. Validity rests on the fairness of consequences across relevant groups. Ethical and social justice considerations in the use of tests, and in evaluating their consequences, are integral to the validity argument.

Reliability/Generalizability as Integral to Validity

Reliability typically refers to the consistency, or invariance, of scores across replications of a testing procedure; it is essential to the validity argument. Consistency of scores may vary across samples of tasks, occasions, raters, contexts, and other relevant facets, and measurement error results from this inconsistency. Generalizability theory provides a useful framework for evaluating the generalizability of score inferences to the broader domain, and it allows for the estimation of error across relevant facets (Cronbach et al., 1972). Of interest is the generalization from a person’s test score to the person’s expected score over the hypothetical universe of tasks, raters, occasions, and other defined facets in the universe. Under classical reliability theory, scores are simply partitioned into true and error components. With generalizability theory, in contrast, analysis of variance techniques are marshaled to estimate separately the variability in a set of scores attributable to multiple sources of error, such as tasks, contexts, and occasions (Brennan, 1992; Cronbach et al., 1972).

The IUA typically makes claims about generalizing from the test score to the universe score (the score obtained over different samples of items, raters, occasions, and

other defined facets), and the validity argument calls for evidence to support the generalization inference. Generalizability of score inferences therefore is a necessary component of the IUA and the validity argument. In discussing reliability/precision of scores, the *Standards* state that the “level of reliability has implications for validity” and that reliability “of data ultimately bears on the generalizability or dependability of the scores and/or the consistency of classifications of individuals derived from the scores” (AERA et al., 2014, p. 34).

Cronbach et al. (1972) advocated a unified approach to validity and reliability, acknowledging the blurring of the distinction between them. In their text on the generalizability and dependability of measurements, they argued that the “theory of ‘reliability’ and the theory of ‘validity’ coalesce” (Cronbach et al., 1972, p. 234). As Kane (1982) suggested, “reliability is a necessary condition for validity because generalization is a key inference in interpretive arguments, but it is not a sufficient condition because generalization is not the only inference in the argument” (p. 529). Messick (1989) elevated construct validity to a superordinate role for evaluating score meaning and properties, including reliability. He indicated that an appropriate level of reliability depends on construct meaning; therefore, evidence of reliability consistent with the meaning of the construct is also evidence of construct validity (Messick, 1998). Following Cronbach and others, we contend that reliability and generalizability rightfully belong in, and are subsumed by, the validity argument.

EVOLUTION OF VALIDITY

This section traces the evolution of validity theory, emphasizing the seminal work of Cronbach and Meehl (1955) on construct validation and how it has shaped validity theory over the years. We also discuss the evolution of validity in the past editions of *Educational Measurement* as well as the *Standards*.

Validity for Test Use and Score Inferences

It has been long established that validity is a property not of the test, but of the test score inferences and test uses, with the acknowledgment that there could be multiple uses for a particular test. In 1946, Rulon asserted that it is unsatisfactory to view validity as the extent to which a test measures what it is purported to measure; rather, validity is concerned with “whether the test does the work it is employed to do” (p. 290) and it “depends on the propriety of the use made of the test” (p. 290). Rulon acknowledged that the type of validity evidence required depends on the particular use of a test: “We should not ask always for the same kind of proof of validity” (p. 291). In the first edition of *Educational Measurement*, Cureton (1951) reinforced the idea that validity refers to the purpose(s) of the test: “The essential question of test validity is how well a test does the job it was employed to do” (p. 621). The stance that validity is not an all-or-none proposition was explicitly stated by Cureton (1951): “The same test may be used for several purposes, and its validity may be high for one, moderate for another, and low for a third” (p. 621).

In their seminal article, Cronbach and Meehl (1955) advocated that validity refers to test score inferences and not the test itself: “One does not validate a test, but only a principle for making inferences” (p. 297). Referring to the *Technical Recommendations for Psychological Tests and Diagnostic Techniques* (American Psychological Association [APA], 1954), the first precursor to the *Standards*, Cronbach and Meehl (1955) indicated that validity is not an all-or-none proposition but, rather, that there are degrees of validity of score inferences: “If a test yields many different types of inferences, some of them can be valid and others invalid” (p. 284). They argued that the objective of validity inquiry is “to specify how one is to defend a proposed interpretation of a test” (p. 284). In the second edition of *Educational Measurement*, Cronbach (1971) maintained that a test is not validated, “but an *interpretation of data arising from a specified procedure . . . evidence that justifies one application [of test use] may have little relevance to the next*” (p. 447). He also saw validity falling on a continuum, in that “every interpretation has its own degree of validity; one can never reach the simple conclusion that a particular test ‘is valid’” (p. 447).

Criterion, Content, and Factorial Validity

The history of validity theory can be traced from the criterion model, to the content model, to, eventually, the construct model, with arguments for the sufficiency of one type of validity model for a particular test purpose to arguments for the need for multiple forms of validity evidence. In the early 1900s, validity was widely regarded as the correlation between test scores and a criterion measure—“validity coefficients”—which was considered sufficient validity evidence. Sireci (1998) cited Kelley (1927) and Thurstone (1932) as supporting correlational evidence as validity, but he also discussed their concerns, such as the relevance of the criterion to test use, the restrictiveness of an empirical approach, and the need to supplement validity coefficients with professional judgment.

Guilford (1946, p. 429) proposed two kinds of validity, where factorial validity involves an investigation of the internal structure of the test and practical validity calls for the correlation between a test score and a practical criterion. In discussing the limitations of professional judgment in test development and validation, Guilford argued that factor analysis can shed light on what is being measured. “In test construction and in job analysis,” he said, “things are not always what they seem” (p. 437). Thurstone (1952) extended his earlier thinking and, given the coarseness of criterion validity coefficients, argued for investigations of internal consistency when measuring cognitive functioning. Considering the psychological tests developed in the late 1880s and early 1900s, Gulliksen (1950) raised concerns about the assumption that a criterion has “intrinsic value.” He maintained that the appraisal of tests based on the relationship of test results with the expert judgment of a teacher or supervisor is fallible. He was concerned that this fallible judgment serves as a criterion, which is assumed to have “intrinsic value,” and that the test should approximate this criterion. Rather, empirical relationships between test scores and criterion measures should make theoretical sense in terms of what the test is intended to measure and what the criterion is presumed to encompass; Gulliksen warned, “[It is] dangerous to depend entirely on correlational validity to evaluate a test” (p. 514).

Regarding achievement testing, Rulon (1946) recommended that the appropriateness of the test be evaluated. He argued that the relationship between test scores and a criterion measure is not sufficient and that evidence to support validity depends on the purpose of the test. Rulon therefore proposed different types of evidence for different uses of achievement tests. As he discussed, when using a shorter version of an achievement test, the correlation between scores on an achievement test and a sampling of the items from the original test provides evidence for the shorter test as a replacement for the original test. For addressing whether the achievement test is appropriate for measuring student achievement, he proposed an evaluation of the content of the test, including the processes engaged in by the student. The question that needs to be addressed for this purpose of the achievement test is, “Are the materials of this test, and the processes called for on these materials, the same things and processes we are trying to teach the children?” (Rulon, 1946, p. 4). Support for this inquiry provides “the final proof of validity” (Rulon, 1946, p. 4). In his examples, Rulon proposed only one form of evidence to support a particular use of an achievement test.

Gulliksen (1950) argued for more than one form of evidence to support a particular test use, advocating, for example, that an evaluation of test content alone is not sufficient validity evidence. He suggested the use of factor analysis to better understand what is assessed, even if the results are inconsistent with expert judgment (because of the limitations of expert judgment). Loevinger (1957) supported the claim that considerations of test content alone are insufficient to establish validity. However, a decade later, Ebel (1961) dismissed the need for multiple forms of evidence for an achievement test, indicating that content validity is sufficient.

In the validity chapter in the first edition of *Educational Measurement*, Cureton (1951) initially defined validity as the “correlation between the actual test scores and the ‘true’ criterion scores” (p. 623), where the true criterion scores are a result of correcting the observed correlation for attenuation due to unreliability. He proposed two aspects of validity—relevance and reliability—where relevance is the “closeness of agreement between what the test measures and the function that is used to measure” (p. 622) and reliability refers to the consistency of scores. Later in his chapter, Cureton broadened his definition of validity by including logical relevance for a job knowledge test (i.e., job analysis), factorial relevance, and curricular relevance (or content validity) for an achievement test.

Emergence of Construct Validity

The *Technical Recommendations for Psychological Tests and Diagnostic Techniques* (APA, 1954) proposed four types of validity: content, predictive, concurrent, and construct. Each type of validity required different types of evidence for different types of interpretations. The *Technical Recommendations* first proposed that construct validity be used only when “the test has no definitive criterion measure of the quality with which he is concerned and must use indirect measures to validate the theory” (APA, 1954, p. 54). However, the *Technical Recommendations* acknowledged that there may be more than

one purpose of a particular test and that the test's purpose sheds light on the type of validation needed. A year later, the *Technical Recommendations for Achievement Tests* (AERA & National Council on Measurements Used in Education, 1955) maintained that content validity is established by demonstrating that a test's items are a sample of the intended universe of items and advocated that establishing content validity was not sufficient for achievement testing. Rather, construct validity should play a prominent role in evaluating achievement tests. Predictive validity and concurrent validity are "criterion-oriented validation procedures" (Cronbach & Meehl, 1955, p. 282), where the criterion is obtained after the test is given for the former and, for the latter, the criterion score is obtained at the same time as the test score.

As indicated by Cronbach, chair of the initial APA Committee on Psychological Tests, and Meehl, a member of the committee, in their seminal article on construct validity, the "chief innovation" (Cronbach & Meehl, 1955, p. 281) of the 1954 *Technical Recommendations* was the inclusion of construct validity. The 1954 *Technical Recommendations* proposed that construct validity requires both logical and empirical investigation for validating the theory underlying the test by accumulating data to confirm predictions about the "variation of scores from person to person or occasion to occasion" (APA, 1954, p. 14).

Cronbach and Meehl (1955) extended the treatment of construct validity set forth in the 1954 *Technical Recommendations*.² Cronbach and Meehl defined a construct as a postulated attribute of individuals, and the goal of validation is to verify what constructs account for variance in test performance. They proposed construct validity for situations where content and criterion-related validity were inapplicable or insufficient for defining what the test is intended to measure. While establishing the importance of construct validity for personality tests, they also called for investigations of which constructs account for test performance on other tests (e.g., measures of aptitude, achievement, and interests) in addition to other forms of validity evidence, because different types of validity evidence may provide meaning for scores for a particular test.

Construct validity, along with criterion-related (predictive and concurrent) and content validity, was adopted by the 1966 *Standards for Educational and Psychological Tests and Manuals* (AERA et al., 1966). The 1966 *Standards* replaced the 1954 and 1955 *Technical Recommendations*.

Construct Validation as Scientific Reasoning

Construct validation, as scientific reasoning, begins with an investigator's claim that the test measures a construct that has certain meanings, leading to identifying and testing hypotheses to confirm or disconfirm the claim (Cronbach & Meehl, 1955, p. 290). This position is consistent with the view of Campbell (1957) that researchers are obliged to consider rival hypotheses, rather than taking a confirmationist perspective, when examining the validity of causal inferences from the results of experiments. The validation of

the claim that the test measures a construct requires a nomological network, “a system of laws [propositions] which constitute a theory” (p. 290), that represents the construct meaning. “[The] laws may relate (a) observable properties or quantities to each other; or (b) theoretical constructs to observables; or (c) different theoretical concepts to one another” (Cronbach & Meehl, 1955, p. 290). To provide construct meaning, the propositions relate the test to the construct, the construct to other constructs, and the construct to observable variables. As summarized by Cronbach and Meehl (1955), a “construct is defined implicitly by a network of associations or propositions in which it occurs” (pp. 299–300), requiring a strong chain of inference to demonstrate that a test, in fact, measures the construct. One uses inductive argumentation to verify the network by demonstrating that the construct measured is consistent with the evidence (Cronbach, 1971), and alternative interpretations are considered and evaluated (Cronbach & Meehl, 1955). Cronbach and others underscored the need to include criterion measures in the construct validation framework to ensure that the evaluation of the criterion measures are held to the same psychometric standards as other measures (Cronbach, 1971; Cronbach & Meehl, 1955; Messick, 1965). Although they were suggested by Cronbach and Meehl (1955), Campbell and Fiske (1959) formalized multitrait, multimethod approaches for simultaneously evaluating convergent and discriminant evidence in construct validation.

Cronbach and Meehl (1955) argued for the importance of documenting construct validation research, including delineating the proposed interpretation, how well the interpretation is substantiated, and the evidence and reasoning to support the claim, as well as including alternative interpretations that were considered and rejected. They emphasized the need to specify what parts of the proposed interpretations are “speculations, extrapolations or conclusions from insufficient data” (Cronbach & Meehl, 1955, p. 297). Both logical and empirical evidence have a role in construct validation. The 1954 *Technical Recommendations* outlined different types of construct validation studies, including examining factor structure, whether experimental manipulation induces changes aligned with theory, and whether test scores are related to similar and dissimilar measures. Cronbach and Meehl (1955) broadened the scope to include studies of change over occasion (stability measures) as well as studies of processes engaged by the test taker.

Loevinger (1957) proposed that construct validity has three components—substantive, structural, and external—which are mutually exclusive, exhaustive, and mandatory. The substantive component of validity encompasses content validity and refers to the “extent to which the content of the items included in (and excluded from) the test can be accounted for in terms of the trait believed to be measured and the context of measurement” (Loevinger, 1957, p. 661). The structural component refers to the “extent to which structural relations between test items parallel the structural relations of the manifestations of the trait being measured” (p. 661). The external component refers to the relationship between the test score and other variables (including relevant criteria) with assumed relationships (including no relationship) with the test

score. The content of the items should be consistent with the proposed interpretation, the structural relations of the items should be consistent with the structural relations of other measures of the same trait, and the external correlations of the test score should be consistent with predictions based on knowledge of the proposed trait (Loevinger, 1957).

The validity chapter by Cronbach (1971) in the second edition of *Educational Measurement* elaborated on Cronbach and Meehl (1955) regarding validation as scientific inquiry into score meaning. The 1971 chapter reinforced the proposition that validation is an inductive argument used in the verification of the proposed network, which “is a representation of present knowledge, not the only possible representation” (Cronbach, 1971, p. 483)—hence, the need for proposing and testing counterhypotheses. Construct validation begins with a statement of the proposed interpretation, which will suggest the evidence needed to support the interpretation. It is a process of “reasoning from data to conclusions” (Cronbach, 1971, p. 484). Messick (1975) advocated for this conceptualization of construct validation, which “links a particular measure to a more general theoretical construct, usually an attribute or process or trait, that itself may be embedded in a more comprehensive theoretical network” (p. 955). Both the 1966 *Standards* and the 1974 edition (AERA et al., 1974) discussed validity in terms of criterion-related, content, and construct validity. The 1974 *Standards* proposed that validity questions are of two types: those dealing with the intrinsic nature of the meaning of the measure and those dealing with the test score as an indicator of other variables. Messick (1980) endorsed this perspective: “Evidence bearing on the meaning of the measure embraces all of construct validity, whereas evidence for certain predictive relationships contributes to that part called nomological validity” (p. 1016). Similarly, Embretson (1983) distinguished between nomothetic span and construct representation, where the former is an empirical network of relationships of the test with measures of other constructs and criterion measures, while construct representation involves the identification of theoretical components that underlie task performance, including processes, strategies, and knowledge. Partitioning the task into these features allows for the building of these components into a process model that provides meaning to the construct (Embretson, 1983).

Cronbach (1989) later reflected on his and others’ confirmationist perspective on construct validity, with its focus on accumulating evidence in support of the interpretation rather than evidence in support of plausible rival hypotheses. He encouraged the use of both empirical and logical methods to test plausible rival hypotheses as part of validation. Messick (1980) also promoted the perspective that both confirmatory and disconfirming strategies should shape construct validation studies. He advocated that “corroborative evidence provisionally supports both the construct theory and the test interpretation, while disconfirming evidence undercuts either the theory or the measure, or both” (Messick, 1980, p. 48). Cronbach (1989) further advocated that validation is a “community process”; external critics with differing perspectives need to play a role in the validation process. We agree, and we later argue that multiple stakeholder groups

should have a voice in shaping both the IUA and the validity argument, in part, to address equity and social justice issues.

Construct Validity as a Unitary Concept With Types of Evidence

Construct validity as a unitary concept surfaced in the work of Loevinger (1957), who urged the measurement community to view “psychometrics with construct validity as its central concept” (p. 689). She argued that construct validity is the “whole of validity from a scientific point of view” (p. 636), but acknowledged other forms of evidence, such as predictive validity coefficients, for more practical applications. Cronbach and Meehl (1955) also spoke to a unified validity, noting that many forms of evidence are relevant to construct validity, including “content validity, inter-item correlations, inter-test correlations, test-criterion correlations, studies of stability over time, and stability under experimental intervention” (p. 300). In a similar vein, the 1954 *Technical Recommendations* stipulated that content validity and criterion-related validity provide evidence in support of construct validity.

Messick (1980) solidified the unitary view, advocating that validity is “an overall degree of justification for test interpretation and use” (p. 1014). He further argued that “different kinds of inferences from test scores require different kinds of evidence, not different kinds of validity” (Messick, 1980, p. 1014), thereby moving the discussion from types of validity to types of validity evidence. The *Standards* endorsed this unified view with the 1985 edition, referring to validity as the “appropriateness, meaningfulness, and usefulness of the specific inferences made from test scores” (AERA et al., 1985, p. 9), where “there is often no sharp distinction between test content and test construct” (p. 11). There are not different types of validity; rather, there are different types of validity evidence: construct related, content related, and criterion related (AERA et al., 1985).

Messick (1989) argued for the need to integrate and synthesize different forms of validity evidence because they “are interrelated operationally and logically” (p. 26). Both the 1999 and the 2014 *Standards* endorsed the integration of different forms of evidence: “A sound validity argument integrates various strands of evidence into a coherent account of the degree to which existing evidence and theory support the intended interpretations of test scores for specific uses” (AERA et al., 1999, p. 17; 2014, p. 21).

Messick’s Unified Validity

In the third edition of *Educational Measurement*, Messick (1989) characterized validity as “an integrated evaluative judgment of the degree to which empirical evidence and theoretical rationales support the *adequacy* and *appropriateness* of *inferences* and *actions* based on test scores or other modes of assessment” (p. 13). Messick (1980, 1989) employed a progressive matrix as a heuristic to represent two sources of justification of testing crossed with two outcomes, or functions, of testing (Table 4.1). The two sources of justification of testing are the evidential basis of score meaning and the consequential

Table 4.1 Messick's Facets of Validity

Basis	Test Interpretation	Test Use
Evidential basis	Construct validity	Construct validity + score relevance + score utility
Consequential basis	Construct validity + value implications	Construct validity + score relevance + score utility + value implications + social consequences

Note. Adapted from "Validity," by S. Messick, 1989, in R. L. Linn (Ed.), *Educational Measurement* (3rd ed., p. 20), American Council on Education and Macmillan.

basis of score valuation. The two functions of testing are test interpretation and test use leading to validation processes, which include meaning and values as well as test interpretation and test use. Expanding on the view that construct validity is a unified validity, Messick (1989) argued that construct validity binds the validity of test interpretation to the validity of test use.

Messick extended Cronbach and Meehl's perspective on validity as a unitary concept. He proposed his unitary conceptualization of validity because he was concerned with what he considered weak validation practice driven by the tripartite approach to validity and validation. For example, he was concerned that evaluators were claiming that strong content-related evidence for achievement tests was sufficient for establishing the validity of score inferences, without considering the threats to validity arising from other sources, such as poorly written items, the ways in which test takers interact with the items, test-taker motivation, and distractions during testing.

Messick's conceptualization of construct validity is the core of the interpretation and use functions, underscoring score meaning and values in both test interpretation and test use. Construct validity is represented in each cell of Table 4.1, along with aspects that depend on the particular justification and use of testing. The evidential basis of test score interpretation is construct validity, providing evidence to support score meaning. The evidential basis of test use includes construct validity along with the relevance of scores for the given test purpose and the utility of the scores in the testing application. The consequential basis of test interpretation is the appraisal of value implications of score meaning, including value assumptions associated with the construct label, the theory underlying the construct and score meaning, and the ideologies that provide the theoretical perspective. The consequential basis of test use accumulates all aspects of the progressive matrix and is the appraisal of potential and actual social consequences of testing (Messick, 1989). Intended and unintended consequences of testing represent intended and unintended action implications of score meaning. Adverse consequences bear on the meaning of test scores and, therefore, on the meaning of the construct. Messick (1989) advocated that information about the utility of scores for a given testing purpose is both validity evidence and a value consequence.

Kane (2012) expressed concern with Messick's unitary approach to validity because it does not lend itself to a pragmatic approach for validity investigations. The unified

view is “conceptually rich and suggestive, but it is not easy to implement effectively, because it does not provide a place to start, guidance on how to proceed, or criteria for gauging progress and deciding when to stop” (Kane, 2012, p. 8). His development of the IUA and validity argument provides a more pragmatic approach to validation. Shepard (1993) agreed with Messick’s conceptualization of validity but disagreed with the segmented presentation of the facets, arguing that the “matrix was a mistake because it led to false dichotomies between aspects of validity that are inherently entwined” (p. 269). As an example, she argued that the matrix could lead to potential misinterpretations, such as thinking that values are only relevant for the consequential basis. In fact, values are inherent in the evidential basis of test interpretation, where constructs are conceptualized and labeled. What was intended as a helpful heuristic has led to considerable controversy in educational measurement. For example, Cizek (2012, 2020) argued for separating the interpretation and use columns, while Newton and Shaw (2016b) argued for separating questions of social value from those of technical quality. We agree with Shepard (2016, p. 275) that “Messick’s two columns were intended to deepen our thinking about each aspect, but these aspects or facets cannot be addressed independently.”

Values and Ethics in Testing

The measurement of psychological and educational constructs is value laden (Cronbach, 1976; Messick, 1975). Deciding whether “a test should be used for a particular purpose raises the issue of values in measurement” (Messick, 1975, p. 962) because test use is an “ethical issue” (Messick, 1980, p. 1020). In his early writings on personality tests, for example, Messick (1965) argued that whether to use a test for a particular purpose may require justification that draws on social values. Ethical issues arise in the use of personality measures for selection, and the choice of a measure involves an inherent value judgment; it involves decisions regarding what personality characteristics are desirable, which may result in reduced diversity. The field has become more aware of, and sensitive to, this issue, with the recognition that many personality traits such as assertiveness as well as other constructs are culturally shaped.

Messick (1989) later argued that validity and values are one. Validity is an “ethical imperative of testing” (Messick, 1980, p. 1020), involving judgments about accumulated evidence. Validity entails an evaluation of the value implications of test interpretation and use, and these value implications derive primarily from the test’s construct meaning; however, they also derive in part from ideologies of social science, education, and social justice, and therefore they go beyond construct meaning. Test use rests on assumptions about possible test consequences—both intended and unintended—of score-based decisions and on the values associated with these different consequences (Messick, 1975, 1980, 1989). Messick (1994) contended that validity, reliability, comparability, and fairness involve evaluative judgments that reflect social values.

Decisions made in test design, development, and use rest on value judgments (Kane, 2006; Messick, 1989). There are competing, and potentially conflicting, values that

bear on validity, fairness, and social justice issues. Value judgments are involved in the articulation of the test's intended purposes and uses, the conceptualization of the construct to be assessed, the design and development of items and scoring rules, the development of performance standards for determining competency, and the design of score reports and accompanying interpretive guides (Kane, 2006). Importantly, values play a significant role in translating the targeted construct (or knowledge skills, and other attributes) into test specifications because of the prioritization inherent in this test design exercise. Value judgments are inherent in the articulation of the intended positive consequences and in the search for unintended negative consequences. Consider the case of using tests in decisions regarding high school graduation. This use was intended to raise standards and improve learning, but it had a differential effect on schools and groups of students—in particular, underserved students. Judgments regarding whether the benefit of using tests in graduation decisions to raise standards outweigh their undesirable effect on different groups of students vary depending on the beliefs, values, and assumptions held by different stakeholders (Lane, 2020). Zwick (2018) warned that using college and career on-track labels, such as a “not ready” designation, may result in lower educational expectations and, consequently, lower student outcomes, especially for underrepresented groups in higher education.

Threats to Validity

As described by Messick (1989), construct underrepresentation and construct-irrelevant variance are two potential threats to the validity of score interpretations and uses. Construct underrepresentation occurs when the assessment is too narrow and fails to capture important facets of the targeted construct. Construct-irrelevant variance occurs when the assessment scores reflect factors that are irrelevant to the targeted construct or when other extraneous factors (e.g., language barriers, test speededness) influence test scores. Construct-irrelevant variance negatively affects the scoring inference, which in turn threatens the validity of decisions and uses. Construct underrepresentation likely undermines generalizability claims and extrapolations from test performance to the real-world criterion, which also threatens the validity of decisions and uses. These two threats to validity play a central role in the evaluations of the validity of score meaning and use for all testing programs. We discuss these and other threats to validity and fairness throughout this chapter.

ARGUMENT-BASED APPROACH TO VALIDITY AND VALIDITY EVIDENCE: FROM THEORY TO IMPLEMENTATION

Previous chapters in *Educational Measurement* discussed the current conceptualization of validity and validation. A key shift between Messick (1989) and Kane (2006) was in Kane solidifying an argument-based approach to validation. While Messick's (1989) seminal chapter crystalized the unified view of validity, the theoretical and philosophical

orientation in his chapter left many wondering how to go about evaluating the validity of test score inferences and uses. Kane's (1992, 2006, 2013) argument-based approach to validation was a practical way to carry out validity evaluations. The terms *interpretation and use argument* and *validity argument* have been pervasive in the literature since 2006, and these concepts are well represented in current validity evaluations. This section reviews how validity arguments have been conceived, how this conceptualization has evolved (e.g., Kane, 2013), and how it has been applied. We discuss how the increasing use of principled approaches to test design and development intersects with argument-based approaches to validity. We conclude this section with an exploration of the use of theories of action in test validation and how such theories of action can bridge test validation and program evaluation.

Validation and Argumentation

The beginnings of an argument-based approach can be seen as far back as Cronbach and Meehl (1955): "We seek to specify how one is to defend a proposed interpretation of a test: *we are not recommending any one type of interpretation*" (p. 284). But Cronbach (1971) generally was seen as advocating a scientific inquiry approach to validation rather than having the evaluative focus proposed by Kane and others. Haertel (2018) characterized Cronbach (1971) as considering validation a scientific inquiry activity, but noted that Cronbach invited value judgments by, for example, asking developers to consider whether the names they gave their test allowed for overly broad score interpretations.

Following publication of Messick's (1989) validity chapter, researchers and practitioners began wrestling with how to conduct validity evaluations in practice that were faithful to his unified conception of construct validity. Shepard (1993), reaching back to Cronbach (1971, 1988), advocated a straightforward means to prioritize validity questions. Using an evaluation framework, she proposed that validity studies be organized in response to the questions, "What does the testing practice claim to do? What are the arguments for and against the intended aims of the test? and What does the test do in the system other than what it claims, for good or bad?" (Shepard, 1993, p. 429). These questions are directed at concerns about the construct relevance, interpretation, and social consequences, respectively. This framing is consistent with Kane's approach.

Kane's Framework

Kane (2006) proposed using two types of arguments:

An interpretive *argument* specifies the proposed interpretations and uses of test results by laying out the network of inferences and assumptions leading from the observed performances to the conclusions and decisions based on the performances, [whereas] the *validity argument* provides an evaluation of the interpretive argument. (p. 17)

Kane (2013, 2016) later renamed his interpretive argument the interpretation and use argument, signifying the inseparability of score interpretations and test uses. Kane (2016)

summarized this updated view of validation succinctly: “I think of validity as the extent to which the proposed interpretations and uses of test scores are justified” (p. 198).

The IUA outlines what the user/evaluator believes should occur—and why—as a result of the testing and related systemic data collection, whereas the validity argument involves weighing the available evidence and logic to decide whether the specific interpretations and uses are justified. Explicitly specifying the proposed interpretations and uses of the assessment, developing a measurement procedure consistent with these proposed uses, and then critically evaluating the plausibility of the initial assumptions and resulting inferences is more straightforward than evaluating the validity of an assessment under a construct model. Kane was not abandoning Messick’s unified view of construct validity; rather, he was providing a more pragmatic approach for evaluating the validity of score inferences and uses than under a strict construct model. The construct model is based on a research approach in which one searches for causal connections (e.g., Markus & Borsboom, 2013), whereas Kane’s argument-based approach works from an evaluation perspective to determine whether an assessment program is operating as planned, with minimal unintended negative consequences.

Kane (2006, 2013) pushed for the development of the IUA in the assessment design phase. Specifying purposes and uses up front and then designing an assessment to fit these intentions is embedded in principled approaches to test design (e.g., Mislevy & Haertel, 2006; Mislevy et al., 2003; see also Huff et al., this volume). Such design approaches require a detailed specification of the assessment argument early in the design process. This works well for new tests, but there has not been sufficient attention to validity in the design of many of the current state and certification assessments; consequently, evaluators likely have to retrofit a validity argument to the existing testing system. This is not an excuse to avoid validity evaluations, but a recognition that it is more challenging to do so after the fact.

The IUA

The IUA is essentially a mini-theory that provides a framework for making sense of score inferences and test use. Like a theory, the IUA guides data collection and methods for conducting validity analyses. And IUAs, like theories, also are falsifiable. Thus, validation is not a confirmationist exercise. It is helpful to think of the IUA as a series of if–then statements, such as, “If the student scores at the proficient level on the state achievement test, then the student has a solid understanding of the required grade-level content and skills.” Of course, there are many more if–then statements for any given test and test scores across and within the different inferences.

Kane (2006, 2013) noted two stages of the IUA. The development stage focuses on the development of measurement tools and procedures, as well as the corresponding IUA. Kane suggested that it is appropriate to have a confirmationist bias in this stage—a stance favoring evidence and interpretations that support the current state of the assessment program—because the developers are trying to make the program work as well as possible. Kane also argues that, in the development stage, likely challenges to the IUA

can be identified and addressed. The appraisal stage, in contrast, focuses on the critical evaluation of the IUA, where the most questionable assumptions and the intended and unintended consequences are deliberatively evaluated.

One of the most effective challenges to IUAs is to propose and substantiate alternative claims (or plausible rival hypotheses) that are equally or more plausible than the proposed proposition. Using the earlier example, an alternative inference could be as simple as, “If the student scores at the proficient level on the state achievement test, it indicates the student benefited from their background knowledge and out-of-school enrichment experiences.”

From a pragmatic level, test validation is the process of offering assertions (propositions) about a test or a testing program and then collecting data and posing logical and empirical arguments to challenge those assertions. Using the assertion and alternative hypothesis in the previous example, the evaluator should design studies that evaluate the degree to which test scores are sensitive to differences in the quality of instruction compared with students’ background knowledge and alternative hypotheses. In essence, validity evaluators are continually trying to challenge the claims being made.

Enacted Interpretations and Uses

The IUA focusses largely on *proposed* interpretations and uses (Kane, 2013). O’Leary et al. (2017) argued that *enacted* test score interpretations and uses must be part of the validity evaluation. Haertel (2018) suggested that following these IUAs to their logical conclusions must lead to enacted interpretations rather than intended score interpretations only. Haertel (2018) pointed out that misinterpretations associated with standards-based reporting practices (e.g., *Proficient*) are a key example supporting the focus on enacted interpretations and uses in addition to intended ones. The documentation and validity evidence associated with defining achievement levels is often lacking (e.g., National Research Council [NRC], 2017), particularly in terms of the enacted interpretations and appropriate uses of the achievement levels.

Focusing on enacted interpretations and uses clearly establishes the centrality of evaluating potential unintended consequences in validation efforts. Kane (2016), in his more recent writings, shifted to using the term IUA to stress the importance of test use and resulting consequences, although his previous conceptualization of the interpretive argument did embody use. Kane (2016) discussed the difference between Messick’s more limited and Cronbach’s more expansive view of the role consequences in validation, leading up to his discussion of the interpretation and use model:

The interpretation-and-use model adds an element to the consequences-as-indicators model. It adds Cronbach’s notion that negative consequences count against the validity of test use, even if they are not attributable to any flaw in the test or testing procedures, to Messick’s notion that negative consequences that are attributable to a flaw in the test or testing procedures count against the validity of the test score interpretation. (pp. 207–208)

Kane (2016) argued further that “the responsibility for evaluating specific claims would fall on those who make the claims, explicitly or implicitly. . . . To make consequential decisions without bothering to consider the consequences of these decisions would seem to be irresponsible” (p. 209).

Sources of Validity Evidence and the IUA

To frame validation efforts, Messick (1989) proposed six aspects of validity:

- content: evidence of content relevance, representativeness, and technical quality
- substantive: theoretical rationales for consistencies in test responses, including cognitive process models of task performance
- structural: evaluations of the appropriateness of the scores relative to the structure of the targeted construct(s)
- external: convergent and discriminant evidence from comparisons, as well as evidence of test–criterion relationships
- generalizability: evidence of the extent to which score properties and inferences generalize both to and across population groups (i.e., fairness), settings, contexts, and tasks; evidence of test–criterion relationships
- consequential: the value implications of score interpretation as a basis for action, as well as the actual and potential consequences of test use, particularly regarding sources of test invalidity related to issues of fairness and social justice

The 1999 and 2014 *Standards* adopted a similar frame for discussing validity evidence by proposing five types of evidence: evidence based on test content, response processes, internal structure, relations to other variables, and consequences of testing.³ The forms of validity evidence proposed by either the *Standards* or Messick (1989) provide a structure for evaluating test score interpretations and test uses. Researchers (e.g., Sireci, 2013) have suggested using these sources of validity evidence as a framework for validation research; however, we agree with others that these sources are insufficient (Chapelle, 2011; Newton, 2016). As Chapelle (2011) warned, validation involves examining the inferences in the argument instead of merely consulting a list of types of validity evidence. Similarly, Newton (2016) argued that the “five sources framework provide an impoverished view of validation evidence, which thereby risks practitioners designing suboptimal validation research programs” (p. 9).

The IUA provides a comprehensive framework for validation by linking intended inferences and uses to evidence, as well as linking plausible alternative inferences and uses to evidence. Kane (2006) offered examples of inferences that could be applied to many testing programs:

- scoring inferences
- generalization inferences
- extrapolation inferences
- decision/use inferences

These inferences involve, respectively, evaluating the link between test performance and a test score; generalizing the test score to the expected score over the hypothetical universe of items, testing occasions, raters, and other relevant facets; extrapolating from the hypothetical universe to the broader domain of practice; and making appropriate decisions and uses.

While often interpreted as a conjunctive set of inferences that must be evident in all testing programs' IUAs, these instead were meant to illustrate potential inferences to investigate (Kane, 2006, 2016). The IUA must outline the inferences and intended uses specific to each testing program.

In addition to Kane's four inferences, we propose a performance inference that links the tasks to the test taker's performance. This requires evidence to support the claim that tasks elicit the intended knowledge, skills, and other attributes and that the assessment is representative of the construct. This explicitly positions the conceptualization of the construct and test design at the forefront of the IUA and validity argument. In the context of language assessment, Chapelle et al. (2007, 2010) expanded Kane's IUA by adding the domain description prior to the scoring inference, which is similar to the inclusion of construct representation by Shaw et al. (2012). The evaluation of the construct representation of tasks in terms of theoretical attributes (e.g., processes, strategies, and knowledge) underlying item performance proposed by Embretson (1983), as well as principled approaches to test design, provide backing in support of the performance inference. As the first link in the interpretive chain, the performance inference is made from the task to performance, with the warrant for this inference being that the tasks elicit performance that represents the intended construct and the assessment is representative of the construct.

To be sure, the *Standards* outline critical sources of evidence for evaluating the validity of test score interpretations, but they provide little guidance for organizing, implementing, and synthesizing validity evaluations. Therefore, an IUA should be used to frame validity evaluations while integrating the *Standards*' five sources of evidence, as well as other sources of evidence as appropriate. We now consider in more detail the performance inference along with Kane's four inferences, providing examples of the types of evidence that could be used to support the various claims.

Performance Inferences

The performance inference explicitly positions assessment design and development within the IUA and validity argument. There are many tools and processes for evaluating the performance inference that map nicely onto the categories of the *Standards*. For example, evaluations of test content—the degree to which the items and tasks are representative of the targeted construct and whether the targeted construct is appropriately represented by the items and tasks—is critical to the performance inference. Evidence related to response processes has received little attention as being critical to the score inferences until recently, but such evidence now is regarded as fundamental to evaluating the performance inference (Ercikan & Pellegrino, 2017; Leighton, 2017).

The following statements are examples of the types of evidence that support performance inferences while drawing on sources of evidence described in the *Standards*.

- The assessment tasks evoke the intended knowledge, skills, strategies, and processes.
- The assessment is representative of the intended construct and does not assess irrelevant constructs.
- Test takers' cultural, linguistic, and disability characteristics do not limit access to, and demonstrate knowledge of, the targeted construct.
- Cognitive models used in test design are appropriate for different groups in the targeted population.

Score Inferences

According to Kane (2016),

The validation of a score interpretation involves an investigation of whether the scores mean what they are supposed to mean, and the interpretation is said to be valid if the claims inherent in the interpretation are supported by appropriate evidence. (p. 199)

Scoring inferences form the basis of almost any validity evaluation because if the scores do not reflect the intended evaluations of test-taker performance, test score inferences are unwarranted.

Kane's articulation of the scoring inference receives little attention in the *Standards*. For example, validity evaluators likely would state the following scoring claims, but they do not relate directly to any source of evidence outlined in the *Standards*.

- The scoring rules are appropriate for defining differences in score levels for the constructed-response items.
- The scoring rules are consistently and accurately applied to all test takers (i.e., there is no bias in the scoring rules).
- There are adequate procedures for ensuring consistency and accuracy of scoring.
- The procedures used to link scores across various test administrations are employed appropriately to ensure comparable score meaning across administrations.
- There is a clear description regarding the quality of the selection, training, and monitoring of scorers.

Generalization Inferences

Generalizability theory is a sampling theory, where the assessment is viewed as a sample from a universe of generalization (Brennan, 1992; Cronbach et al., 1972). Generalizability theory addresses the accuracy with which we can generalize from a person's score on a particular set of test items to the person's universe score over the population of items, raters, occasions, and other specified facets (Brennan, 1992; Cronbach et al.,

1972). There are extensive tools and processes for evaluating error (measurement and sampling) and reliability, both of which are subsumed by generalizability theory. Mapping to the *Standards*, generalizability requires a careful specification of the universe of generalization, which can be part of the evidence related to test content. The following statements are examples of the types of evidence an evaluator would collect to support inferences related to generalizability.

- There is evidence related to the test's internal structure, that is, how items fit together or how test-taker performance generalizes across items and/or domains (e.g., factor analysis results).
- There is evidence that the internal structure is similar across identifiable groups (e.g., cultural, racial, language) to support generalization across groups.
- There is evidence that accommodations yield valid score inferences.
- There is evidence of an appropriate approach for evaluating various errors associated with test scores (e.g., interrater consistency, person-by-item interactions).
- There is evidence that various sources of error associated with items and tasks are minimized.
- There is evidence that test scores have the appropriate level of reliability/generalizability for the intended purposes and uses of the scores.

Extrapolation Inferences

Many validity evaluations either ignore or downplay extrapolation—making inferences from the hypothetical universe to the broader domain of practice—in part because it is challenging to provide convincing evidence of it (e.g., Haertel, 2018). Nevertheless, evidence based on the relationships between test scores and other variables can help evaluate inferences regarding whether test scores represent the larger domain beyond the universe of generalization—the real-life criterion. Such evidence includes concurrent and predictive validity evidence, because both establish the relationship between test scores and a criterion representing the domain of interest. For college entrance examinations, for example, the predictive relationship with the criterion—first-year grade point average (GPA), typically—is a critical aspect of the validity argument for using such tests. For certification tests, content experts' review of the knowledge, skills, and other attributes (KSAs) tested in relation to the KSAs used in practice provide evidence for the extrapolation inference. The following statements are examples of the types of evidence that support extrapolation inferences.

- There is evidence of the expected relationships of test scores with results from tests hypothesized to measure both similar constructs and dissimilar constructs.
- There is evidence that the relationships between test scores and results from other measures are similar across identifiable groups (e.g., cultural, racial, language).
- There is evidence from expert judgment and other studies that the KSAs measured by the test are required for success in the targeted domain, such as for a particular job or subsequent education.

- There is evidence demonstrating the relationship between scores on college admissions tests and success in postsecondary education.
- There is evidence that test results reflect skills critical to successful job performance.

Decision/Use Inferences

Kane (2016) endorsed consequences as part of validity evaluation, in that evidence related to consequences is necessary for evaluating decisions and uses: “A score use involves a sequence of claims that culminates in a decision, and decisions are justified in terms of their expected consequences” (p. 198). As such, evidence related to consequences plays a critical role in evaluating the validity of decision/use inferences. Evaluators examining the plausibility of decision/use inferences likely would collect evidence along the lines of the following examples.

- There is evidence that supports the standard-setting process (e.g., documentation of process and materials used, surveys of panelists).
- There is evidence that the inferences associated with the labels (e.g., *Proficient*, *Basic*), descriptors, and interpretations of the achievement levels resulting from the standard-setting process are justified and understood.
- There is evidence that classification decisions based on test scores (e.g., *Proficient* or *Basic*, *Competent to Practice* or *Not Competent to Practice*) are supported through multiple types of studies (e.g., decision consistency and accuracy, content alignment, performance in the next grade).
- There is evidence that classification decisions based on test scores (e.g., *Proficient* or *Basic*, *Competent to Practice* or *Not Competent to Practice*) do not lead to unintended negative consequences, such as restricted or denied opportunities or negative labeling.
- There is evidence that decisions based on test scores (e.g., college admissions) are supported and do not lead to unintended negative consequences for identifiable groups of students.

Synthesizing Validity Arguments

Construct validation is . . . never complete. Construct validation is better seen as an ever-extending inquiry into the processes that produce a high or low test score and into the other effects of those processes (Cronbach, 1971, p. 452).

Cronbach’s proclamation may have discouraged users from engaging in validation for fear of getting stuck in never-ending studies. An advantage of Kane’s argument-based approach to validation is that it provides considerably more structure to validity evaluations than Cronbach’s construct model. Similarly, Haertel (1999) emphasized that individual pieces of evidence do not render an assessment system valid or not; rather, evidence and logic are synthesized to evaluate the IUA. Such activities should allow users and others to make overall judgments about the efficacy of the testing program. Yet, there are few examples, in practice or the literature, of validity argument syntheses.

The *Standards*, in a short section at the end of the validity chapter, provides general guidance for integrating the various sources of evidence into a summary judgment:

A test interpretation for a given use rests on evidence for a set of propositions making up the validity argument, and at some point validation evidence allows for a summary judgment of the intended interpretation that is well supported and defensible. At some point the effort to provide sufficient validity evidence to support a given test interpretation for a specific use does end (at least provisionally, pending the emergence of a strong basis for questioning that judgment). (*Standards for Educational and Psychological Testing* (AERA, APA, NCME), 2014, p. 22)

Unfortunately, the *Standards* does not provide guidance for how evaluators should weigh the various sources of evidence when making a judgment about test use. For example, does response-process evidence count more than test score relationships with other variables (assuming both are relevant to a particular test use)? Kane's argument-based approach appears fairly conjunctive because the evaluator weighs evidence related to performance, scoring, generalization, extrapolation, and ultimately decision/use inferences—a high bar, to be sure.

Integrating and synthesizing various types of empirical evidence and logical arguments into an evaluative judgment can be a challenging activity. In operational assessment programs, furthermore, new and varied information comes in over an extended time interval (particularly consequence evidence), which exacerbates this challenge. Kane (2006) anticipated the timing issue, suggesting that initial evaluations of the IUA could adopt confirmationist biases. This does not give evaluators and users a pass from planning longer term studies, especially those related to consequences and fairness; but the initial synthesis and evaluation of the program should, at a minimum, substantiate that the development of the assessment has occurred generally as designed and that the design has empirical and theoretical support.

Dynamic Evaluation

Dynamic evaluation acknowledges that validity evaluations of most assessments are completed over a long period (Marion, 2010). Evaluators rarely have all the evidence to make conclusive judgments at a single point in time. Therefore, evaluators must engage in ongoing, dynamic evaluations as new evidence is produced. Gerasimova (2024) aptly referred to this approach as a “Living Document.” Working in this fashion requires that each proposition be written to allow judgment of whether the evidence collected thus far supports a particular claim and, further, whether alternative hypotheses are plausible. Judgment about evidence may suggest the need to collect additional evidence in support of a claim. In most operational testing programs, evaluators rarely have the luxury of concluding that the system is not working and then either ending or restarting the testing program. Rather, when critical evidence does not support the claims and intended inferences, test developers and users must quickly search for ways to improve the system.

However, the evidence might be so stacked against the intended claims that users are left only with the option of starting over.

Ryan (2002) emphasized the important role of diverse stakeholders in conducting validity studies. As we note throughout this chapter, stakeholders from diverse linguistic and cultural backgrounds must be involved in the design and evaluation of assessments to help ensure fair and equitable assessments. Therefore, the crucial activity of synthesizing validity arguments must meaningfully involve diverse stakeholders so that judgments regarding the validity of score interpretations and test use do not reflect only the dominant group.

Validity evaluators need pragmatic guidance for synthesizing the multiple lines of validity evidence so that users, developers, and stakeholders can consider this evidence, in light of the IUA, when determining the degree to which the inferences associated with the testing program are supported, with unintended negative consequences minimized. There have been some recent efforts, guided by state technical advisory committees (TACs), such as the Multi-State Alternate Assessment Consortium committee, to frame technical documentation around a validity argument (Cognia & Multi-State Alternate Assessment Consortium, 2019; see also Marion & Pellegrino, 2006). The technical report concludes with a summary of the validity evidence collected to date and its completeness. We do not suggest that this is the only way to synthesize validity evidence, and logic, but it serves as a useful example.

Multilevel and Multilayer IUA and Validity Arguments

Chen et al. (2004) discussed the need to address multiple levels in organizational research, adopting the term *multilevel construct validity*. Zumbo and colleagues (Forer & Zumbo, 2011; Hubley & Zumbo, 2011; Zumbo & Forer, 2011) expanded this concept to test score interpretation and use by reinforcing the need for evaluation of the consequences of score meaning and test use at the student, school, district, and state levels. This multilevel approach to validity investigations can better address equity and social justice issues by evaluating both individual and systemic, intended and potentially unintended negative consequences.

To illustrate how an individual test score can assume different forms and meaning, Haertel and Ho (2016) proposed a multilayer IUA that accounts for the use of various derived scores (e.g., aggregated scores) as well as the individual score. They suggested additional types of evidence to support the validity of interpretations and uses of these derived scores, based on construct definitions that differ from those specified by the test developer for the individual score. As described by Haertel and Ho (2016), common examples of derived scores in measurement include

- performance levels, such as *Proficient*, produced by standard-setting studies;
- aggregated scores, such as at the school or district level, produced by methods that change the level of measurement from the student to an aggregated group of interest;

- adjusted scores, where, for example, posttest scores are adjusted using pretest scores when measuring teacher effectiveness (see Kane, 2017); and
- score linking, for projecting from one score scale to another.

Haertel and Ho discussed how the definition of a construct takes on a different form depending on its use and how validity and fairness issues regarding test use arise from construct underrepresentation and construct-irrelevant variance. Test developers begin with the construct a test is designed to measure, but if the construct is then reframed because of its use as a derived score, evidence must be provided to support the derived score's representation of the reframed construct and its use (Haertel, 2018; Haertel & Ho, 2016). Multilevel IUA and validity arguments proposed by Zumbo and colleagues and multi-layer IUA and validity arguments proposed by Haertel and Ho allow for a more robust, comprehensive framework for evaluating score (and derived score) meaning and use.

Alternate Views of Validity Theory

Although the conceptualization of validity as pertaining to the appropriateness of test score interpretations, uses, and resulting consequences is widely recognized, some still adhere to more restricted views of validity (Borsboom et al., 2004; Cizek, 2012). For example, Borsboom et al. (2004) argued that “a test is valid for measuring an attribute if and only if: (a) the attribute exists; and (b) variations in the attribute causally produce variations in the outcomes of the measurement procedure” (p. 1061). This view tethers validity to a causal explanation, implying that differences in the tested attribute are causally related to differences in the item responses and that validation does not extend to score-use considerations. Holland (1986) illustrated the significant challenges associated with validating such causal inferences directly. Further, such a view is, of course, blind to test uses and their consequences as integral aspects of the IUA and validity argument.

Cizek (2020) offered a “comprehensive framework for defensible testing” (p. 90), in which he outlined the role of test use in determining whether test scores should be used for the intended purposes. Cizek restricted his definition of validity to inferences about variations in test scores in relation to variations in the measured construct; test use, he believes, is not part of validity. His original reasoning was that he wanted to avoid validation as “an endless process,” in Cronbach's words. Similarly, Russell (2022) proposed separating evaluation of assessment scores, decisions, and uses into investigations of (a) “instrument validity” and (b) “verifications of interpretation(s) and decision(s) made based on instrument scores. Verification explores whether the instrument scores are used appropriately to inform decisions” (p. 26). However, he did not conceptualize verification as validation.

Both Cizek (2020) and Russell (2022) required marshaling evidence in support of the intended score use, justification of this use, and an evaluation of the evidence related to the justification claims. Cizek (2020) acknowledged the significance of test use—“tests are commonly used to inform important decisions” (p. 16)—but then argued for the separation of score inferences and uses. We contend that separating inferences

from uses, where only inferences are validated, and then bringing them back again later in the process risks having certain critical validation (e.g., uses and consequences) fall by the wayside.

Theories of Action and Validation

Haertel (2018) noted that an IUA is like a “theory of action that explains how testing is supposed to confer a benefit in some particular situation” (p. 207). Other researchers have suggested using a theory of action more directly to frame an IUA and validity argument. Ryan (2002) and others suggested that providing a theory of action is a useful starting point for users when developing a more complete IUA. The theory of action requires the explication of the intended components of an assessment and decision system, as well as the mechanisms by which a test user could reasonably expect to get from one step to the next. To address equity issues, Kane (2006) and Shepard (1993) encouraged evaluators to attend to values and consequences when evaluating a decision procedure, especially when a testing program is used as a policy instrument (as in state tests). When conducting such a validity evaluation, the values inherent in the testing program must be made explicit, and both intended and unintended consequences of decisions based on test scores must be evaluated. Values favoring social justice aims must be prioritized when considering the consequences of a testing program. Theories of action have been applied to many types of assessments, including assessment systems (Bennett, 2010; Bennett et al., 2011), assessments for students with significant disabilities (Marion, 2010; Marion & Perie, 2009), language testing (Bachman, 2002), and certification testing (Crisp, 2017).

The Cognitively Based Assessment of, for, and as Learning (CBAL) program was guided by an extensive theory of action (Bennett, 2010). The CBAL theory of action explicates the processes and mechanisms connecting the design of the assessment program with the intended outcomes. It emphasizes “the effects of the assessment system on individuals and institutions as well as to the underlying mechanisms behind those effects” (Bennett, 2010, p. 71). In the case of CBAL, these mechanisms focus on such considerations as how well teachers use tools and resources, including the use of research-based learning progressions, to adjust instruction to improve student learning.

Assessments for students with significant cognitive disabilities are relatively new components of state and district testing systems, initially required as a result of the Individuals With Disabilities Act and the No Child Left Behind Act in the early 2000s. Researchers, test developers, and state specialists grappled with how best to assess the KSAs of students who had difficulty communicating their thinking. One advantage of working in this area is that, because many of these assessments were being designed for the first time, researchers were able to articulate a validity evaluation plan as part of the development work (e.g., Marion & Pellegrino, 2006).

Given the field’s lack of clarity around these alternate assessments, a well-developed theory of action is perhaps even more critical than it might be for other validation

initiatives. Policy makers, developers, stakeholders, and technicians need to explicate why implementing an alternate assessment for students with the most significant cognitive disabilities would lead to improved educational opportunities for these students. In addition to the *why*, these theories of action, like the CBAL case, described the mechanisms by which these improved learning opportunities would occur. For example, one might postulate that alternate assessment scores provide accurate depictions of what eligible students know and can do so that teachers can offer more appropriate learning opportunities for them. The evaluator and user must specify the mechanism by which these score reports will lead to anticipated changes in teaching practices, such as targeted instruction or more appropriate curricular materials (Marion, 2010; Marion & Perie, 2009).

Bachman (2002) provided an example of an important use of a theory of action when developing a validity argument. He used theories of action as a bridge to a validity argument to illustrate how to attend to potential alternative explanations for score meanings and unintended negative consequences. He noted that performance-based assessments were designed to measure complex constructs, such as those found in language testing. While the validity issues associated with performance assessments have received considerable attention (e.g., Lane & Iwatani, 2016; Lane & Stone, 2006; Linn et al., 1991; Shepard, 1993), Bachman's theory of action helped uncover alternative interpretations of test scores due to language knowledge, content knowledge, and their interaction.

Theories of action provide a framework for bringing together meaning and impact claims, with an emphasis on claims about the intended consequences of the assessment as well as potential unintended negative consequences for both individuals and groups (Bennett, 2010; Marion & Perie, 2009). This has become increasingly important over the past 20 years as tests have played a more prominent role in educational and social policy, resulting in unintended negative consequences for marginalized students. Haertel (2018) discussed two classes of indirect effects of testing: incentive effects and messaging effects. He argued that the use of testing for its indirect effects is a significant change: "Instead of using tests to *evaluate* educational treatments, testing itself had now *become* the treatment" (p. 207, emphasis in original). For example, an incentive effect occurs when the teacher tells students, "This will be on the test." The students have an incentive to pay attention and study. Messaging effects often occur through the news media and shape perceptions of schools and schooling, particularly when tests are part of accountability systems.

The use of a theory of action to frame the IUA serves to identify the particular claims about benefits that are most critical to investigate (Shepard, 2016), as well as potential unintended negative consequences, particularly for historically underserved students. The development of a theory of action, with input from multiple stakeholder groups, fosters the consideration of different values and social justice concerns (Ryan, 2002). Finally, evaluating the IUA through the validity argument is not a mere formula-driven exercise. The many pieces of evidence are just that; they do not form a validity argument in and of themselves (Haertel, 1999). The various instances of theoretical, logical, and empirical evidence need

to be woven into a coherent argument. Creating and appraising the theory of action is one way to help synthesize sources of validity evidence in the evaluation of the IUA.

CONSEQUENCES IN VALIDITY THEORY AND VALIDATION

The best way to encourage adequate consideration of major intended positive effects and plausible unintended negative effects of test use is to recognize the evaluation of such effects as a central aspect of test validation. (Linn, 1997, p. 16)

The soundness of test-based decisions and uses has been an integral aspect of validity, resulting in the need to identify the IUA's claims regarding intended positive consequences and potential negative consequences (Cronbach, 1971; Kane, 1992, 2002, 2006; Lane et al., 1998; Linn, 1997, 2009; Shepard, 1997). The validity argument should attend to potential adverse consequences, particularly for individuals who have been underserved by the educational system. Five decades ago, Cronbach (1971) considered the evaluation of decisions and actions based on tests as part of validity evaluation. In response to the debate about whether consequences of test use are an aspect of validity, Linn (1997) argued that "the evaluation of consequences rightly belongs in the domain of validity" (p. 16) and, thus, called for the appraisal of intended positive consequences and potential unintended negative consequences as fundamental to validation efforts. Popham (1997) and Mehrens (1997) argued in opposition.

Messick's (1989) progressive matrix made the role of consequences explicit in validity theory. The inclusion of the appraisal of the soundness of decisions based on test scores underscores the need to examine consequences as a "logical part of the evaluation of test use, which has been an accepted focus of validity for several decades" (Shepard, 1997, p. 5). We contend that score meaning cannot be evaluated without considering use and resulting consequences; therefore, we disagree with the contention that validity pertains to only score meaning (e.g., Cizek, 2020).

Because consequences are integral to validity, IUAs should identify claims associated with intended positive consequences and potential unintended negative consequences of the testing program. An examination of consequences in the validity argument involves a critical evaluation of both the anticipated positive and the potential unintended negative consequences of test use (Kane, 1992, 2006; Lane, 2014; Lane & Stone, 2002; Lane et al., 1998; Linn, 1997; Shepard, 1993, 1997). Judicious attention to potential adverse consequences, particularly for historically underserved individuals, is critical as we work toward a more equitable and just society in which the negative effects of testing are minimized. Adverse social and personal consequences of testing bear on both validity and fairness issues. As articulated by Campbell (1979), "the more any quantitative social indicator is used for social decision making, the more subject it will be to corruption pressures and the more apt it will be to distort and corrupt the social processes it is intended to monitor" (p. 49).

Tests as mechanisms of social action have direct and indirect consequences. In consideration of validation as a persuasive argument, Cronbach (1988) asserted that "*the argument*

must link concepts, evidence, social and personal consequences, and values” (p. 4). Although consequences of test use have been included in the evaluation of test decision procedures, the attention to social consequences, differential impact, and adverse systemic effects for different groups did not occur until the 1960s. The civil rights movement and corresponding legislation elevated discussions of the social consequences of testing, with a focus on the adverse effects on ethnic and racial minorities and women (Cronbach, 1971, 1988; Messick, 1965, 1975, 1980). Social consequences were given prominence because of their impact on society, not just those involved in the testing process (Kane, 2016). This resulted in the need to integrate such consequences into validity and validation.

Messick (1989) explicitly addressed the relationship between validity and consequences: “Validity is an integrated evaluative judgment of the degree to which empirical evidence and theoretical rationales support the *adequacy* and *appropriateness of inferences* and *actions* based on test score and other modes of assessment” (p. 13). Newton (2012) contended that justifying test use is an enormous undertaking, believing it is reasonable “to separate distinguishable elements of evaluation into manageable components—validity, efficacy, legality, and so on” (p. 15), and suggested the need for cleaner distinctions when consequences are part of validity arguments. Cizek (2020) argued for decomposing the components of a validity evaluation, especially when consequences are part of the mix. But that begs the critical question of synthesizing the evidence and logic from the various components into some sort of judgment regarding the validity of using the test for a particular purpose. Newton and Shaw (2014) addressed the challenges of synthesizing the evaluation components within a cost–benefit judgment concerning the acceptability of a testing policy.

Kane (2006) supported Cronbach’s (1971, 1988) position that consequences have an integral role in the validity argument and that “tests that impinge on the rights and life changes of individuals are inherently disputable” (Cronbach, 1988, p. 6). Those responsible for providing evidence in support of the validity argument have an obligation to evaluate whether a use has “appropriate consequences for individuals and institutions, and especially to argue against adverse consequences” (Cronbach, 1988, p. 6). Kane (2013) later wrote that consequences that have “potential for substantial impact in the population of interest, particularly adverse impact and systemic consequences” (p. 61), should be a central aspect of the validity argument. The evaluation of consequences of testing programs is an inherent aspect of the IUA and validity argument.

Consequences and the 2014 *Standards for Educational and Psychological Testing*

The 2014 *Standards* backtrack on the connection between scores and uses by conceptualizing validity as “the degree to which evidence and theory support the interpretation of test scores *for* [emphasis added] proposed uses of tests” (AERA et al., 2014, p. 11). This distinction is critical: It suggests that use alone is not central to validity. The 2014 *Standards* also adopted Messick’s limited view that consequences are considered an aspect of validity if they result from other interpretative threats to validity—principally, construct irrelevance or construct underrepresentation.

An evaluation of subtle, but critical, modifications in the 2014 *Standards* validity chapter uncovers how consequences play a marginal role in validity theory when compared with the 1999 *Standards* (Lane & Niepokoj, 2018). The comment associated with Standard 1.6 in the 2014 validity chapter states that

certain educational testing programs have been advocated on the grounds that they would have a salutary influence on classroom instructional practices. . . . To the extent that such claims enter into the justification for a testing program, they become part of the argument for test use. Evidence for such claims should be examined—in conjunction with evidence about the validity of intended test score interpretation and evidence about unintended negative consequences of test use. (AERA et al., 2014, p. 24)

In contrast, the 1999 *Standards* clearly placed consequence in the validity argument, arguing that “to the extent that such claims enter into the justification for a testing program, they become *part of the validity argument for test use* [emphasis added] and so should be examined as part of the validation effort” (AERA et al., 1999, p. 13).

Note how the 2014 *Standards* replaced “validity argument for test use” with “argument for test use,” implying that the 2014 standard is not part of a validity argument. The 2014 *Standards* similarly removed consequences from the validity argument for tests used as levers of educational change.

Two other chapters in the 2014 *Standards* addressed consequences. Standard 12.1 in the “Educational Testing and Assessment” chapter supports the need to consider consequences for educational assessments, but it does not acknowledge that consequences are part of the validity argument:

When educational testing programs are mandated by school, district, state, or other authorities, the ways in which test results are intended to be used should be clearly described by those who mandate tests. It is also the responsibility of those who mandate the use of tests to monitor their impact and to identify and minimize potential negative consequences as feasible. Consequences resulting from the uses of the test, both intended and unintended, should also be examined by the test developer and/or user. (AERA et al., 2014, p. 195)

The comment for Standard 12.1 refers to the validity of score interpretations—not score uses, test uses, and the resulting consequences:

The need to monitor the impact of educational testing programs relates directly to fairness in testing, which requires ensuring that scores on a given test reflect the same construct and have essentially the same meaning for all individuals in the intended test-taker population. (p. 195)

Standard 13.7, in “The Uses of Tests for Program Evaluation, Policy Studies, and Accountability” chapter, refers to consequences:

When tests are selected for use in evaluation or accountability settings, the ways in which the test results are intended to be used, and the consequences they are

expected to promote, should be clearly described, along with cautions against inappropriate uses. (p. 212)

The only reference to consequences as potentially included in the validity argument surfaced in this comment for Standard 13.7:

The use of tests is often justified on the grounds that it will improve the quality of education by providing useful information to decision makers and by creating incentives to promote better performance by educators and students. These kinds of claims should be made explicitly when the system is mandated or adopted, and evidence to support their validity should be provided when available. The collection and reporting of evidence for a particular validity claim should be incorporated into the program design. (p. 212)

The 2014 *Standards* endorsed the importance of evaluating the consequences of test use but, until page 212, did not consider consequences as part of the validity argument. Throughout the validity chapter and elsewhere in the *Standards*, the validity of score interpretations *for* proposed uses was adopted instead of the validity of score interpretations *and* uses. This seemingly subtle difference arguably limits the role of consequences as an integral aspect of validity. Newton and Shaw (2016a) discussed the 1999 and 2014 *Standards* references to validity as related to score interpretations for proposed uses, instead of “and” uses, calling for clarification of the treatment of both use and consequences in validity theory. The 2014 *Standards* represented an unfortunate backtracking by understating the importance of consequences in validity and validation.

Consequences and Credentialing Testing Programs

Tests that certify or license individuals for professional practice must provide a definition of minimally competent qualified candidates (see Margolis et al., this volume). Such definitions rely on the judgments of content experts. Kane (2004) identified pertinent inferences for a credentialing testing program’s IUA, including the decision inference. The decision inference is that those scoring above the cut score have the requisite KSAs for entry-level practitioners, and those scoring below the cut score lack the necessary KSAs and pose a risk to the public. Both intended and unintended consequences arise from this decision inference. The practice analysis that identifies the critical KSAs in the domain, the test design and development process, and standard setting provide backing to support this decision inference—all of which rely on expert judgments.

Consequences and Setting Performance Standards

Factors that introduce uncertainty in the cut score include the standard-setting panel size and composition, the standard-setting method, the implementation of the standard-setting method, and the types of data and information provided to panelists to make informed judgments (Hambleton & Pitoniak, 2006; see also Ferrara et al., this volume). Various factors can lead to inconsistencies in a standard-setting method, such

as regression effects in item ratings and the tendency for statistically easy items to be rated as more difficult and statistically harder items to be rated as easier (Shepard et al., 1993; Wyse, 2018). In the bookmark method, for example, the choice of response probability value to be used for anchoring items to the score scale, response probability 50 versus response probability 67, will yield different cut scores (Wyse, 2011). Competing values, beliefs, and assumptions inherent in any standard-setting method pose trade-offs. Standard setting, and the choices made throughout the standard-setting process, can impact individuals' livelihood.

Kane (1994) identified two inherent assumptions in his discussion of arbitrariness in setting performance standards. First, candidates who score above the cut score meet the performance standard, and those scoring below do not. Second, the standard is reasonable for the purpose of the decision. This second assumption rests on values and beliefs about consequences in an adopted policy that are "likely to be subject to dispute" (p. 426). These policy decisions are consequential.

Shepard (1980) expressed her concern with the dichotomization of the scale for decision-making: "Individuals immediately on either side of the standard will be virtually indistinguishable from one another. . . . Pass-fail distinctions near the cutoff will have poor validity because a continuum of performance has been 'arbitrarily' dichotomized" (p. 448). In the context of teacher certification tests, Jaeger (1990) echoed Shepard's concern:

No conventional test validation procedure will provide evidence that any score-based dichotomization of the ability scale into two categories labeled "competent" and "incompetent" is correct. We know that dichotomization is judgmentally based, arbitrary, and, wherever placed on the ability scale, will not result in reliable differences in distributions of performance on any valued criterion for groups adjacent to the point of dichotomization. (p. 18)

In a similar vein, Kane (1994) stated that a defensible standard is chosen from a range of performance standards, and there is arbitrariness in this choice insofar as there is no technical basis for identifying a particular "correct" standard (p. 434). Various stakeholders, such as content experts and policy makers, may have different assumptions and values they apply to standard setting. While advances in standard setting have minimized the degree of arbitrariness, different standard-setting methods and different standard-setting panels can produce different results, which threatens the generalizability of the results across different standard-setting methods, panels of experts, contexts, and occasions.

These issues with standard setting and resulting cut scores (or performance standards) apply to any testing program that sets cut scores for decision-making. We acknowledge that society requires certain cut scores (e.g., competent to earn a driver's license) even though, as noted previously, adjacent candidates separated only by a point or two are generally indistinguishable. This is why setting cut scores requires consequential evidence. In the context of testing for college and career readiness, for example, Zwick (2018)

cautioned that dichotomization into readiness levels reduces accuracy of prediction while “paradoxically convey[ing] an increased sense of certainty: the message is that a ‘college-ready’ student is qualitatively different from an ‘unready’ one, even though their scores may differ by a psychometrically negligible amount” (p. 101). Using additional measures that account for variance in the criterion, rather than relying on a single score, would improve classification accuracy (Zwick, 2018).

Maximizing Equity in Standard-Setting Policy Decisions

Policy decisions that lead to the performance standards and corresponding cut scores reflect values associated with the potential consequences. The justification of a decision rule depends on an evaluation of intended positive and potential negative consequences of a decision rule. Cronbach (1989) argued that test-based decision rules could reflect value assumptions aiming to increase diversity. Policy makers balance competing values when evaluating proposed cut scores. Any differential impact for test takers from different cultural and language groups requires careful consideration in decision-making. Information on measurement and sampling error, along with a reasonable range for the cut score, informs the policy makers’ decisions on the final cut score. There are different consequences for the two types of decision error: not passing a test taker who nonetheless has the requisite KSAs (false negatives) and passing a test taker who lacks the requisite KSAs (false positives). Consideration of the consequences of each type of error is needed when setting the cut score (Hambleton & Pitoniak, 2006). Information on differential impact on population groups provides the opportunity for decision-makers to maximize diversity while maintaining rigorous standards. All involved in the standard-setting process, whether for credentialing testing or for K–12 achievement testing, should have a clear understanding of the judgment and uncertainty inherent in setting cut scores and the potential effect of decision rules on the livelihoods of individuals.

Legal issues that arise in credentialing testing programs bear on constitutional claims of due process and fairness, where fairness necessitates that the testing process avoids arbitrary procedures (Atkinson, 2012). The use of testing as a social control mechanism, and the deprivation of rights without due process, unduly affects historically underserved groups. The adherence to professional standards and best practices in testing promotes thoughtful decisions in testing practices (including standard setting) while enhancing informed judgments. That said, a degree of arbitrariness will always remain. Therefore, an independent evaluation of standard setting, along with other testing practices, is recommended.

Consequences When Extrapolating to Performance in Practice

The backing for the decision and extrapolation inferences for credentialing tests also includes evidence from the test design and development process, such as evidence from the practice analysis that identifies the KSAs necessary for effective practice. Kane (2009) argued that the test is “viewed as a measure of KSAs that are considered necessary but not sufficient for effective practice, and as a result, the test scores are not expected to provide

very accurate estimates of performance in practice [emphasis added] for individual candidates” (Kane, 2009, p. 142). What is assessed is not sufficient for effective performance; when test items refer to a practical scenario, the testing situation differs substantially from the practice situation, which affects the validity of extrapolation from the score to the application of the knowledge and skills in practice (Kane et al., 2017). The behaviors and processes involved in responding to multiple-choice items are unlike those when responding in practice, so there is a need for additional backing that shows the relationship between performance on multiple-choice items and performance on high-fidelity simulations (Haertel, 2004). This is reinforced in the 2014 *Standards*:

When the responses elicited by a test neither sample nor closely simulate the use of tested knowledge or skills in the actual criterion domain, participants are not likely to approach the task with such clear understandings of adequacy or quality. (AERA et al., 2014, p. 108)

This jeopardizes the validity of inferences involving extrapolation to both the broader domain of KSAs and the practice domain. Adverse consequences can arise if there are concerns with any of the design and measurement procedures that affect the validity of inferences and uses. There are limitations to the validity of inferences and uses for credentialing testing programs that rely on selected-response item types, with or without a practice scenario. Even if one adopts the narrow view of consequential evidence, construct underrepresentation and construct-irrelevant variance can differentially affect diverse groups or individuals, resulting in validity and social justice issues. This is one of the rationales for the use of performance assessments: They arguably represent the intended practice with more fidelity compared with items that only serve as a proxy at best.

Consequences and K–12 Assessment and Accountability Systems

The intent of current test-based accountability systems is to improve the educational opportunities afforded to all students by holding schools, educators, and (sometimes) students accountable (see Ho & Polikoff, this volume). As educational change agents, tests serve as powerful tools to support educational reforms while at the same time exposing societal and educational inequities. Therefore, the appraisal of test-based decisions and uses in terms of their consequences is integral to the validation efforts of tests used in these systems (Lane, 2014, 2020). The use of a test as an instrument of policy requires an evaluation of the consequences of its use (Cronbach, 1982).

Educational reform policies that involve testing are intended to result in certain consequences, including improved student achievement and learning, enhanced instruction, narrowed achievement gaps, and students being prepared for college and careers. Tests used in accountability systems provide policy makers with tools to hold schools, administrators, educators, and students accountable for student achievement and learning. Tests appeal to policy makers as agents of educational change because they are relatively inexpensive, can be mandated externally and implemented relatively quickly, and have quantifiable results that are perceived to be objective or at least independent (Linn, 2000). Advocates view

test-based accountability systems as a means to raise academic standards for students and to focus instruction on content aligned with rigorous content standards. The intent of tests as educational change agents involves incentivizing and/or signaling to educators and leaders to provide all students an opportunity to learn rigorous content described by the standards and to achieve the knowledge and skills reflected in those standards.

Evaluating the match between the intended interpretation and uses of test scores and the enacted interpretations and uses of test scores is integral to the validity argument for test-based accountability systems. The validity of a decision inference is threatened if there is a mismatch between intended and enacted interpretations and uses, resulting in unintended social and personal consequences. Enacted interpretations and uses by educators and administrators are more diverse and complex than intended interpretations and uses (Coburn & Turner, 2011; Moss, 2013, 2016), and they may result in undesirable consequences for some individuals or groups. Tests are used locally in different contexts by educators and administrators to address a variety of their own needs (e.g., grade promotion), and these local uses need to be understood and evaluated in terms of their appropriateness and potential negative consequences for students.

Decisions made in test design, development, and use rest on value judgments that affect the consequences of test use (Kane, 2006; Messick, 1989). Value judgments are involved in the articulation of the intended purposes and uses of a test, the specification of the construct (or content standards) to be assessed, the design and development of items and scoring procedures, the development of performance-level descriptions, the setting of cut scores for determining student proficiency or passing, and the design of score reports and accompanying interpretive guides. Value judgments inherent in each of these test design decisions impact the validity of test score interpretations, uses, and resulting consequences. Value judgments are also inherent in the specification of the intended positive consequences and in identifying potentially unintended adverse consequences.

Different stakeholders—policy makers, advocacy groups, administrators, educators, parents, students, business leaders, the community—have different, and sometimes conflicting, perspectives on the purposes and uses of tests in instruction and accountability systems because of corresponding differences in their assumptions and values. One way to address these potentially competing interests is to construct different IUAs (Bachman, 2002), although such an approach would make validation an even more cumbersome endeavor. Nevertheless, the documentation of competing assumptions and values among stakeholder groups will promote a better understanding of the potential consequences, both positive and negative, of test use. It would be more efficient, however, to do so within a single IUA.

The use of tests as policy levers bears on equity and social justice issues. The use of test-based accountability systems typically has different consequences for different student groups, schools, and districts, which should be examined as part of the IUA and validity argument (Lane & Stone, 2002). Differential test outcomes for students living in economically marginalized communities, African American students, Hispanic students, Indigenous students, English learners, and students with disabilities have led

to undesirable and inequitable consequences, such as a narrowing of the curriculum and instruction (Booher-Jennings, 2005)—ironically, for the very same students the tests were intended to support. The evaluation of test use in accountability systems should determine whether the intended positive consequences are realized and potential unintended negative consequences are minimized. The inequities of educational opportunities compromise the validity and fairness of test score interpretations and uses, as well as the use of tests as vehicles for educational change, all resulting in undesirable consequences.

Validity Evaluation for Consequences in K–12 Contexts

Evaluating the effectiveness of tests used as policy instruments in accountability systems requires attention to how well the tests are achieving their goals, both in terms of the motivation and practices of school administrators and educators and in terms of student achievement and learning (Lane & Stone, 2002). Those who mandate and use tests are obliged first to make a case for the appropriateness of the decision rules in the use context and then to consider whether any potential unintended negative consequences outweigh intended positive consequences. The articulation of intended and potential unintended consequences should occur in conjunction with the specification of the test purposes and claims. The validity argument should entail a systematic evaluation of whether, and how, the test achieves its goals, as well as the costs of doing so. The relevant stakeholders, who may hold different, and perhaps competing, values, should be involved in identifying the questions for evaluating both positive and potentially negative consequences of test use.

A principled approach to the evaluation of consequences must be central to the validity argument to avoid continued “begging the question” (Kane, 2006). The claim that test-based accountability systems will lead to better instruction and student achievement often is taken for granted. Rather, integral to the IUA and validity argument is the empirical evaluation of whether testing programs, used as levers for educational change, have the intended positive effects on instruction and student learning while minimizing potentially negative unintended effects.

Lane and colleagues developed and implemented a conceptual framework for evaluating the consequences of assessment and accountability systems—intended and unintended, positive and negative—for a state performance-based assessment program that held schools and educators accountable for improved instruction and student learning (Lane & Stone, 2002; Lane et al., 1998). The proposed IUA addressed the intended consequences at multiple levels (individual, school, district, state) by articulating a set of claims that could be either supported or refuted by logical and empirical validity evidence at each level. This involved specifying the needed evidence relevant to both positive and potentially negative outcomes for different stakeholders (students, teachers, administrators) and different levels (state, district, school, class, student). For each form of evidence, the sources to provide the evidence were delineated. The framework stipulated the need for contextual information to inform the evaluation of consequences, such as the percentage of students receiving free or reduced lunch; amount of funding per student; access to quality curriculum and materials; and stability of administrators,

teachers, and students. Contextual information also can identify barriers to achieving intended outcomes that must be overcome. The framework provides a mechanism for synthesizing the evidence for consequences in the validity argument.

Consequences and the Use of Performance Assessments in Education

Consequential evidence in support of the validity argument is “especially compelling for performance-based assessments . . . because particular intended consequences are an explicit part of the assessment system’s rationale” (Linn, 1993, p. 6). If a performance assessment is intended to achieve positive outcomes, the enacted program should achieve these goals while minimizing negative consequences. The implementation of large-scale performance assessments in the 1990s improved instruction and student learning, with a greater emphasis on problem-solving, critical thinking, and reasoning (NRC, 2010). Lane and colleagues examined validity evidence for the consequences of the Maryland School Performance Assessment Program (MSPAP), which served as a lever for educational change. To provide consequential validity evidence, they used growth model analyses to examine the impact of the performance assessment and accountability system on both student learning and classroom instruction (Lane et al., 2002; Parke & Lane, 2008; Parke et al., 2006; C. A. Stone & Lane, 2003). Teacher-reported use of performance-based instruction accounted for differences in school performance on MSPAP reading, writing, mathematics, and science. Schools emphasizing performance-based instruction, such as engaging students in critical thinking and reasoning, had higher MSPAP scores than schools where instruction was less performance based (Lane et al., 2002; C. A. Stone & Lane, 2003). A systematic evaluation of mathematics classroom instructional artifacts revealed a stronger alignment with MSPAP and the state content standards for higher achieving and higher gain schools compared with lower achieving and lower gain schools (Parke & Lane, 2008).

Furthermore, trends in mathematics on the state National Assessment of Educational Progress and MSPAP mathematics assessments were similar, suggesting that improved student performance on MSPAP most likely was real (Linn et al., 2002). These results support extrapolating score-gain inferences on MSPAP to other assessments measuring somewhat different content and using different item formats. Such positive results, in part, may have resulted from schools using MSPAP data, along with other information, to guide instructional planning (Ferrara, 2010; Michaels & Ferrara, 1999).

Contextual information can inform inferences and resulting actions when using test scores to evaluate the quality of education (Haertel, 1999). In the MSPAP studies, for example, the percentage of students in a school who receive free or reduced-price lunch (a school-level proxy for socioeconomic status [SES]), was significantly related to school-level MSPAP performance (Lane et al., 2002; C. A. Stone & Lane, 2003). However, there was no significant relationship between SES and school performance *gains* in mathematics, writing, science, and social studies. This offers some evidence that MSPAP did not have an adverse impact on students who lived in economically disadvantaged areas, given the

comparable growth in school scores in these subjects regardless of school SES. Stakeholders might argue that greater gains for lower SES schools should have occurred insofar as initial performance was lower for these schools. In short, comparable gains in performance may not be a sufficient positive consequence since the goal is to decrease achievement gaps.

Evaluating the consequences of performance assessments provides evidence primarily to support the decision/use inference. Evidence is also needed in support of the performance, scoring, generalization, and extrapolation inferences. In particular, the generalization inference requires careful scrutiny, given that performance assessments typically comprise a small number of tasks.

Consequences and the Use of College Admission Tests as High School State Assessments

The IUA and validity argument must consider consequences when states use college admissions tests as high school state assessments for their accountability systems (see Camara et al., this volume, for a discussion of tests used for admissions). Such tests often underrepresent the intended construct by measuring only a portion of state content standards, which may tempt teachers to either (a) narrow the curriculum to cover only tested material or (b) maintain fidelity to the intended curriculum and potentially leave their students underprepared for the high-stakes test. Either choice may carry significant negative consequences for students. The validity argument must include an independent evaluation of the alignment between the admissions test and the state content standards. There are gaps in the alignment between content standards and admissions tests (Achieve, 2018), which, for states that adopt college entrance exams for accountability, could change how mathematics and English language arts are taught. This potential negative consequence should be weighed against the positive consequence of using a college entrance exam as the high school accountability test, such as furthering the educational opportunities of students who may not have considered higher education. However, validity threats associated with college entrance exams cannot be considered in the absolute. The evaluation must be weighed against the threats of using a state survey test, such as lack of motivation and a weak link to students' course-taking patterns (Marion, 2018b; Marion & Domaleski, 2019). States that have adopted college entrance tests should address these consequences in their IUA and validity argument by providing evidence related to content alignment, changes in college enrollment rates for students (especially from underserved populations), and the impact on instruction at the classroom, school, and district levels.

Maine was one of the first states to adopt a college entrance exam as its state test in high school. Maine began administering the SAT in 2006 as its high school accountability test, but needed to augment the SAT mathematics section with additional items to improve its alignment with state content standards. Hurwitz et al. (2015) found that a 2%–3% increase in college-going rate was associated with the use of the SAT in Maine. Michigan adopted the ACT as its high school accountability test, which resulted in approximately 50% more low-SES students achieving a college-ready score (because most of those students would not have tested previously). Unfortunately, this translated into an increase of only 6% more of these low-SES students later enrolling at a 4-year

institution (Hyman, 2017). Nonetheless, these studies provide some backing for the use of college admission tests to increase higher education opportunities for students, including those who are underserved.

Consequences and Language Testing

Researchers in various academic disciplines have given test use and resulting consequences a prominent role in validity theory and validation. In the context of language assessments typically used for selection purposes, Bachman (2005) and Bachman and Palmer (2010) provided an assessment use argument (AUA), which agrees in spirit with Kane's IUA. Their AUA offers a framework for linking test performance to decisions and use, delineating the intended consequences and potential unintended adverse consequences, as well as the corresponding validity argument. Figure 4.1 displays a simplified version of this AUA. The AUA links score interpretations to decisions and consequences, specifying four claims about outcomes: intended and actual consequences, intended and actual decisions, intended and actual interpretations, and test scores.

The articulation of the intended beneficial, and potentially unintended, consequences of test use occurs at the beginning of the testing process. The warrant associated with consequences in the AUA states that “the *consequences* of using the assessment and making intended decisions will be beneficial to individuals, the program, company, institution, or system, or to society at large” (Bachman, 2005, p. 19). This sentiment captures Messick's

FIGURE 4.1
Inferential Links in the Assessment Use Argument

Note. Adapted from “Language Assessment in Practice: Developing Language Assessments and Justifying Their Use in the Real World,” by L. F. Bachman and A. S. Palmer, 2010, Figure 5.1, p. 91. Oxford University Press.

notion of social consequences embedded in his progressive matrix (Table 4.1). But in contrast to Messick's position that consequences are an aspect of validity only if they can be traced to construct underrepresentation or construct-irrelevant barriers, Bachman (2005) believed that "it is quite possible for adverse consequences and inappropriate uses of tests to occur that are *not* a result simply of sources of invalidity" (p. 16) in the score interpretation.

Importantly, in addition to emphasizing intended score interpretations, decisions, and consequences, the AUA also emphasizes *actual* interpretations, decisions, and consequences. This broadens the evaluation demands by now including the appraisal of actual test use and resulting consequences. The inclusion of consequences as an integral aspect of the AUA allowed for encompassing investigations of test consequences on teaching and learning as part of the AUA. Lack of access to the assessment because of financial, geographic, personal, and educational limitations ultimately restricts individuals from consideration in the decision-making process (Bachman, 2005). The claims and counterclaims specified in the AUA provide a framework for guiding assessment design and developing procedures for appraisal of the test use and resulting consequences (Bachman, 2005).

Chapelle et al. (2007, 2010) used aspects of Kane's IUA and Bachman and Palmer's AUA in the context of an assessment of English as a foreign language. In doing so, they provided an example of a decision/use inference⁴ for Test of English as a Foreign Language (TOEFL) scores used for admission decisions at English-medium universities. The warrant for the use inference is that these scores are useful for making decisions about admissions, placements, and curricula for test takers. Using TOEFL scores for admissions and placements assumes there will be appropriate score interpretations by admission officers, test takers, and teachers, while using these scores for curricula decisions assumes the test will have positive consequences for English language instruction. Support for this warrant and the corresponding assumptions comes from standard-setting studies, score reports, interpretative materials, available instructional supports, and studies examining the consequences for instruction (Chapelle et al., 2007, 2010). Counterevidence includes any potential differential impact for individuals from different cultural and language backgrounds. Additional backing for placement decisions would include evidence that the scores appropriately identify the needed level of English instruction for individuals.

Investigations of Consequences of Selection Decisions

The validity argument for using language tests for making selection decisions should include the appraisal of the relationship between language test scores and subsequent performance in college. This relationship has been evaluated in terms of correlation coefficients, but this approach has limitations. Cho and Bridgemen (2012) reported that although the correlation between the TOEFL Internet-Based Test (iBT) and GPA is relatively small, the likelihood of being in the top 25th percentile GPA group doubled for students who had iBT scores in the top 25% compared with those who had scores in the bottom 25%. They discussed several typical factors that affect correlation coefficients for selection test scores, including restriction of range for the test scores as a result of

only being able to use admitted students and lack of variability in university GPAs. Deygers et al. (2018) investigated whether a small sample of international students at Flemish universities had the language skills needed for successful performance in college even though they failed the language tests. The researchers posited that using the tests as gatekeepers to universities for admission decisions is just, with the warrant that students who do not pass would not meet the linguistic demands of college and hence would be unsuccessful. Their results did not support this claim and warrant because one in five successful university students would have been denied admission had their test scores been used for the admission decision. Although there also were false positives—students who passed the tests but subsequently demonstrated significant language difficulties at the university—Deygers et al. argued for paying attention to the false negatives that result in restriction of opportunities (Rawls, 2001).

Investigations of Consequences on Instruction and Learning

In the context of the testing English as a foreign language, Alderson and Wall (1993) posited a series of potential consequences of language tests: what and how teachers teach, what and how learners learn, the rate and sequence of teaching and learning, the degree and depth of teaching and learning, and teachers' attitudes toward content and method of teaching and learning—all of which could be part of the IUA and validity argument. Similar to earlier studies (Alderson & Hamp-Lyons, 1996; Alderson & Wall, 1993), Barnes (2016) concluded that test preparation materials can improve teaching and learning in English language preparation classes for the TOEFL iBT, which provides an integrated approach to assessing speaking, listening, reading, and writing. Barnes (2016) found that the TOEFL iBT preparation materials determined the content of instruction (including speaking) and, to some extent, the way this content was taught. However, the curriculum arguably should not be defined solely by test preparation materials.

Concluding Thoughts

Test use and resulting consequences are inseparable from validity. Therefore, IUAs should identify claims associated with intended positive consequences of the testing program as well as potential unintended negative consequences. Validation efforts should pay close attention to potential adverse social and personal consequences, particularly for individuals who have been historically underserved, because of the impact consequences have on society and the livelihood of individuals.

ASSESSMENT OF INDIVIDUALS WITH VARYING CULTURAL AND LINGUISTIC BACKGROUNDS

It is imperative that we take the next step, which is to begin empirically based investigations in the design, validation, and meaningful utility of culturally responsive assessments (Hood, 1998, p. 4).

There has been a strong call for more equitable and culturally inclusive testing practices and uses so that one cultural group is not privileged over another. This call stems from the increasing diversity of tested groups as well as the recognition of structural racism and the role testing plays in it (Gould, 1981; Randall, 2021; see also the following chapters in this volume: Ercikan & Solano-Flores, Rodriguez & Thurlow, and Zwick). Culture is a mediator of human practices, values, and beliefs (Cole, 1996). Testing is a cultural practice situated within a cultural context with tests as cultural artifacts, reflecting primarily the ideologies, values, practices, and beliefs of the culture of those who mandate and design the tests. Importantly, the field is moving toward a more inclusive testing paradigm, allowing for the design of assessments that provide more valid and equitable score interpretations and uses for culturally and linguistically diverse groups.

Shifting the current testing paradigm requires adopting a critical lens to examine what is valued, and not valued, in the testing process and by whom—from conceptualizing the construct to articulating the intended and potential negative consequences of test use. This lens entails critical analyses of our own culturally informed values, beliefs, and assumptions to uncover potential biases underlying the testing process. Refocusing testing to address validity and equity issues for diverse cultural and linguistic groups requires the inclusion of critical individuals from these groups who can advocate for such identities in the design, development, implementation, use, and validation of tests. Varying, and perhaps competing, perspectives and values need to be considered throughout the testing process. This view of testing has significant implications for validity theory and practice, particularly by considering the linguistic and cultural practices that influence how students learn, as well as the learning theories that explain how students are expected to learn within certain domains.

Although current practices, such as item sensitivity and bias reviews and examination of DIF, have improved the assessment of individuals from diverse backgrounds in some cases, these practices are inadequate. Rather, the field needs to develop and implement testing practices and methodologies that produce more equitable and fair assessments, with a corresponding program of research to evaluate whether these assessments are, indeed, more equitable.

We first discuss testing as a situated cultural practice before considering the importance of learning theories in shaping the design and validation of more equitable educational assessments. We discuss the challenges of framing and conducting validity evaluations of assessments designed to be responsive to test takers' unique cultural and linguistic heritages, but we feature principled assessment design approaches as potential paths forward in this area. Following this, and referenced throughout the section, we address the tension between score comparability and the need for flexibility in test design to foster more equitable assessments of individuals from different cultural and linguistic groups. We end with a proposed IUA and validity argument that may facilitate the design and validation of more culturally responsive assessments. We suggest testing practices for the design and use of assessments that foreground equity and fairness considerations. Addressing equity and social justice issues should lead to improved validity of score inferences and uses for

all forms of testing, including credentialing and licensure testing as well as selection tests, even though there will be several design challenges to overcome.

Testing as a Situated Cultural Practice

As a culturally situated and socially constructed process for understanding what test takers know and can do, testing may not adequately represent the construct as manifested in various cultural, linguistic, and social contexts. In the testing situation, the targeted construct is not necessarily assessed in the same way; rather, it reflects each individual's cognitive skills and knowledge as shaped through social and cultural experiences and ways of knowing (Hood, 1998; Mislevy, 2018; Nortvedt et al., 2020). Performances on tests “are a function not only of the items, tasks, or stimulus conditions but of the *persons* responding and the *context* of measurement” (Messick, 1989, p. 14). The knowledge and processes evoked by test takers when performing a task depend on the test taker's cultural, linguistic, and experiential histories as well as the testing situation (Mislevy, 2018). To date, testing generally has overlooked the critical role of situated knowledge, disregarding how cultural and linguistic experiences and practices shape what individuals know and can do. Assessment of test takers from different cultural backgrounds bears on validity and fairness issues in score interpretation and test use because of differential access to, and representation of, the targeted construct (Camilli, 2006; Solano-Flores, 2011).

Tests designed to reflect how individuals learn and express their understandings, and account for different knowledge systems, can provide more valid score meaning and use (Trumbull & Nelson-Barber, 2019). The required backing in support of score meaning and test use for individuals with diverse cultural, social, and linguistic backgrounds needs attention throughout the testing process, from defining the construct and laying out the test design specifications to examining the differential consequences of test use. As an example, Messick (1989) argued that standardization in test materials and administration could be a source of invalidity across different cultures because “individuals from different cultural backgrounds might display their skills or engage task processes more in line with the respondent's cultural context” (p. 57). We acknowledge the need for many licensure and certification tests to adhere to common industry standards (e.g., pilot certification tests) requiring specific ways of demonstrating high levels of knowledge and skills. However, most educational applications can embrace cultural and linguistic heritages and practices to improve the representations of how all students come to know what is being assessed.

The equity and fairness concerns raised by Solano-Flores (2011) bear on the validity of score meaning and test use. Tests are designed to meet particular social needs, including compliance with laws and regulations; they are written in the dialect used by test developers; and test content reflects the knowledge, skills, and communication styles valued by the dominant culture. There is an inherent assumption that test takers are familiar with task contexts, ways of representing problems, and expected ways of responding (Solano-Flores, 2011, p. 3), yet each test taker approaches test items

through their own lens, drawing on their social and cultural experiences and ways of knowing. Experiences of the test takers during an assessment, and consequently their performances, are affected by a complex interaction of test characteristics (e.g., academic content, test language, item type, scoring) and cultural, language, economic, and educational histories of the test takers (Abedi, 2006; Solano-Flores & Trumbull, 2003). Language is central to the design of more equitable assessments because it is associated with the way test takers process, interpret, and understand the language of the task (Solano-Flores & Trumbull, 2003). The need to code-switch—altering tone and language depending on the context—can have undesirable effects on performance (Gregory & Fergus, 2017). Rater language background can be a source of construct-irrelevant variance because raters may interpret test-taker performance through their own cultural and linguistic lenses (Kachchaf & Solano-Flores, 2012). These issues are grounded in the recognition that testing is a situated cultural and social practice, and ways of knowing by test takers are culturally bounded. Both have significant implications for how IUAs and validity arguments are framed and how validity evaluations are conducted.

Addressing these concerns requires thoughtful attention to validity, equity, and social justice issues throughout test design and use, as well as cognizance of how values are reflected in the design, development, implementation, and use of tests. The design of culturally responsive and sustainable assessments requires attention to cultural characteristics as well as cultural assets of individuals, affording the opportunity for individuals from different cultural and linguistic groups to demonstrate what they know and can do. An important goal of culturally responsive assessments is to minimize disparate testing outcomes by race, culture, and language dominance due to the effects of the tests and testing practices. Of course, addressing testing issues is only one step of many to better serve a multicultural society.

Situated Learning, Assessment, and Validity

Modern conceptions of learning expand the range and nature of the evidence that must be addressed in validity arguments, even if the core of validity remains largely unchanged (Mislevy, 2016). Wilson (2018) and Shepard et al. (2018), among others, argued that the validity of assessment results can be enhanced if they are interpreted through a lens that connects assessment and instruction to how students learn. Not surprisingly, Cronbach and Meehl (1955) foreshadowed this work with their conception of the nomological network. The concept of a network makes clear that tests operate within educational systems, and their use cannot be validated without understanding how students are expected to progress through the domain in addition to other aspects of students' cultural and experiential backgrounds and instructional systems.

Socially Situated Learning Theories and Assessment Practice

Sociocultural (e.g., Penuel & Shepard, 2016a; Shepard et al., 2018) and sociocognitive (e.g., Mislevy, 2016, 2018) learning theories are two of the most prominent frameworks researchers are using to reconsider the foundations of educational assessment.

As Mislevy (2016) noted, the “socio” describes “the knowledge and activity patterns that structure individuals’ interactions with the world and others” (p. 267). Mislevy (2016) described three key types of patterns—linguistic, cultural, and substantive—that people learn for work and school, such as concepts and practices. Shepard et al. (2018) effectively summarized sociocultural theory, particularly in how it goes beyond cognitive development:

Sociocultural theory offers a powerful, integrative account of how motivational aspects of learning—such as self-regulation, self-efficacy, sense of belonging, and identity—are completely entwined with cognitive development. Unlike the social psychological and developmental psychology literatures, where each of these variables and related interventions are studied separately, sociocultural theory helps us see how knowledge and self-beliefs are jointly developed in communities of practice, and correspondingly how sense of self and meaningful participation may be harmed in unsupportive learning environments where children may be positioned as unable or deficient learners. (pp. 23–24)

Sociocognitive models are somewhat more limited than sociocultural models in that the former attend more to linguistic, cultural, and substantive patterns, whereas the latter attempt to account for the unique cultural and historical identities individuals bring to learning and motivation. This difference allows sociocognitive models to be a useful foundation for creating and understanding learning progressions based on “common starting points rather than making students’ interests and community experiences part of how interventions are designed” (Shepard et al., 2018, p. 25). However, this requires validity evidence demonstrating the applicability of learning progressions across diverse groups.

The Role of Situated Learning Theory in Assessment Validation and Validity

Validity is judged in relation to the inferences drawn from assessment responses, but how students come to learn the content of the test can influence the inferences one can draw. Insights from situated learning theory should be incorporated into the IUA. It is relatively straightforward to see how claims related to performance, scoring, and generalization inferences would benefit from an examination of how students are expected to come to know the targeted constructs.

Mislevy (2016) describes three types of evidence useful for supporting claims: student performance features, characteristics of the assessment situation, and other information about the student in the assessment situation. Evidence about student performance generally forms the basis of most validity investigations. Considering the linguistic, cultural, and substantive patterns indicated by sociocognitive theory provides richer understandings of the assessment situation, such as how test takers might interact with complex tasks like performance-based assessments.

There has been little attention paid to evidence related to the interaction of the student in the assessment situation, although such information is critical for understanding equity and fairness in assessment, as well as understanding the different evidentiary bases of contextualized classroom assessments compared with more distal large-scale achievement tests (Mislevy, 2016). That said, adhering to a sociocultural rather than a sociocognitive model could very well challenge the validity of inferences from standardized tests that, by design, ignore the uniqueness of individual students. However, Shepard et al. (2020) offered a set of principles to guide the design, implementation, and use of classroom assessment and instructional systems using a sociocultural lens.

Research is needed to explore the interaction among sociocultural theory, large-scale assessment, and validation. Recent work on the validation of instructionally relevant assessments (Pellegrino et al., 2016) is a promising step in this regard. Evaluators must adopt a critical stance when evaluating claims that culturally responsive assessments are more equitable. A strong logical and empirical program of research is needed to address the validity and equity of the assessment of diverse student populations at all levels of an assessment system.

Comparable and Valid Score Meaning

Employing a sociocultural or sociocognitive perspective for test design raises significant challenges for validating large-scale assessments. Comparability of scores is a key use case of large-scale assessments; consequently, the validity of score inferences and uses for most large-scale tests requires evidence of comparability across relevant entities (e.g., students, schools, states). Measurement invariance, a critical assumption in large-scale testing, means the same construct is being measured across different groups (e.g., different cultural and linguistic groups), resulting in the stability of item parameters across these groups. If this assumption is untenable, the validity of score interpretations and uses may be compromised. Principled test design procedures are intended to ensure comparable score meaning for individuals and aggregated groups. Depending on the IUA, aspects of comparability that may need to be examined across different groups include the following:

- response processes elicited
- precision of scores
- accuracy of decisions
- internal structure of the test
- accuracy of equating and scaling
- generalizability of the scores
- relationship between test scores and other measures
- intended and unintended consequences of score interpretations and test uses

For examples, in this section we address how analyses of internal structure and response processes can be adjusted to evaluate the validity of test score interpretations and uses in a more culturally responsive testing context.

Accounting for the heterogeneity of cultural and linguistic groups poses a challenge to these types of validity investigations. Future practices would benefit by reconceptualizing traditionally held beliefs about which individuals constitute a group. At a minimum, the variability of each group must be considered in the interpretation and use of the results.

The validity of score interpretations and uses, however, does not necessarily require all empirical relationships to be consistent across groups because of several factors, including different score ranges across different groups (Linn, 1983). Restriction of range can account for lower reliability estimates and poorer predictive validity evidence for some groups. Distributions of some test-taker groups may be centered in a different region on the score scale as compared with the general test population, and any lack of measurement invariance therefore may be due to nonoverlapping proficiency distributions rather than group status. Examining measurement invariance using a distribution of test takers from the general population that is similarly located on the score scale as the distribution of the group of interest provides more accurate and meaningful results (Buzick & Stone, 2011; Lane & Leventhal, 2015; Quesen & Lane, 2019; Sireci, 2009).

Internal Structure Evidence

Invariance of the internal structure of the test across different groups, and similar performance on items across different groups of similar competency level, support the validity of score meaning and use. DIF can be conceptualized as multidimensionality in test data. DIF could be a shift in the distribution of ability along a secondary construct that influences the probability of a correct response (Camilli, 1992). For example, one group may be more able on a secondary construct, such as English reading skills, when taking a mathematics test. Zwick (this volume) describes a variety of approaches for examining DIF and item bias that can shed light on differential validity of score interpretations and uses. Another approach to evaluate whether an item behaves similarly across different groups of test takers uses person fit indices based on item response theory (see, for example, Engelhard et al., 2014).

Treating a cultural or linguistic group as homogeneous in measurement invariance investigations may inaccurately portray the degree of score comparability (Ercikan et al., 2014; Oliveri et al., 2014; Solano-Flores & Li, 2009). Using Programme for International Student Assessment (PISA) data for Canada, for example, Ercikan et al. (2014) detected a lower percentage of DIF when conducting separate analyses for students who speak French at home and those who do not as compared to when conducting the analyses for the combined group. Such results underscore the need to consider the heterogeneity within each of the linguistic groups. A review of the DIF sources revealed that the linguistic load of the item, vocabulary, and complexity of sentence structure may be factors that disadvantage linguistic-minority students. While there has been more research on the heterogeneity of linguistic and special education student groups, the within-group diversity for racial, ethnic, and cultural groups must be attended to as well.

Response Process Evidence

The processes that test takers use to interpret, understand, and respond to test items are mediated by cultural, linguistic, and experiential factors. The interaction among test-taker characteristics (e.g., culture, language, learning style) and item features (e.g., problem context, graphics, language, response mode) deserves attention in test design and validation. Because different groups of test takers may employ different cognitive processes and strategies when responding to tasks, this differential use of response processes and strategies should be considered in the design of assessments. Similarly, response processes should be evaluated for different groups to inform the interpretation of across-group differences in score meaning (Lane, 2017). Cultural, linguistic, and experiential factors may influence performance in ways not anticipated by the test designer, which can impact the validity and fairness of score meaning and use for different groups. Therefore, cultural and linguistic factors that shape an individual's understanding of a construct must be considered in the design phase. Response process studies may challenge score meaning or the conceptualization of the construct.

Using think-aloud methods, Winter et al. (2006) showed that test-taker characteristics and item features interact to affect access to mathematics problem-solving tasks for English learners. Test takers were more likely to use a successful problem-solving process when items were varied to support better access to, and understanding of, the item. When items allowed for multiple modes of representation, students were more able to demonstrate their knowledge and skills. Using a response process analysis, Proser and Solano-Flores (2011) illustrated that English learners and non-English learners comprehended text differently for science and nonscience content terms and in the way they approached and understood more linguistically challenging sentences. Conducting think-aloud sessions, Ercikan et al. (2010) found that differences in item language in multilingual assessments explained differences in relative item difficulty for different groups. Kopriva and Wright (2017) proposed a conceptual framework for evaluating response processes in the assessment of nonnative speakers based on the premise that test design and score meaning requires an evaluation of the interaction between construct-irrelevant factors that test takers experience when responding to items (e.g., production skills) and conditions that are barriers in accessing the intended content and processes, including linguistic, cultural, and multisemiotic features (communication mode). These researchers proposed a system allowing test takers to use multiple modalities (e.g., nontext), enabling them to better access the assessment and, in turn, communicate their knowledge and skills. By better understanding how test takers use response processes when solving tasks (particularly complex problem-solving tasks) and how these processes may vary across different groups, test developers can improve test design and ensure valid and fair score interpretations and uses for different groups.

Comparability and Culturally Responsive and Sustainable Assessment

A major challenge when implementing culturally responsive and sustainable assessments is achieving the right balance between sufficient flexibility in addressing the needs of diverse cultures and sufficient standardization to meet comparability claims. Comparability among scores is required to make inferences about the relative performance of students and the effectiveness of programs and to monitor the progress of individuals or cohorts. Comparability generally requires some amount of standardization in assessment procedures and design, such as in the content and skills assessed, administration conditions, and scoring rules. Such standardization should support comparable and valid inferences within and across schools and over time (DePascale & Gong, 2020; Keng & Marion, 2020; Lane & DePascale, 2016).

However, flexibility in the design, implementation, and scoring of assessments arguably will better match how students have come to know the content and skills being assessed and, therefore, allow more valid score inferences and equitable assessments. An IUA delineating the intended inferences and assumptions also must describe the required comparability across tasks, across subpopulations, in scoring, and in administration conditions for the stated score interpretations and uses. To obtain a desired level of comparability, assessment features that can be altered must be specified and have accompanying guidance for altering those features (Lane & DePascale, 2016). The assessment designer must pay close attention to features that would allow students to demonstrate different ways of knowing and doing based on their culture, language, disability, and other relevant personal, social, and experiential characteristics. This discussion has focused on large-scale (e.g., state) assessments. Classroom assessments, as well as other tools intended to improve teaching and learning, should adopt more tailored approaches to address validity, equity, and social justice concerns (Shepard et al., 2018).

The Challenges to Validation

Advances in situated learning theory are helping to usher in a new era of educational assessment that holds great promise for improving the validity of score inferences. Similarly, designing assessments to reflect varying cultural and linguistic heritages promotes more valid interpretations and uses and supports more equitable education systems. These advances have considerable implications for validity, but they also complicate the drawing of defensible inferences from students' test scores. Mislevy (2016, p. 266) outlined eight challenges to validity posed by adopting a sociocognitive approach to assessment design and development:

- What do we want to assess?
- What kinds of performances do we need to observe, and in what kinds of situations?
- How should we think about constructs?
- How do we assess higher order skills?

- What is the role of measurement models?
- How do we “score” complex, interactive, performances at scale?
- How do we assess interactional skills?
- How do we take advantage of complex performance tasks?

Mislevy (2016, 2018) reflected on how operating from a sociocognitive perspective highlights the resources individuals have developed to engage in activities prescribed by the linguistic, cultural, and substantive patterns as practices valued by the community. Recognizing the heterogeneity of each cultural and linguistic group, he acknowledged that different linguistic, cultural, and substantive patterns may emerge within a particular cultural and linguistic group. Additionally, he and others (e.g., Ercikan & Pellegrino, 2017; Leighton, 2017) raised concerns that current testing is almost exclusively focused on the final product, whereas sociocognitive and sociocultural theories stress the importance of understanding the processes students pursue to shape their understandings on their way to a final product. Again, it is critical to understand and support these learning processes for almost all K–12 educational assessments.

Mislevy (2016) suggested that, from a sociocognitive perspective, constructs are ways to predict patterns of acting in common situations (or at least somewhat common) based on the resources individuals have developed. In this sense, a construct is as an “aggregation over clusters of individuals’ unique constellation of resources” (Mislevy, 2016, p. 274). Further, Mislevy (2016) noted, a sociocognitive perspective emphasizes that “there is no simple one-to-one correspondence between constructs, assessments, and measures” (p. 275).

Working from a sociocultural perspective, Solano-Flores (2019) provided a framework—more specifically, a “matrix of evidence for validity argumentation”—for evaluating the extent to which the practices and artifacts in a large-scale testing program address cultural diversity. His framework serves as “a tool for systematically gathering, contrasting, and integrating pieces of evidence that confirm or disconfirm the validity of interpretations and use of test scores for a culturally diverse population in a large-scale assessment program” (Solano-Flores, 2019, p. 7). It crosses 6 assessment process components and artifacts with 10 procedural assumptions. The framework serves as criteria for evaluating the rigor of the testing process. The process components include, for example, policies, uses, and consequences, whereas procedural assumptions include, for example, the specification of the population reflecting different cultural and linguistic groups; the inclusion, representation, and sampling of the cultural and linguistic groups; and the intersectionality of test data with other information about cultural and linguistic groups informing test use. Although Solano-Flores (2019) developed this conceptual framework in the context of large-scale educational assessments, much of it is applicable to other types of assessment.

Burns et al. (2019) specified general criteria used by university faculty in the United Kingdom for the design and use of culturally responsive assessments, which are applicable to other classroom assessment contexts as well. To ensure that these assessments yield more valid score interpretations and uses, criteria for the design

process include the consideration of cultural differences in how students interact with the teacher (as an expert authority or as an equal), engage with learning, approach knowledge, collaborate, and experience failure, while also attending to their previous real-life experiences.

Using Situated Learning Theory to Enhance Validity and Validation

Beyond improving how transfer and generalizability are understood, modern theories of situated learning will improve how we design assessments and investigate validity. We have witnessed since the beginning of the 21st century, considerable theoretical and empirical advances in principled assessment design for improving the validity of inferences from assessment results (Mislevy & Haertel, 2006; Mislevy et al., 2003; NRC, 2001; see also Huff et al., this volume). Principled assessment design has been employed purposefully to connect advances in learning theory with assessment design so that validity is incorporated from the design phase and is not an afterthought. We will consider two instantiations of principled assessment: evidence-centered design (ECD) and universal design for learning (UDL). The use of principled approaches allows for intentional and systematic design and validation of assessments that is responsive to different cultural, linguistic, and educational groups.

ECD was proposed as a framework for test design and interpretation that would provide better validity evidence to support inferences from test scores (Mislevy et al., 2003). ECD has three models that are sources of validity evidence: a student model, an evidence model, and a task model. The student model includes the domain modeling of the construct that is the intended focus of assessment. (Although Mislevy refers to *the student model*, this can be considered *the test-taker model* in other testing contexts, including licensure and certification testing.) The task model describes task characteristics (e.g., work products, demonstrations) and the environments in which students produce the desired evidence. Variable features in the task model can influence task difficulty and cognitive complexity. The evidence model, which links the task and student models, describes the evidence necessary to evaluate the student model and how that evidence should be considered when determining whether students mastered the intended knowledge and skills. The evidence model directly connects to the assessment argument by identifying the critical features of performance data scored through rubrics or other means.

UDL is a powerful framework for addressing issues of access and representation in learning and assessment (Dolan & Rose, 2000). Originally conceived to support access to learning and assessment for students with disabilities, UDL principles include the need for multiple means of representation, action and expression, and engagement (Thompson et al., 2002). UDL is now used to address how individuals from different cultural and educational backgrounds can demonstrate their understanding. The application of UDL principles throughout every phase of test design and implementation affords accessible assessments by minimizing

construct-irrelevant barriers that may negatively affect test performance. Moreover, UDL principles can attend to cultural assets to further minimize linguistic and cultural barriers to test performance. The application of universal design principles may differ for large-scale assessments as compared with classroom assessments, where task features can be modified more easily to account for differences in student experience and background. By including constructed-response items, however, large-scale assessments also can be responsive to different cultural and social experiences by permitting multiple means of demonstrating what individuals know and can do. Universal design principles are relevant in the design of tests for other purposes as well, such as licensure and certification.

Mislevy (2018) proposed applying the UDL principle of multiple means of action and expression by modifying scoring rubrics in light of cultural and linguistic considerations and, further, by conditioning differential familiarity into psychometric models using Bayesian networks. The UDL principles of multiple modes of representation and multiple means of engagement inform test design by conditioning task situations on information about test-taker background. Task models allow for variants of content that are more familiar, and of potential interest, to test takers, which provides a “conditional approach to inference” (Mislevy, 2018, p. 241). The use of task models allows for features of task and evaluation procedures to “be varied with respect to construct-irrelevant features across which individuals differ, in ways that leverage the resources each examinee has developed” (Mislevy, 2018, p. 241). Although test takers may be assessed with different variations of a task, each task variant aligns with the construct. Mislevy (2018) advocated enhanced construct representation through a greater reliance on the “theory of the construct,” even at the cost of reduced comparability (p. 242). This approach can enhance the validity of score meaning and use for test takers from different cultural, educational, and social backgrounds. We acknowledge the challenges that such an orientation poses to traditional test design and analysis, but if the validity of score inferences and test use is to be improved, taking us one step closer to social justice in testing, then student diversity must be addressed seriously throughout the testing process.

To be sure, approaches like those described above would be difficult to enact with some tests such as certification and licensure tests, compared with assessments used to inform instruction and student learning. However, even the design, scoring, and analyses of the former should be guided by equity and fairness considerations. The individualization and contextualization required for certification and licensure tests, however, likely will be considerably less than for assessments used to support and evaluate learning in schools.

To achieve fairness and equity in testing, collaboration is required among multiple parties, such as assessment specialists, psychometricians, learning theorists, content experts, and sociocultural experts. Indeed, the design of culturally responsive assessments requires this collective knowledge. The assessment-design advice from Qualls (1998) still resonates in the third decade of the 21st century:

What is perhaps most obvious with regard to this discussion of culturally responsive assessment is the need for collaboration across all stages of development. One must realize, however, that the person most knowledgeable in subject-matter content is not necessarily those most knowledgeable about relevant contextual cultural influences. (p. 297)

IUA and Validity Argument for Culturally Responsive Assessments

IUAs that reveal differing, and sometimes competing, values can enhance score meaning and use for individuals from culturally and linguistically diverse groups. IUAs that account for the different ways of knowing and doing that are relevant to the construct, as well as potential construct-irrelevant barriers for different cultural and linguistic groups, position the design and validation of assessments to be more culturally responsive. The validity argument used to outline the evidence required to support or refute warrants and assumptions should provide backing for claims that the tasks are relevant and meaningful to different cultural and linguistic groups. Additionally, principled assessment design approaches tuned to account for the unique linguistic and cultural backgrounds of test takers can support advances in equitable testing practices.

Table 4.2 provides an initial example of a general IUA and validity argument, focusing on those aspects that are most relevant to the design and validation of culturally responsive assessments. We are aware that the educational measurement field is rapidly advancing its understanding of how to infuse social justice principles throughout the assessment design and validation cycle, and there remains much work to be done. The parts of Table 4.2 that will be deemed relevant for a particular assessment will depend on the specific interpretation and use argument. Our intention here is to foster discussions of principled practices for the design and validation of culturally responsive assessments. The inclusion of stakeholders representing relevant groups will enrich such conversations.

For example, we propose that the performance inference must attend to potential differences in how the construct is defined, depending on different values and perspectives. We also address how potential differences in how individuals from various cultural and linguistic backgrounds internalize task features and contexts may require flexibility in assessment design. The specific use case will determine the extent to which standardization of tasks, scoring, and administration can be relaxed. Evidence to support the scoring inference includes response process evidence for raters. Particularly informative in this regard are evaluations of how raters internalize and apply scoring criteria, which can uncover potential biases, especially those that are subtle and arise from different ways of demonstrating competence in the domain. The generalization inference is supported by studies showing that inferences from the score to the broader domain are warranted for different groups. This includes evaluation of the equating error for different groups (when sample sizes permit).

Table 4.2 Interpretation and Use Argument and Validity Argument Components for Culturally Responsive Assessments

Interpretation and Use Argument		Validity Argument	
Inference	Warrant	Assumptions	Backing or Evidence
Performance: Infer from tasks to performance	Tasks elicit intended KSAs for all test takers	• Defined construct is relevant for different cultural groups • KSAs selected to be assessed are culturally relevant to as many groups as possible • Tasks and rubrics reflect KSAs • Individuals from different cultural groups were not prevented from accessing the test content because of construct-irrelevant features	• Documentation indicating how sociocultural and sociocognitive theories of learning are used for defining the construct • Construct-definition documents, including specifications of how competing values were addressed in defining the construct • Relevant groups involved in defining construct • Documentation indicating how, and by whom, KSAs were identified for inclusion in the blueprint • Documentation of how principled approaches were used in test and task design, including UDL principles • Task and rubric design and development procedures and diverse-expert review • Test-taker response process evidence, such as think-aloud studies for different cultural and linguistic groups
Scoring: Infer from performance to the score	Scoring rule that assigns a score to test performance reflects KSAs for all test takers	• Scoring procedures are appropriate for all test takers and lead to intended score meanings • Rubrics account for different ways of knowing and understanding • Scoring rules and rubrics are applied accurately and consistently for all test takers • Administration procedures are appropriate for all test takers	• Documentation of the design of scoring procedures that account for different ways of knowing and demonstrating what test takers know • Diverse-expert review of rubrics • Studies of comparability of score meanings • Studies examining the appropriateness of flexibility/variations in design • Rater-response process evidence, such as think-aloud studies, to evaluate raters' internalization and application of scoring criteria in ways that reflect equity goals

(continued)

Table 4.2 (continued)

Interpretation and Use Argument		Validity Argument	
Inference	Warrant	Assumptions	Backing or Evidence
			• Rater-consistency and -accuracy monitoring for different cultural and linguistic groups • Evidence of consistency and accuracy of automated scoring algorithms for different cultural and linguistic groups • Evidence of the appropriateness of administration procedures
Generalization: Infer from score to the broader construct or domain	Allows for dependable inferences from performance to score to the expected performance in the broader domain for all test takers	• Test provides a sufficient representation of the KSA in the broader domain • Scaling and equating procedures are appropriate for different cultural and linguistic groups	• Generalizability studies for tasks, occasions, and other relevant facets for different cultural and linguistic groups • Studies of the internal structure for different cultural and linguistic groups (e.g., multi-group factor analyses, person-fit analyses) • Equating error is minimized and similar across cultural and linguistic groups
Extrapolation: Infer from test performance to expected performance in the real-world contexts	There is a relationship between test performance and using KSAs in real-world contexts for all test takers	• Task contexts are relevant for different cultural and linguistic groups • Relationships between test scores and real-world criteria are similar across cultural and linguistic groups	• Expert review of the alignment of KSAs tested to the KSAs used in diverse real-world contexts • Expected relationships between test scores and other criterion measures are similar across different cultural and linguistic groups
Decision/use inference and consequences	Decision rule and uses of test are appropriate for all test takers	• Assignment to performance levels is appropriate across cultural and linguistic groups • Decisions and uses of test results are appropriate and fair across cultural and linguistic groups • Use of tests leads to equitable consequences	• Standard-setting method and procedures are appropriate and address possible adverse impact • Decision consistency and accuracy are similar across cultural and linguistic groups • Evidence that there is a shared understanding by different stakeholder groups of intended positive consequences and potential unintended negative consequences (with any differences documented) • Decisions and uses do not result in negative unintended consequences for individuals from different cultural and linguistic groups

Note. KSA = knowledge, skills, and other attributes; UDL = universal design for learning.

The extrapolation inference calls for evidence that expected relationships between test scores and criterion measures hold for different groups. These are nuanced studies that should consider the reciprocal relationships between academic concepts and concepts developed within one's own culture and community. Consequences are at the core of the decision/use inference; however, unfortunately, there are few studies that have evaluated the consequences of testing programs. When setting performance standards, potential adverse impact should be investigated and minimized, and perceived positive consequences and potential unintended negative consequences held by different stakeholder groups should be documented and evaluated.

Standardization Versus Flexibility

The IUA that lays out the intended inferences and assumptions will shed light on the degree of comparability needed across tasks and student populations and in scoring and administration conditions. The required level of comparability will depend on the purpose and use of the assessment results. For scores to be comparable within a testing occasion and over time requires a level of standardization in assessment design, including the content and skills assessed, administration conditions, and scoring rules and procedures (DePascale & Gong, 2020; Keng & Marion, 2020; Lane & DePascale, 2016; for a discussion on administration and scoring, see Shermis et al., this volume). Departures from standardization in design features, such as task modifications, on the one hand may pose threats to score comparability but, on the other hand, may provide for more equitable assessments. Flexibility in classroom assessments may result in a better alignment with the goals of instruction and more fair and equitable assessments. Validity researchers and other stakeholders must adopt a critical stance when evaluating the claims that culturally responsive assessments are more equitable. A strong logical and empirical program of research is needed to address the validity and equity of the assessment of diverse populations.

CURRENT APPLICATIONS OF VALIDITY THEORY AND PRACTICE

We discuss in this section the application of validity theory to testing, including K–12 assessment systems and technology innovations in assessment design.

K–12 Assessments and Assessment Systems

There are many examples in the K–12 context showing how validity theory and practice are applied when evaluating the quality and usefulness of inferences from test scores. We highlight two applications: interim assessments and balanced assessment systems.

Interim Assessments

Interim assessments have proliferated since the passage of No Child Left Behind (NRC, 2010), to the point where most school districts in the United States use a commercial or state-provided interim assessment. This led Perie et al. (2009) to delineate the variety of terms and uses associated with these assessments, which are situated somewhere between classroom- and state-level assessments. Perie et al. (2009) coined the term *interim* to distinguish between (a) formative assessments having research-based uses to inform instruction and improve student learning (e.g., Black & Wiliam, 1998) and (b) other assessments, which are administered more formally and controlled outside the classroom and lack a research base to support their use.

Perie et al. (2009) documented the many purposes interim assessments are purportedly designed to serve, which they categorized as instructional, evaluative, and predictive (see Table 4.3).

Validation occurs in the context of specific uses to serve particular purposes. There is little independent empirical evidence in support of the quality of interim assessments (e.g., Dadey & Diggs, 2019) or in support of any of the uses for interim assessments summarized in Table 4.3 (e.g., Goertz et al., 2009; Konstantopoulos et al., 2016). Validating score inferences and uses for these purposes would be a considerable undertaking. Nonetheless, if providers claim their assessments support these uses—and do so efficiently and effectively—these providers are obligated to provide the corresponding validity evidence.

IUAs for Interim Assessments

The choice of an interim assessment, whether by state, district, or school leaders, should be driven by the intended purpose of the assessment (Perie et al., 2009). An interim assessment chosen for instructional purposes should be linked to specific instructional

Table 4.3 Interim Assessment Uses

Category of Use	Most Common Stated Uses
Instructional	• Modify or improve instruction • Identify students needing additional support • Identify content to reteach • Differentiate instruction • Document individual student growth within a school year
Evaluative	• Monitor program initiatives • Monitor performance for accountability • Evaluate curricular programs • Monitor performance trends of identified student groups • Improve overall school performance
Predictive	• Forecast performance on the end-of-year summative assessment

units, thereby providing teachers with meaningful results that inform instruction and student learning. Such assessments likely are more aligned with local instruction and assessments than other types of interim assessments. An interim assessment chosen for evaluative purposes should provide information for modifying and improving curriculum and, consequently, instruction. An interim assessment chosen for predictive purposes should provide information regarding how well the student is likely to perform on the end-of-year assessment. Depending on their purpose, interim assessments should have different designs and require different validity evidence to support score meaning and use. We focus here on the purported instructional uses of interim assessment.

Pellegrino et al. (2016) provided a helpful framework for evaluating the validity of test score inferences from assessments intended to support instruction and student learning. They identified three types of validity—cognitive, instructional, and inferential—that should be used to structure validity arguments and evaluations of such assessments. Although we do not agree with their terminology—their three categories arguably are types of evidence, not types of validity—we believe their framework can be applied to the validation of interim assessments intended to improve teaching and learning. Cognitive evidence refers to how an assessment elicits evidence of test takers' KSAs and ties to an underlying research-based model of learning. Instructional evidence reveals the extent to which the assessment is aligned with the enacted curriculum and students' opportunities to learn the targeted knowledge and skills. This facet also includes evidence regarding how well assessment results provide insights into student understanding, enabling educators to adjust their teaching practices accordingly. This important use clearly overlaps with the consequential evidence that a more typical IUA speaks to. As such, instructional evidence should be collected to determine whether, and how, the assessment results lead to missed instructional opportunities or more egregious unintended negative consequences. Finally, inferential evidence is important for evaluating the use of assessment score inferences for instructional purposes. As Pellegrino et al. (2016) stated, this line of evidence focuses on “the extent to which an assessment reliably and accurately yields model-based information about student performance, especially for diagnostic purposes” (p. 62).

These three forms of evidence overlap with the types of evidence called for in the 2014 *Standards*. Further, they should be integrated into an IUA to support a pragmatic approach for evaluating the validity of assessment results and uses that are intended to support teaching and learning. Most interim assessment providers make strong claims about the utility of their assessments to improve student learning by better directing teacher actions. Such claims require strong evidence, along the lines Pellegrino et al. (2016) argued for. Unfortunately, there is essentially no independent evidence to support the strong claims made by the providers of interim assessments (e.g., Dadey & Diggs, 2019).

We have stated throughout this chapter that validity is evaluated in light of specific intended interpretations and uses. Ing et al. (2021) recently emphasized and extended this point. They provided compelling evidence that one cannot simply assert that validity evidence transfers from one purpose to another. Rather, validation must attend to specific contexts, which is important advice for interim assessment providers to bear in mind. Just because a set of interpretations and uses are justified in a wealthy suburban district, for example, does not mean these interpretations and uses are therefore justified in a different context.

Balanced Assessment Systems

There has been a long-standing belief that a balanced and integrated system of assessment, curriculum, and instruction would inform instruction and enhance student learning (Pellegrino et al., 1999; Shepard, 2000). Shepard (2000) discussed the need to reconceptualize classroom assessment practices so that they support student learning. This includes changing the content and form of classroom assessments to better reflect critical thinking and problem-solving skills and changing what information is collected to better inform the teaching and learning process. Coherence across classroom assessments and large-scale assessments requires a reconceptualization of classroom assessments, as well as a restructuring of state assessment and accountability programs. A balanced assessment system is achieved when the assessments in the system are coherently linked through a clear specification of the learning targets, comprehensively support multiple purposes and uses, and continuously monitor student learning over time (NRC, 2001). These properties of coherence, comprehensiveness, and continuity inform the design, use, and validation of high-quality balanced assessment systems (NRC, 2001).

Research-based theories of situated learning must form the basis of large-scale assessments and classroom assessments to ensure coherence across them and to improve the instruction and learning process (NRC, 2001; Shepard et al., 2018; Wilson, 2018). This requires tailoring the shared theories of situated learning to the assessment purpose and use, where the corresponding model of learning could be broader for large-scale assessments that monitor trends and are used for accountability purposes and finer grained for assessments used to inform instruction and improve student learning. Theories of learning situated in a social context support teaching and assessment practices that recognize different ways of knowing and doing and, consequently, can promote equity and social justice (Penuel & Shepard, 2016b). Sociocultural learning theories must form the basis for these balanced assessment systems, requiring that both assessments and instruction are responsive to different ways of knowing, shaped by the social and cultural experiences of students. Flexibility in the design of formative assessments allows for the experiences and backgrounds of students to be considered. However, evidence should be collected to support, or potentially refute, that such flexibility in assessment design leads to more valid score meanings and uses for the intended subpopulation.

A Tightly or Loosely Coupled System

Marion (2018a) suggested that designing a comprehensive assessment system requires a “loose coupling” (p. 45) between large-scale and local assessments, relaxing the criteria of a “tightly coupled system” advocated in *Knowing What Students Know* (NRC, 2001). A tightly coupled system may threaten the validity of score meaning and use for assessments at one or more of the levels of the system. If classroom assessments mirror large-scale assessments—which measure a restricted depth of KSAs—the former will therefore provide limited useful information for improving instruction and learning. Marion (2018a) provided examples of states that have loosely coupled systems where information from one level (e.g., classroom) does not necessarily support the purposes at another level (e.g., accountability). This allows for the assessment of the content more deeply at appropriate levels of the system to provide more meaningful information to assessment users. An IUA that specifies the claims for each level of the assessment system allows score interpretations and uses to be tailored to each level.

IUAs for the Assessment System

A multilevel IUA is required for evaluating the validity of an assessment system. Each assessment (or at least the major assessments) in the system must be evaluated in view of the assessment’s intended interpretations and uses, as articulated in the IUA. The IUAs for the assessments in the system must address the degree to which each assessment contributes to supporting the quality of the system as a whole. A prominent challenge for large-scale summative assessments is to produce score information that is explicitly tied to the specific content and skills students are expected to learn (i.e., content referenced growth). *Knowing What Students Know* (NRC, 2001) addressed this challenge over 2 decades ago, but, unfortunately, little progress has been made in this regard (Marion et al., 2019).

As we have noted, the NRC proposed three criteria—coherence, comprehensiveness, and continuity—for evaluating the balance of an assessment system (NRC, 2001). These criteria have not been operationalized so that the field has sufficient guidance for judging, say, how much coherence is required for concluding that an assessment system is balanced. Nevertheless, an assessment system’s IUA must clearly delineate the goals and purposes, intended score interpretations and uses, and intended consequences and potential undesirable consequences of each assessment in the system and the system as a whole. The system-level IUA should articulate claims regarding coherence, comprehensiveness, and continuity in terms of overall system goals. Further, because assessment systems are designed to support multiple users and stakeholders in the educational system, the utility and consequences of assessment scores must be central to any validity evaluation of the assessment system.

There is no question that creating and evaluating a multilevel IUA will be challenging for validity evaluators and assessment system stakeholders. Like other complex evaluations, validity evaluators should begin with the system’s highest-priority goals. In the case of assessment systems, these often will address considerations regarding utility and consequences, while the evaluation of score interpretations generally will be based on evaluating arguments associated with individual assessments.

Technology Use in Testing Programs

Many testing programs make use of technology, such as technology-enhanced items, automated scoring, and computer-based simulations, which provide opportunities for enhancing the validity of score meaning and test use (see Bennett et al., this volume). The rapid development of technology provides both opportunities and challenges to the design, development, implementation, and use of assessments. For example, a key advantage of computer adaptive testing is its capability to select tasks appropriate to the test taker's competency level. However, if the content specification targets used to guide this selection are too coarse, it threatens the representation of the assessed construct for the test taker and, therefore, compromises the validity of score interpretations and uses. Evidence to support the construct representation of a computer adaptive test requires an evaluation of the alignment of the test that test takers actually receive with a more refined, meaningful level of test specifications.

The use of technology in testing programs varies, from the design and development of technology-enhanced items (e.g., drag and drop, audio and video clips) to simulation tasks and game-based assessments. The latter require innovative assessment designs that present dynamic, engaging interactive tasks assessing complex knowledge and skills. In the assessment of language learners and students with disabilities, technology can promote access to test content by providing accommodations that enhance the validity and fairness of score interpretations and uses (E. Stone et al., 2016), but it also can introduce a new source of construct-irrelevant variance.

Recent technological advances, such as educational data mining and machine learning, have potential to assess difficult-to-measure competencies, competencies based on cognitive models of achievement and learning, and competencies that require complex problem-solving, strategies, and reasoning. An overarching goal in the use of these technological advances in test design is to improve construct representation while minimizing construct-irrelevant variance. Educational data mining and machine learning can capture salient features of the processes and actions used by tests takers. They are used in the design of simulation-based assessments, game-based assessments, and collaborative problem-solving assessments with the goal of obtaining rich data on individuals' actions and processes in real time for primarily formative purposes. These advances, however, must be critically examined for potential threats to validity.

Technology Use in Capturing Response Processes

Researchers have leveraged technology in designing assessments that better measure response processes critical to claims regarding complex problem-solving. Technological advances allow for capturing evidence of the processes underlying performance in real time and for assessing a wider range of test-taker behaviors, thereby improving construct representation. Response process data are essential to the design, development, and interpretation of assessments measuring complex cognitive constructs (Ercikan & Pellegrino, 2017; Zumbo & Hubley, 2017). Oranje et al. (2017) discussed three types of data—logs, response time, and eye tracking—that are indicators of underlying processes

and can therefore shed light on score meaning. In game-based learning environments, for example, data logging and educational data mining can capture behavioral events that link game play to the individual's knowledge, cognitive skills, and strategy use. Statistical methods such as cluster analysis can then be used to analyze and summarize the logged behaviors by extracting clusters of behaviors representing different cognitive patterns (e.g., different strategy use). These data types can shorten the inferential distance between claims and test performance by testing proposed inferences pertaining to the intended construct. These data types also can improve test design and user interfaces, provide a context for the inference about the intended construct, serve as indicators of engagement, and remove noise from the process data (Oranje et al., 2017).

Process data obtained throughout test design, development, and implementation can inform the validity of score interpretations and uses by identifying potential sources of construct-irrelevant variance and providing evidence to support (or refute) process models. Although technology-based assessments can produce a large amount of data, one must determine which data are relevant and how they are to be aggregated to justify score inferences and uses. Response process data are as important for disconfirming IUA assumptions as they are for corroborating them (Kane & Mislevy, 2017). Automated scoring, simulation-based assessments, game-based assessments, and collaborative problem-solving are examples of rapidly developing areas that are harnessing advances in technology and machine learning (Mislevy, 2018; Mislevy et al., 2012, 2014; von Davier et al., 2017).

Automated Scoring

As the field moves away from human raters to automated scoring, as in the evaluation of test-taker responses to virtual performance tasks and constructed-response tasks, a paramount validity consideration is the meaning of scores generated by scoring algorithms. Automated scoring involves traditional methods (e.g., regression) as well as more contemporary ones (e.g., natural language processing and machine learning) and has potential to improve the validity of score inferences and uses. Specifically, automated scoring applies the scoring rubric consistently, enables test designers to control the features considered in scoring, captures multiple aspects of performance, and allows for timely score reporting (Powers et al., 1998; Williamson et al., 2006). Further, its uniform application across individuals has the potential to promote score comparability. These benefits notwithstanding, automated scoring carries potential threats to validity. For example, the assessment is vulnerable to construct underrepresentation by only measuring KSAs amenable to machine scoring. Also, test length is a strong predictor of human essay scores; unless its weight is decreased in the automated scoring system, this will contribute to construct irrelevant variance.

Williamson et al. (2012) provided an argument-based validity framework for evaluating automated scoring, identifying the evidence needed to support scoring, generalization, extrapolation, and decision/use inferences. (This work extended the validity framework offered by Clauser et al., 2002.) A common source of validity evidence to support the scoring inference is the relationship between automated and human scores,

relative to the relationship between two human scores. Bejar (2012, 2017) argued that human scores require an appraisal of their own IUA before they can be used for the design and validation of automated scores. He referred to this as the first-order IUA for automated scoring. Such an IUA also requires evidence to support the human scores of responses used to train the scoring algorithm.

The sample of human scored test-taker responses for training and calibrating the scoring engine needs to be evaluated in terms of its representativeness of the potential types of responses and of the score scale when compared to expert human scorers (Bennett & Zhang, 2016). The sample of responses for training should be drawn to adequately represent different cultural, linguistic, and disability groups in the population of potential test takers to ensure that the algorithm does not favor one group's way of responding over others (Kolen, 2011). Kolen (2011) called for research to investigate the comparability of scores based on using test-taker responses from different cultural and linguistic groups to train the scoring algorithm. For example, one could examine the "difference in scores for African American students if the engine was trained only on African American students, only on White students, or on a combination of African American and White students" (M. J. Kolen, personal communication, June 17, 2019). Such a study would address the concern that assessments of writing proficiency privilege the American English dialect (Randall et al., 2022). Similar studies could be expanded to include other groups (e.g., Hispanics, English learners, Indigenous people, students with disabilities), moving one step closer to the design of more culturally responsive and sustainable assessments that consequently provide more valid score inferences and uses.

Other sources of validity evidence include the generalizability of automated scores to other tasks, settings, and contexts; the extent to which the expected relationships to external criteria hold; and the extrapolation from automated scores to performance on a real-life measure (Bennett & Zhang, 2016; Williamson et al., 2012). Clauser et al. (2002) discussed the degree of judgment inherent in the design of scoring algorithms, calling for investigations of the comparability and generalizability of scoring algorithms developed by equally qualified experts. Harik et al. (2013) studied different groups of content experts who developed rule-based scoring algorithms for virtual simulations. These researchers found a group effect, indicating that it matters what group of content experts is chosen for training the algorithm when using rule-based methods.

Culturally responsive design of scoring algorithms requires investigations of the comparability of score meaning across diverse groups. This includes appraisals of group differences regarding relationships with human scores and relationships with external measures, as well as evaluations of the extent to which generalizations and extrapolations are comparable across groups. In their discussion of threats to the validity of automated scoring, Clauser et al. (2002) indicated that features in the algorithms used to predict human scores can be sources of construct-irrelevant variance. For example, Bejar (2012) found that the extraction of features, and the synthesis of those features in the scoring engine for the GRE Analytic Writing task, were vulnerable to

construct-irrelevant test-taker strategies, such as adding words to increase the length of the response. Some test takers used strategies to maximize their scores in a construct-irrelevant manner, which posed a threat to score meaning and use.

Mao et al. (2018) provided backing for the decision/use inference of an automated scoring system for a formative assessment of science argumentation. Their results supported the assumption that feedback based on students' automated scores would prompt students to modify their responses and improve their scientific argumentation skills as they revised their responses.

Simulation-Based Assessments

Technological advances allow for creating and emulating complex real-life scenarios and provide opportunities to assess individuals' capabilities in such scenarios. Computer-based simulation tasks can entail the measurement of complex reasoning and inferential skills that are difficult to measure in traditional forms of assessment. Many of the advantages and challenges in the design, implementation, and use of simulation-based assessments are not unlike those of other performance-based assessments, such as threats to the generalization inference (Lane & Stone, 2006), but additional challenges and opportunities arise in the virtual environment. Credentialing and K–12 classroom-based assessment programs both have seen the implementation of virtual simulation tasks that vary in their level of complexity and interactivity. Simulation-based assessments, including game-based and collaborative problem-solving assessments, can capture individuals' interaction patterns to assess learning and provide scores for achievement and noncognitive domains alike.

IUAs for Simulation-Based Assessments

IUAs for simulation-based assessments depend on the particular use of the assessment, but there are common aspects across IUAs. Underlying the use of simulation tasks is the expectation of improved construct representation and improved extrapolation from the performance to the real-life context, given a key assumption: The KSAs required by the simulated performance reflect those used in the real-life context. Regardless of how well designed they are, simulation tasks are not identical to the real-life criterion insofar as the simulation task may model some features of the real task while excluding others. Capturing the full richness of complex performances may be challenging because of constraints in the virtual environment. Backing for the assumption that the simulation is sufficiently similar to actual performance would include evidence gathered from the task and scoring design procedures, such as cognitive models used in the design and their appraisal by content experts. The development of cognitive models that underlie test-taker performance is an iterative process, requiring ongoing validity research. Empirically and theoretically based cognitive models are not available or fully developed in most domains; thus, specification of the process features may pose challenges and affect the validity of score meaning and use.

Construct representation, as well as inferences from task to targeted performance, are supported through the use of ECD in that student models comprising the targeted

KSAs are linked to task models, and task models then are linked to evidence models that describe test-taker competency on the targeted KSAs. Construct representation rests on the alignment of (a) the elicited processes and behaviors and interaction patterns in the virtual assessment with (b) those processes, actions, and interaction patterns used in real-life contexts (Mislevy, 2018; von Davier et al., 2017). Explicit delineation of claims and evidence can reduce construct-irrelevant variance and help ensure sufficient and accurate representation of the intended KSAs and interaction patterns. Other sources of construct-irrelevant variance in the design phase requiring attention include irrelevant text and representations that lead to extraneous cognitive processing that may negatively affect performance (Quellmalz et al., 2013).

More equitable assessments will result from having different cultural norms and linguistic patterns represented in the design phase, along with attending to salient features of task design and construct representation (Mislevy, 2018). Including cultural and linguistic experts in the construct definition and design phase will help uncover, and then incorporate, construct-relevant cultural differences in interaction patterns, thus avoiding a source of construct-irrelevant variance and enhancing score meaning (Oliveri et al., 2019). Response process evidence from think-aloud sessions and cognitive labs can provide additional backing for construct representation, as well as for making inferences from the task to performance. Such evidence also can uncover potential sources of both construct-relevant and construct-irrelevant variance.

Clauser et al. (2016) examined the warrants and backing for scoring, generalization, extrapolation, and decision/use inferences for simulation-based assessments. A principled design approach can support the scoring inference because the identification of needed validity evidence is inherent in the design phase, allowing salient features of test takers' competencies to be captured (Clauser et al., 2016). Standardizing the administration of the task based on test-taker actions, and standardizing how scores are derived for test takers who have the same path when working on the task, can provide additional backing for the scoring inference (Clauser et al., 2016). However, such uniformity and standardization may restrict different pathways that reflect diverse backgrounds and, therefore, affect the validity of score meaning and use. Although not focused on linguistic and cultural factors, Zhai et al. (2021) recently advanced a framework for the validation of machine learning for the Next Generation Science Assessment initiative. Their framework addresses the complexity of applying and validating machine-learning processes in the context of multidimensional science assessments. They noted that machine learning may foster the assessment goals of Next Generation Science Standards (2013), but machine learning also may introduce construct-irrelevant factors threatening the validity of score interpretations and use. Addressing how machine learning algorithms interact with various cultural and linguistic backgrounds will undoubtedly pose additional design and validity challenges.

The aggregation of data to produce scores may be problematic in the absence of a cognitive model. While construct representation may be supported for a particular task in terms of assessing KSAs that are used in the criterion context, the generalization

inference may be jeopardized. As is the case with most performance assessments, a few simulation tasks typically are sampled from the domain, which limits the generalizability of the score inferences to this domain. In a formative assessment and learning environment, generalizability to the broader domain of tasks may not be a concern. Because test-taker performance and resulting scores are affected by the choices made in the design phase of simulations, appraising how inferences may vary with different design choices will provide additional backing for the scoring inference (Mislevy et al., 2016).

Validity evidence to support the extrapolation inference derives, in part, from the demonstrated alignment of simulation-task content with the knowledge and skills needed to perform the task in the criterion setting and the demonstrated relationship between assessment scores and performances in the criterion setting (Clauser et al., 2016). If test takers respond to the task differently in a testing context versus the criterion setting, this may contribute to construct-irrelevant variance (Clauser et al., 2016). Test takers may use different strategies and processes when responding to virtual tasks than when in the criterion setting. This may be less of a concern for well-designed, engaging game-based assessments used for formative purposes. Other potential sources of construct-irrelevant variance include the use of virtual agents, interface and representations that are possibly unfamiliar to the test taker, and the level of test-taker engagement and motivation. The interaction of these sources with the test takers' cultural, social, experiential, and personal background may further complicate validity. For example, while not assessment related, racial bias in facial recognition software (Harwell, 2019) arguably has implications for designing and implementing automated learning systems and the corresponding assessments. Undesirable consequences of the decision/use inference include narrowly focusing instruction on the assessment's scoring criteria instead of the KSAs in the broader domain (Clauser et al., 2016).

Collaborative Problem-Solving Assessments

Virtual collaborative problem-solving assessments, designed primarily for formative purposes, carry validity threats as well. For example, construct-irrelevant variance can result from variability in partner skill: A test taker may have insufficient opportunity to demonstrate maximum performance on a collaborative problem-solving task if their human collaborator has limited collaborative skills. The use of a virtual, rather than human, agent may provide the opportunity for test takers to better demonstrate their KSAs (Rosen, 2017; Scoular et al., 2017). Although virtual agents allow for uniformity in paths for those test takers who perform the same action, they may be a source of construct-irrelevant variance because they cannot adjust to unusual test-taker behaviors (Rosen, 2017). Further, the use of virtual agents may impede task engagement by test takers. When the intended population of test takers is diverse, test designers should consider how virtual agents are presented and the language they use (Oliveri et al., 2019). Think-aloud sessions can throw light on whether interaction patterns differ across culturally and linguistically diverse groups and, further, whether features of this interaction space differentially impede the performance of these groups.

Challenges to the scoring inference can arise when disentangling domain-relevant competencies (e.g., science inquiry skills) from collaborative skills, given the data. Supporting evidence is required to generalize test-taker performance across different groups of collaborators (e.g., categorized by skill level, cultural and racial background, gender), tasks (and task features, such as a virtual agent vs. a human collaborator), and occasions (Rosen, 2017). The assumption of an improved extrapolation inference for these assessments over more traditional formats requires support. The challenge of capturing the richness of the real-life interaction in a virtual environment affects construct representation. For example, in a study that modeled different patterns of interaction, where some patterns were more related to learning than others, Andrews et al. (2017) detected a “fake collaboration” pattern where both members of the dyad appeared to collaborate but maintained their own responses regardless of their prior agreement with the other’s response.

Technological advances in assessment design, implementation, and scoring have the potential to assess competencies that have been difficult to measure, assess complex problem-solving and inferential skills, and enhance validity and fairness of score interpretations and uses. However, a critical examination of potential threats to validity and fairness should be undertaken for technology-based assessments.

CONCLUDING COMMENTS

Validity is at the core of every aspect of testing, from conceptualizing and defining the targeted construct to evaluating the consequences of test use. The design of tests begins with an IUA that explicitly links the inferences from the tasks to the decisions and uses and then to the resulting consequences. The validity argument provides a comprehensive framework, including the rationales, assumptions, and backing or evidence, to support (or refute) the inferences and uses laid out in the IUA. IUAs and validity arguments must attend to fairness issues in the testing process.

Fairness issues are fundamental to the validity of score meaning and test use for individuals from diverse groups. We have argued that fairness issues are validity issues and, therefore, must be addressed in the IUA and validity argument. Testing programs that explicitly address how cultural and linguistic experiences and practices shape how individuals learn, know, and demonstrate their understanding can lead to more equitable assessments. Sociocultural theories of learning provide a foundation for the design of assessments that embody different ways of knowing. More valid score meaning and use can be achieved by leveraging technology and advanced psychometric methods in the design of tests to better capture processes and strategies that are construct relevant but may differ across population groups (e.g., Mislevy, 2018). A well-crafted IUA and validity argument must address scoring meaning and use for individuals from all targeted population groups.

We have proposed an approach for crafting IUAs and validity arguments in response to calls for more culturally responsive and sustainable assessments. While some aspects may be more relevant for educational tests than credentialing tests, credentialing tests

must also attend to fairness and equity issues. As an example, medical licensure tests for physicians typically assess communication and interpersonal skills. Assessment of these skills should reflect physicians' need to understand different cultural norms in communicative styles and expressive language. Such sections of licensure exams could assess how the test taker pays attention to and responds appropriately when interacting with individuals from different cultures.

We must accelerate efforts to improve the validity of score meaning and use for individuals with differing cultural, linguistics, experiential, and personal backgrounds. Although they pose challenges, advances in measurement models, sociocultural learning theory, and technology hold promise for the design and use of culturally responsive and sustaining assessments. We support the call for a justice-oriented framework for conceptualizing constructs and identifying construct-irrelevant sources of variance to better promote and assess diverse cultural and linguistic ways of knowing and doing (e.g., Gordon, 1995; Gordon Commission, 2013; Randall, 2021). Similarly, we must ensure that the design of the IUA and validity argument addresses any inherent biases so these arguments are designed to better ensure valid score inferences and test use for traditionally marginalized cultural and linguistic groups.

ACKNOWLEDGMENTS

We are grateful for the thoughtful reviews of the chapter provided by Joan Herman, Michael Kane, Paul Newton, and Lorrie Shepard. We are also in debt to Jennifer Randall and Guillermo (Willy) Solano-Flores for their insightful suggestions on the section "Assessment of Individuals With Varying Cultural and Linguistic Backgrounds." Our editors, Linda Cook and Mary Pitoniak, provided excellent support and advice throughout the process. We would also like to note that this chapter was completed in the beginning of 2022.

NOTES

1. The *Standards* discussed fairness in terms of validity of interpretations for intended uses, whereas we argue that fairness pertains to validity of interpretations *and* uses *and* the resulting consequences.
2. Loevinger (1957) reported that a subcommittee (Meehl and Challman) of the APA committee drafted the first version of the *Technical Recommendations* and was the first to propose the term construct validity.
3. The 2014 *Standards* used the phrase *evidence for validity and consequences of testing*, as if to separate validity from consequential evidence.
4. Chapelle et al. (2010) used the term *utilization inference* instead of *decision/use inference*, which aligned with the terminology used by Bachman (2005).

Reliability in Educational Measurement

Won-Chan Lee

University of Iowa

Deborah J. Harris

University of Iowa (Retired)

This chapter is dedicated to exploring the concepts, quantification, and estimation of reliability and measurement errors, primarily within the framework of three prominent measurement theories: classical test theory (CTT), generalizability theory (GT), and item response theory (IRT). CTT, a well-established presence in the field of educational measurement, has consistently featured in previous editions of *Educational Measurement*. GT, having a shorter history than CTT, is often perceived as an extension or liberalization of CTT. The reliability chapters in prior two editions of *Educational Measurement* (Feldt & Brennan, 1989; Haertel, 2006) have provided relatively extensive treatments of GT. While the concept of reliability and measurement error can be discussed in the context of IRT, previous emphasis in IRT literature has typically centered around other aspects of the theory, such as model types, estimation of item and proficiency parameters, model fit, test construction, and scoring (see Hambleton, 1989; Yen & Fitzpatrick, 2006). With the growing applications of IRT in research and operational settings, it has become commonplace to present reliability information based on IRT models. Therefore, there is a pressing need to develop a cohesive framework for discussing reliability-related issues under the general assumptions of IRT. These three measurement theories offer distinct perspectives on various aspects of reliability, grounded fundamentally in their assumptions, which have significant consequences for the quantification and interpretation of reliability. This chapter primarily focuses on highlighting the similarities and differences among the theories in terms of conceptualizing and estimating various reliability statistics.

TERMS AND BACKGROUND

Measurement procedures are developed in accordance with the intended purposes of testing and the use of test scores for specific objects of measurement (e.g., test takers). This involves the identification of a set of tasks (e.g., multiple-choice items, essay prompts), administration modes (e.g., paper-pencil, computerized adaptive), scoring procedures (e.g., number correct, human rating), types of reported scores (e.g., summed raw scores, transformed scale scores), and score interpretations (e.g., norm-referenced, criterion-referenced). A specified set of measurement conditions constitutes a *test form*, with alternate forms encompassing different sets of similar (or parallel) measurement conditions. A sample of a test taker's responses to a test form is collected to generate one or more observed scores, which are then used to make general inferences about the test taker. The *observed score* for a test taker is considered a realization of a hypothetical distribution of all possible observed scores across repeated measurements using parallel forms of a measurement procedure. This observed score functions as an indicator or proxy for the underlying, unobservable *construct(s)* (i.e., domain of knowledge or skills) that a measurement procedure intends to measure. In IRT, proficiency estimates serve a similar role to observed scores.

Reliability, broadly conceived, is concerned with quantifying the extent to which observed scores are consistent over replications of a measurement procedure. However, the term *reliability* is often used to refer to *reliability coefficients*, which represent just one of many types of measures assessing the consistency of test scores. In this chapter, we make a clear distinction between these two terms. We use *reliability* to encompass a wide array of concepts and statistics used for quantifying the consistencies and/or inconsistencies in scores for individual test takers or groups of test takers. In a similar vein, the term *measurement error* is used broadly here to refer to both the sources of score inconsistencies and the summary statistics quantifying them for individual test takers or groups of test takers. It is evident that the characteristics of a measurement procedure play a crucial role in shaping the definition, interpretation, and estimation of statistics for reliability and measurement error. A particular focus will be placed on emphasizing the importance of reporting results for various statistics on the metric of *reported scores* used to make decisions about test takers. This is crucial because switching from one score scale to another, especially when the transformation is nonlinear, can lead to markedly different results and interpretations.

In his last paper, Cronbach (2004) stated,

In the history of psychometric theory, there was virtually no attention to this distinction [between sample and population] prior to 1951. . . . It was not until Lord's (1955) explicit formulation of the idea of random parallel tests that we began to write generally about the sampling, not only of persons, but of items. This two-way sampling had no counterpart in the usual thinking of psychologists. No change in procedures was required, but writing had to become more careful to recognize the sample–population distinction. (pp. 401–402)

This statement recognizes Lord's significant contribution in bringing attention to the concept of *replication*, particularly in terms of sampling items. The distinction highlighted here is between an estimate of reliability specific to a particular sample of items and the desired population value that would be obtained over many other random sets of such items. The concept of replications becomes a central element in modern theory of reliability (Brennan, 2001a; Feldt & Brennan, 1989; Haertel, 2006), and it is used as a unifying framework throughout this chapter for discussing various theories, models, and estimators of reliability. The sample–population distinction mentioned in the above quote naturally draws attention to two overarching notions or phases in reliability analysis: *conceptualization* and *estimation*. Brennan (2001a, 2001b, 2006) similarly emphasized this distinction, albeit in a slightly different manner.

The notion of *conceptualization* refers to an investigator's conception of the intended use and interpretation of reliability, which calls for defining a set of measurement conditions for replications of the measurement procedure. The set of conditions allowed to vary across replications are the sources of inconsistencies in scores (i.e., measurement error), which need to be considered when estimating reliability. It is important to note that there is no universally correct or optimal definition of replications.

The determination of which sources of measurement error to include is at the discretion of the investigator and depends primarily on the intended uses and interpretations of test scores.

The *estimation* phase involves quantifying reliability estimates (i.e., estimated reliability statistics) that best capture the characteristics defined in the conceptualization phase and requires decisions on the appropriate reliability statistics and data collection designs. The meaningfulness of interpretations from a reliability estimate hinges on how faithfully the specifications in the conceptualization phase are reflected in the estimation phase. Thus, it is essential to choose and compute a reliability estimator using an appropriate data collection design that effectively incorporates, within practical constraints, the influence of the specified sources of measurement error deemed important by the investigator. If the chosen reliability statistic involves sources of measurement error different from those conceptualized, an explanation is necessary. This is because the results could either overestimate or underestimate the parameter of interest, and understanding any divergence is crucial for accurate interpretation.

Consider, for example, an investigator wanting to estimate how consistent the rank orders of IRT proficiency estimates for candidates applying to a degree program remain when tested with a different set of multiple-choice items, possibly at different times. The measurement procedure involves the target population, exam characteristics, score metric, and score interpretation. The conceptualization envisions replication involving the use of different items and testing occasions.

For a direct estimation, data from two alternate test forms are collected from the same group at two separate occasions, applying the same IRT scoring method to both data sets. The estimated reliability coefficient is derived from the correlation between the proficiency estimates, aligning with the investigator's conceptualization of using different items and occasions.

Now, suppose the investigator chooses to report coefficient alpha based on a single administration with number-correct scores. This fails to address the original question, given that the metric of interest is IRT proficiency, not number-correct scores. Additionally, coefficient alpha overlooks testing occasions as a source of error, likely resulting in an underestimate of error variance and, consequently, an overestimate of the reliability coefficient. This example underscores the importance of selecting a reliability estimator that aligns with the conceptualized replications and is consistent with the intended use of the measurement procedure.

The preceding discussion on the conceptualization-estimation scheme is mostly aptly characterized within the framework of GT. However, the same principle is applicable to reliability analyses under CTT and IRT. The key distinction lies in the fact that, in CTT and IRT, investigators often select a reliability estimator and/or a data collection design without giving serious consideration to what constitutes replications. In effect, the investigator is making assumptions about replications, whether intentionally or unintentionally, through their choices. It should also be noted that

the three measurement models differ not only in their mathematical representations, but also in the framework for conceptualizing replications, true score, and measurement error, leading to potential ambiguities when interpreting results. The following section discusses some of the conceptual similarities and differences among the three measurement models regarding the definitions of true score and measurement error.

Throughout this chapter, the term *consistency* is primarily used to depict the variability of scores over replications. The term *precision* has also found use in the literature, including in the current *Standards for Educational and Psychological Testing* (*Standards*; American Educational Research Association [AERA] et al., 2014), particularly in the context of reliability. Although the term precision literally denotes *exactness*, which diverges in meaning from the concept of consistency, it is occasionally used in this chapter when the context deems it more suitable. The term *accuracy* is specifically reserved for one of the classification indices, known as classification accuracy. This usage is retained to describe the degree of *correctness* of a measurement relative to the true value.

NOTIONS OF TRUE SCORE AND MEASUREMENT ERROR

Comprehending the concept of reliability requires grasping the notions of true score and measurement error. Almost all measurements in scientific disciplines involve observing the objects of measurement under certain conditions to produce *observed scores*. When observed under different conditions, the resulting observed scores are likely to differ, even if both measurements are intended to measure the same construct on the same objects of measurement. *True score*, by contrast, cannot be directly observed; rather, it is *defined*. True scores are pivotal in reliability, and how they are defined significantly affects the estimation and interpretation of reliability statistics. CTT and GT share similar perspectives on true score, while IRT employs a few distinct versions of true score.

In essence, true score in both CTT and GT is perceived as the *expected value* of observed scores over replications of a measurement procedure. This perspective precludes the platonic interpretation, which considers true score as a definitive indication of what the measurement intends to assess. The platonic view of true score has faced criticism because of its limited scientific utility, particularly in the context of psychological and educational measurement, where the constructs of interest are often intricate and challenging to explicitly define (see Lord & Novick, 1968, chap. 2).

The expected-value notion of true score requires specifying what constitutes a replication, implying that there is no singular definition of true score. The investigator has control over defining parallel forms for replications, such as different sets of items, raters, and/or occasions. Many well-known results in CTT rely on the assumption that replications are performed over forms that are *classically parallel*.

In contrast, later developments of single-administration reliability coefficients use less stringent assumptions, such as essentially tau-equivalent or congeneric forms. Meanwhile, true score in GT (also referred to as universe score) is defined as the expected value of observed scores over measurement conditions or forms that are *randomly parallel*. This distinct conception of parallelism for replications stands out as a key difference between the two theories, carrying considerable theoretical and practical implications.

The term *measurement error* refers to the discrepancy between a test taker's true score (i.e., the average of observed scores over replications) and the actual observed score. This implies that the definition of measurement error depends on how true score is conceptualized. Measurement error arises due to the random variation of observed scores over repeated testing using specified conditions of a measurement, which are used to define true score. Other error sources, deemed less important and thus not explicitly modeled by the investigator, are assumed to operate randomly. In CTT and GT, it is assumed that specified and unspecified (i.e., residual) sources of measurement error behave randomly such that their expected value over replications is always zero. If there are factors unrelated to the construct the test aims to measure that influence test-taker scores in some *systematic* way (e.g., verbal skills in math computation, bias in raters, model misfit), they are considered sources of construct-irrelevant variance and are deemed threats to *validity* (Kane, 2006). Rarely does construct-irrelevant variance play any role in estimating reliability under CTT or GT. However, it does hold implications in the context of IRT, as discussed next.

In unidimensional IRT, the notion of true score is conceptually linked to the person proficiency parameter, denoted θ . Although the proficiency parameter is explicitly defined and specific to a particular IRT model, subsequent discussions are intended to be general, applicable to any model. The proficiency parameter θ represents a person's location in a latent trait space and plays a role similar to that of true score. Consider a biased estimator of θ , such as the maximum likelihood estimator. Due to this bias, the expected value of the estimates across replications, denoted $\mathcal{E}\hat{\theta}$, does not equal the parameter θ —that is, $\mathcal{E}\hat{\theta} \neq \theta$. Unlike CTT, which adopts the expected-value notion of true score, the two possible definitions of a person's proficiency in IRT (i.e., θ and $\mathcal{E}\hat{\theta}$) contribute to some inconsistencies and ambiguities in estimating and interpreting reliability coefficients for IRT proficiency estimates. In this chapter, θ is referred to as *latent proficiency*, while $\mathcal{E}\hat{\theta}$ denotes *expected proficiency*, the latter being considered a more suitable definition in the context of reliability. Clear distinctions between these two definitions are not always made, and both have been used in various formulas for estimating reliability in IRT.

Different definitions of true proficiency inevitably result in distinct definitions of measurement error. Error of measurement, defined by the discrepancy between $\hat{\theta}$ and $\mathcal{E}\hat{\theta}$, constitutes random error, and its variance is referred to here as the *expected error variance*. By contrast, the variance of discrepancies between $\hat{\theta}$ and θ —referred to

simply as *error variance* here—involves both systematic error (i.e., bias) and random error. While bias can diminish validity, it does not impact reliability. If the variance (and covariance) of bias is incorporated into a reliability coefficient, it should contribute to true score variance rather than error variance, thereby increasing reliability. In practice, there is often an argument that the bias in proficiency estimates, particularly its variance, is negligible, making the distinction unnecessary. However, empirical examples presented by W. Lee et al. (2025) demonstrate that differences can sometimes be substantial.

In IRT, the definition of true score expressed in the number-correct (or summed raw) score metric is represented by a test characteristic curve (TCC). The TCC is a nonlinear transformation of θ , where values of θ with an unbounded range from $-\infty$ to ∞ are transformed into a score range of 0 to the maximum possible summed raw score. A TCC value represents the expected value of the model-based distribution of observed scores for a given θ , assuming known item parameters. Measurement error is characterized by the variability of model-based observed scores for a given θ . The TCC definition of true score in IRT is akin to true score in CTT in two key aspects: (a) It is expressed on the summed raw score metric, and (b) it employs the expected-value notion of true score as opposed to the latent-trait definition. Consequently, most results derived in CTT remain applicable for estimating reliability on the metric of summed raw scores in IRT. It is crucial to note that, similar to $\hat{\theta}$ (and θ), a TCC is model-specific, signifying that it is meaningful and can be interpreted properly only under the chosen IRT model.

The consideration that a TCC for a given model is often deemed fixed implies that the expectation is taken over forms containing a set of items with identical item parameters. This argument also extends to the expected proficiency, $\mathcal{E}\hat{\theta}$. Forms with identical item parameters are termed *strictly parallel* forms, effectively implying a fixed form. As a result, reliability coefficients under IRT should be larger than those based on CTT or GT, all other factors being equal.

TYPES OF SCORES CONSIDERED

Scores derived from test-taker responses can manifest in various forms, and the choice of a reporting metric introduces distinct considerations for reliability analyses. In this chapter, our focus centers on specific types of scores:

- *Summed raw scores*: These scores result from the summation of points earned on each individual test item. Variants include percent correct scores and weighted sum scores, where items may be assigned different weights based on content importance or other considerations. Summed raw scores may be referred to simply as *raw scores* in this chapter.
- *IRT proficiency estimates*: Derived from IRT models, proficiency estimates are based on test takers' responses and item parameters. While profi-

ciency estimates are not commonly used for reporting because of their interpretational complexity, they find frequent application in adaptive testing to guide item selection. Two different IRT proficiency estimators are considered in this chapter based on the maximum likelihood and Bayesian estimation methods.

- *Composite scores:* Composite scores are linearly weighted sums of component scores, either subscores from one test or scores from different tests. Multiple components can be characterized by the differences in content areas, constructs measured, item formats, and other aspects. Unlike simple summed raw scores, composite scores treat items across components distinctly.
- *Scale scores:* Widely employed for reporting, scale scores can be crafted in various ways, such as setting target means and standard deviations, incorporating precision information for equal conditional standard errors of measurement, or setting a cut score with a particular scale score value. Scale scores prove particularly useful in reporting when test takers take different sets of items. A conversion table is typically created to convert summed raw scores, IRT proficiency estimates, or composite scores to scale scores.
- *Classification category scores:* Instead of providing a specific numerical score, classification category scores convey a test taker's performance category, such as *Exceeds Expectations*, *Meets Expectations*, or *Below Expectations*. *Pass/Fail* or *Master/Nonmaster* are also common in various assessments.

STATISTICS AND INDICES FOR RELIABILITY

Multiple methods exist for quantifying reliability for individual scores or scores for a group of test takers, and some of these are defined next.

Overall Standard Error of Measurement

The overall standard error of measurement (SEM) represents the standard deviation, over individuals, of observed scores minus true scores for an assessment. Traditionally, it is estimated as a function of a reliability coefficient and observed score variance. This estimation is referred to as the overall SEM, distinguishing it from the conditional SEM. SEMs, both overall and conditional, are expressed in the same units as the reported score, making them specific to the scoring metric used. Consequently, SEMs cannot be directly compared across different scoring procedures. Another notable characteristic of SEM is its relative insensitivity to the characteristics of a specific group of test takers.

Conditional Standard Errors of Measurement

The SEM typically varies across score levels or test takers. The conditional SEM (CSEM), in theory, represents the standard deviation of observed scores over repeated

measurements conditional on a test taker's true score. In practice, estimated CSEMs can be reported either at each true score level based on a psychometric model or for each individual test taker using an observed score as an estimate of the true score. CSEMs provide valuable information about the amount of measurement error for each test taker (or score level) and can also be aggregated over all score levels to compute the overall SEM and reliability coefficients. The section "Estimators of CSEMs" of this chapter is dedicated to discussions on estimators of CSEMs for various types of scores.

Reliability Coefficients

The extent to which test takers' scores are consistent over replications can be quantified using reliability coefficients. These coefficients, originally developed under the traditional assumptions of CTT, take various forms. One such coefficient, for example, involves the correlation between observed scores on the same assessment or parallel forms of an assessment. Reliability coefficients are not reported in score units, making them challenging for users to interpret directly. Reliability coefficients are sensitive to the characteristics of the test-taker group. Some estimators require at least two scores per test taker, which is a challenging requirement to meet in practice, while others can be computed based on a single administration of an assessment. Various approaches to estimating reliability coefficients under each of the three measurement model frameworks are discussed in this chapter.

Classification Consistency and Accuracy Indices

When test scores are used to categorize test takers based on one or more cut scores, a crucial consideration is the likelihood of consistent classification if the test is administered again. Classification consistency serves as a criterion-referenced measure of reliability, assessing whether test-taker performance aligns with established standards or cut scores across replications. In contrast, classification accuracy is concerned with whether a test taker is "accurately" categorized into the performance category corresponding to their true score. This definition implies a closer connection to validity. Because consistency and accuracy are often considered together, both aspects are addressed in this chapter. The section "Reliability of Classification Category Scores" of this chapter is dedicated to presenting methods for estimating various classification consistency and accuracy indices.

ORGANIZATION OF THIS CHAPTER

This chapter builds on concepts discussed in earlier editions of *Educational Measurement*, particularly in Haertel (2006) and Feldt and Brennan (1989). The sections "Reliability in CTT" and "Reliability in GT" delve into classical and generalizability theory approaches. The section "Reliability in IRT" treats IRT approaches to reliability issues, offering a more extensive discussion because of the relatively less explored nature of this area. Some content discussed in the IRT section is novel and has not been previously published. Emphasizing the utility of CSEMs over reliability coefficients,

the section “Estimators of CSEMs” provides various estimation procedures for CSEMs. The section “Reliability of Classification Category Scores” focuses on reliability of classifications, while the section “Other Models, Aggregation, and Precision Issues” tackles various additional issues associated with reliability. The final section offers a concise summary of the chapter and outlines potential areas for future research on reliability. For practical applications and comparisons of different methodologies, readers can refer to two real data examples presented by W. Lee et al. (2025), which demonstrate the computation of various reliability and error statistics across different models and metrics.

RELIABILITY IN CTT

CTT emerged in the early 20th century, initially focusing on studies of individual differences. Its origins are often traced back to Spearman’s (1904) work on methods for correcting correlation coefficients for attenuation due to measurement error (Traub, 1997). Since then, numerous scholars have contributed to further developing and refining the theory. Key texts in the field, such as Gulliksen (1950) and Lord and Novick (1968), are considered highly influential, offering comprehensive treatments of CTT.

Despite its relatively simple set of assumptions and definitions compared to other contemporary theories, CTT yields results that are relevant to many aspects of modern psychometric applications and remains widely used. Not surprisingly, CTT continues to be an important area of study. In recent decades, certain segments of the measurement literature have extended CTT substantially, particularly in areas such as estimating CSEMs for both raw and scale scores, classification consistency and accuracy, and interval estimation (although the latter is not extensively covered in this chapter).

Assumptions, Definitions, and Basic Results

CTT asserts that an observed score for person p on form f , denoted X_{pf} , can be decomposed into two components: a true-score component, T_p , and an error-score component, E_{pf} :

$$X_{pf} = T_p + E_{pf}, \quad (1)$$

where the true score T_p is a constant specific to the person and does not depend on forms. For notational convenience, T_p and τ_p are used interchangeably in this chapter to represent the true score for person p in the total raw-score metric. The intrinsic difficulty of using the model in Equation 1 arises from the fact that only one variable can be observed, while the other two are unobservable. This challenge is circumvented by making certain assumptions about the unobservable true or error scores—assuming either one of them to be known makes the other apparent. One such assumption is that,

for a specific person p , the expected value ($\mathcal{E}$) of error scores over replications is zero: $\mathcal{E}_f(E_{pf}) = 0$, where the expected value is taken over a hypothetically infinite number of parallel forms, as indicated by the subscript f below the expectation operator. Under this assumption, it follows that

$$\mathcal{E}_f(X_{pf}) = \mathcal{E}_f(T_p + E_{pf}) = T_p. \quad (2)$$

Conversely, if the true score is defined as the expected value of observed scores, the expected value of errors is necessarily zero. Therefore, the true score in CTT, which is equal to the expected value of observed scores, can be viewed either as a derived result or as a definition.

Assuming the measurement procedure does not alter a person's true score, any variation in the observed scores over replications is attributed solely to the use of parallel, yet different forms of a test. The question of what constitutes the replications over which the expectations in Equation 2 are taken lies at the core of CTT because the nature of true score and measurement error depends on the answer to that question. One traditional answer, among many possibilities, is that expectations are taken over forms of a test that are *classically parallel*. However, as discussed later, different definitions of replications can lead to different results. It should be noted that there is no universally right or best definition of replications, and the choice depends entirely on the investigator's decision, guided by the intended interpretations of test scores.

Another assumption about error scores is $\mathcal{E}_p(E_{pf}) = 0$, meaning that, for a given test form, the expected value of the errors taken over a population of persons equals zero. This assumption holds for any subpopulation of persons, unless persons are selected based on the magnitude of X_{pf} . Under this and other assumptions discussed previously, the following central results can be derived: (a) true scores and errors for any test form are uncorrelated; and (b) error scores on any pair of parallel forms, f and g , are uncorrelated. It is also true that their covariances are zero, notationally, $\sigma(T, E_f) = 0$ and $\sigma(E_f, E_g) = 0$. It follows that the variance (over persons) of observed scores on a form is simply the sum of true score variance and error score variance:

$$\sigma^2(X_f) = \sigma^2(T) + \sigma^2(E_f). \quad (3)$$

It can be further shown that, under CTT assumptions, true score variance is equal to the covariance between observed scores on a pair of forms and also to the covariance between observed scores and true scores: $\sigma(X_f, X_g) = \sigma(X_f, T) = \sigma^2(T)$.

Reliability Coefficients and SEM

The historical definition of the reliability coefficient is rooted in the conceptually straightforward notion of replication, specifically the correlation between two parallel measurements. The notation $\rho(X_f, X_g) \equiv \rho(X, X')$ denotes the reliability coefficient,

defined as the correlation between observed scores arising from the same form or two parallel forms. Under the CTT assumptions and results set forth previously, other expressions of the reliability coefficient can be derived (note that, without loss of generality, the subscript f for test form will be dropped hereafter):

$$\rho(X, X') = \rho^2(X, T) = \frac{\sigma^2(T)}{\sigma^2(X)} = 1 - \frac{\sigma^2(E)}{\sigma^2(X)}. \quad (4)$$

It is important to note that these equalities are derived under specific assumptions in CTT, particularly those pertaining to classically parallel forms, and should not be universally applied without consideration. For instance, as detailed later, alternative expressions of the reliability coefficient may produce different results in certain IRT contexts. Additionally, in this chapter, the terms *definitions* and *expressions* are used interchangeably to offer clearer distinction in various situations.

Using $R(X)$ as a generic notation for the reliability coefficient in the raw-score metric X , the following symbols distinguish various expressions presented in Equation (4):

$$R(X)_{PF} \equiv \rho(X, X')$$

$$R(X)_{SC} \equiv \rho^2(X, T)$$

$$R(X)_{VR} \equiv \sigma^2(T)/\sigma^2(X)$$

$$R(X)_{EV} \equiv 1 - [\sigma^2(E)/\sigma^2(X)]$$

This distinction gains increased importance and utility in IRT contexts. The parallel-forms definition, $R(X)_{PF} \equiv \rho(X, X')$, stands apart from the others by being expressed solely in terms of observable quantities without referencing the true or error component. One limitation of this definition is the absence of an explicit parameter for the reliability coefficient because the correlation may vary across different pairs of forms unless forms are definitely classically parallel.

In the extant literature, the squared-correlation definition, $R(X)_{SC} \equiv \rho^2(X, T)$, is regarded as the canonical definition of the reliability coefficient (Brennan, 2010). The generalizability coefficient in GT, which is analogous to the reliability coefficient in CTT, takes the form of the squared correlation. The variance-ratio definition, $R(X)_{VR} \equiv \sigma^2(T)/\sigma^2(X)$, employs the ratio of true score variance to observed score variance, indicating that if the quantity is close to 1.0, variability in test takers' observed scores is largely attributable to variability in their true scores rather than errors. This definition forms the basis for the development of many internal consistency reliability coefficients (e.g., coefficient alpha), where a key objective is to express unobservable true score variance in terms of some observable quantities. The last definition involving error variance, $R(X)_{EV} \equiv 1 - [\sigma^2(E)/\sigma^2(X)]$, always yields the same result as the variance-ratio

definition, as long as Equation 3 holds. This definition may be considered the most general form of the reliability coefficient because of its broad applicability to various score types.

The reliability coefficient essentially represents a correlation ranging from zero to 1, which is a convenient unitless scale for comparing different instruments or measurement procedures. By contrast, SEM is expressed in units of a reported score scale and describes the extent to which test takers' scores vary from one testing to another. Traditionally, SEM, in the raw-score metric, is derived through the reliability coefficient as

$$\sigma(E) = \sigma(X)\sqrt{1 - R(X)}. \quad (5)$$

Strictly speaking, this derivation holds only if the assumptions of classically parallel forms are met. However, in practice, these assumptions are often disregarded and loosely applied in conjunction with various reliability coefficient estimates. The consequence of violating these assumptions is relatively unknown.

From the perspective of CTT, the SEM derived in Equation 5 is termed the *overall* SEM for a population of persons. Alternatively, the overall SEM can be defined as the square root of the expected value of individual-level error variances, which typically differ across persons with different true score levels. Symbolically,

$$\sigma(E) = \sqrt{\mathcal{E}_p \sigma^2(E | \tau_p)} = \sqrt{\mathcal{E}_p \sigma^2(X | \tau_p)}, \quad (6)$$

where $\sigma^2(E | \tau_p) = \sigma^2(X | \tau_p)$ is called the *conditional* error variance for persons with fixed true score τ_p , and the square root of it is the CSEM. Numerous theoretical and empirical studies have highlighted that CSEMs exhibit variation along the score scale, raising concerns about the applicability of the overall SEM to all individuals. (Refer to the section "Estimators of CSEMs" for estimators of CSEMs for various score types under all three measurement models.) It is important to note that the exact mathematical relationship between the overall and conditional SEMs in Equation 6 holds only for certain models and estimators.

In the measurement literature, reliability coefficients have been the central focus, with insufficient attention given to the role of CSEMs. CSEMs not only provide information about the amount of measurement error specific to each individual or score point but also can be used to estimate overall statistics such as the overall SEM and reliability coefficients. They can further be integrated into interval estimation procedures (K. Y. Kim & Lee, 2018; W. Lee et al., 2006). In addition, obtaining CSEMs for scale scores is relatively straightforward.

Approaches to Estimating Reliability

Approaches to estimating the reliability coefficient and SEM in CTT can be broadly categorized into two types. In the first type, reliability is directly estimated using data from two independent replications of the "full-length" measurement procedure

administered to a group of test takers. The resulting two sets of observed scores at the group or individual levels are used for computing reliability coefficients, SEM, CSEMs, and other relevant statistics. In contrast, the second type estimates reliability using data collected from a single test administration to avoid the challenges of conducting two actual replications. Most estimators of the second type involve splitting a full-length test form into two or more constituent part-tests. The data from these part-tests from a single group of test takers are treated as replications—a somewhat contrived notion of replications. Statistical quantities derived from part-tests are then used to obtain results for the full-length test form. However, this approach relies on a strong set of assumptions regarding the parallelism of the part-tests.

In principle, data for a reliability analysis are collected in a way that properly reflects the influences of all important sources of error in the reliability statistics of interest. To generalize interpretations of test results beyond a particular incident of a measurement procedure, investigators would need to conceptualize which measurement conditions shall vary over replications and design data collection accordingly. Ideally, in the data collection process, only the measurement conditions contributing to the conceptualized measurement error should be allowed to vary over replications, while all other potential sources of random error remain unchanged or are treated as negligible.

Direct Estimation With Full-Length Replications

Suppose an investigator is interested in generalizing test takers' test scores beyond a particular collection of items on a test form. A straightforward approach is to construct two full-length parallel forms of the test according to the same test specifications. These two forms are then administered (possibly in a counterbalanced manner) to the same group of test takers within a very short time interval, such as on the same day. The correlation between two sets of scores is subsequently calculated. This correlation value serves as a direct estimate of the reliability coefficient for either test form (not the sum or average of the two). Known as a *coefficient of equivalence*, this correlation indicates the extent to which test takers perform similarly on different forms of the test.

When two test forms are administered at different times (e.g., a few days apart), the resulting correlation is affected downward due to the measurement error arising from differences in both testing occasions and test forms. This correlation is referred to as a *coefficient of stability and equivalence*, which is often preferred over other estimates because investigators typically seek to generalize results over different testing occasions as well as different test forms. In this case, the coefficient of equivalence might be an overestimate of the idealized (or conceptualized) reliability. Alternatively, in situations where only one test form is available and administered twice, typically at different times, the estimate is called a *coefficient of stability* or *test-retest reliability coefficient*. This coefficient reflects variability in observed scores over testing occasions,

which may be biased by memory, but it does not account for variability due to different test forms. It is important to emphasize that these coefficients are not interchangeable principally because they involve the impact of different sources of measurement error. The choice of which coefficient to use depends on its consistency with the intended generalization.

The direct estimation approaches using actual full-length replications offer several advantages. First, in theory, they can be applied to any measurement procedure, including performance assessments involving raters, as long as resources permit. Second, these approaches require minimal statistical and psychometric assumptions, although they do rely on other assumptions such as no change in true score or latent traits between administrations, no memory effects on the second responses, and no fatigue or practice effects. Third, the computation is easy and straightforward. Fourth, other reliability statistics, including CSEMs, can be readily computed from the replicated data. Fifth, it provides the investigator an opportunity to carefully consider what constitutes replications of the measurement procedure, with a central focus on the sources of measurement error (e.g., items, occasions, raters). Despite all these benefits, however, direct estimates are less frequently used in practice because of their requirement for double testing time and, for some coefficients, the construction of an additional parallel form.

Estimation Based on a Single Test Administration

Spearman (1910) and Brown (1910) were the first to recognize the necessity of estimating a reliability coefficient using data from a single test administration. Since then, numerous estimators have been developed, collectively known as *internal consistency coefficients*. The well-known Spearman–Brown formula was developed for the purpose of estimating a reliability coefficient based on two split-halves with equal observed score means and variances (i.e., classically parallel). Recognizing the challenge of constructing part-tests with precisely identical means and variances, subsequent developments attempted to relax the strict assumptions of classically parallel forms. In particular, Feldt and Brennan (1989) integrated various internal consistency coefficients and categorized them based on varying degrees of part-test parallelism.

The notions of tau-equivalent and essentially tau-equivalent forms were initially introduced by Lord and Novick (1968). For two forms (or part-tests) that are *tau equivalent*, it is assumed that true scores are the same, thereby necessitating equal observed score means. However, these two forms are allowed to have different error variances, leading to the possibility of differing observed score variances. Under *essentially tau-equivalent* forms assumptions, the requirement of equal observed score means can be relaxed further. Here, true scores may differ by a constant, allowing for variations in observed score means. Despite these differences, true score variances are equal for essentially tau-equivalent forms due to the constant difference in true scores. A less stringent concept of parallelism is *congeneric* forms, where true

scores are assumed to have a linear relationship. Consequently, true score variances may vary, but they are perfectly correlated. Under the congeneric assumptions, observed score variances may also differ due to variations in both error and true score variances.

Extensive discussions and derivations of internal consistency coefficients, considering various definitions of form parallelism, can be found in Feldt and Brennan (1989) and Haertel (2006). In this section, a subset of these coefficients will be briefly introduced, starting with those based on two parts and then extending to coefficients involving more than two parts.

For two-part coefficients, the full-length test X is divided into two scorable part-tests, X_1 and X_2 , such that $X = X_1 + X_2$. The Spearman–Brown formula, the first internal consistency coefficient in the history of measurement, was derived under the assumption that X_1 and X_2 are classically parallel. The correlation between the two part-tests, denoted by $\rho(X_1, X_2)$, serves as a reliability coefficient for a half-test. This coefficient is then stepped up to obtain a reliability coefficient for the full-length test X using the simple formula

$$_{SB}R(X) = \frac{2\rho(X_1, X_2)}{1 + \rho(X_1, X_2)}. \quad (7)$$

Other two-part coefficients developed subsequently relax the classically parallel form assumptions to express the unobservable true score variance in terms of observable quantities based on two parts. Rulon (1939) provided a formula (attributed to Flanagan) under the assumption of essential tau equivalence, where the true score variance for the total test is expressed to be equal to four times the covariance between X_1 and X_2 : $\sigma^2(T_X) = 4\sigma(X_1, X_2)$. Algebraically identical versions were proposed by Rulon (1939) and Guttman (1945). Putting all three versions together, the Flanagan–Guttman–Rulon coefficient is

$$_{FGR}R(X) = \frac{4\sigma(X_1, X_2)}{\sigma^2(X)} = 2 \left(1 - \frac{\sigma^2(X_1) + \sigma^2(X_2)}{\sigma^2(X)} \right) = 1 - \frac{\sigma^2(X_1 - X_2)}{\sigma^2(X)}. \quad (8)$$

The assumption of equal true score variance in essential tau equivalence is rarely satisfied when, for example, two parts have substantially different test lengths or are associated with different content areas. Allowing for different part-test true score variances increases the number of unknown quantities and calls for additional constraints to find a solution. Raju (1970) introduced a constraint that the relative lengths of the two parts, l_1 and $l_2 = 1 - l_1$, are known (e.g., the actual number of items in each part-test). In contrast, Angoff (1953) and Feldt (1975) independently proposed the same solution for situations in which the lengths of part-tests are treated as unknown parameters to be estimated. They used a constraint that the part-test error variances be linearly related to each other as a function of the l terms. It follows that the unknown part-test lengths are equal to *effective test lengths*: $l_1 = [\sigma^2(X_1) + \sigma(X_1, X_2)] / \sigma^2(X)$ and $l_2 = [\sigma^2(X_2) + \sigma(X_1, X_2)] / \sigma^2(X)$. The Angoff–Feldt coefficient is given by

$${}_{AF}R(X) = \frac{\sigma(X_1, X_2)}{l_1 l_2 \sigma^2(X)} = \frac{4\sigma(X_1, X_2)}{\sigma^2(X) - \left(\frac{\sigma^2(X_1) - \sigma^2(X_2)}{\sigma(X)} \right)^2}. \quad (9)$$

Note that Raju's coefficient is a special case of Equation 9 where l_1 and l_2 are predefined constants.

Among many possible methods for splitting a test into two scorable parts, the odd-even split is most frequently employed in practice. The goal in dividing a test is to create two half-tests, each of which reflects the specifications of the full-length test and is as similar as possible to each other in content and item characteristics (e.g., difficulty, format) to closely adhere to parallelism assumptions. Failure to achieve this similarity may introduce bias into estimates of reliability. An inherent limitation of the two-part approaches is that, regardless of the split-half strategy used, there are many possible split halves that are equally acceptable. However, not all such splits will produce the same estimate.

Subsequently, the two-part approaches were extended to multipart. Multipart estimates, often derived from individual items treated as parts, are generally preferred over two-part estimates because they avoid arbitrary divisions of a test, and the sampling errors in reliability coefficients tend to be smaller (Kristof, 1963). However, two-part approaches may be more defensible than multipart approaches concerning parallel-part assumptions. For example, the claim that all items are essentially tau equivalent is rarely justifiable because it implies that any differences in the item-level observed score variances are solely due to measurement error. Constructing two parts that largely satisfy essential tau equivalence might be much easier than developing all individual items with such a high degree of parallelism. Therefore, multipart procedures should not necessarily be perceived as "better" than two-part procedures.

Suppose a full-length test X can be divided into n parallel part-tests: $X = X_1 + X_2 + \cdots + X_n$, where each part-test can be an individual item or a cluster of items. Under the assumption of classically parallel part-tests, the generalized Spearman-Brown (GSB) formula can be derived as

$${}_{GSB}R(X) = \frac{nR(X_1)}{1 + (n - 1)R(X_1)}, \quad (10)$$

where $R(X_1)$ is a reliability coefficient for a unit-length test (i.e., a part-test). If the above equation is solved for $R(X_1)$, one can obtain a prophecy formula for predicting the reliability of a shortened test. Therefore, a more general formula can be written as

$${}_{pred}R(X) = \frac{v \times_{orig} R(X)}{1 + (v - 1) \times_{orig} R(X)}, \quad (11)$$

where ${}_{orig}R(X)$ is the reliability coefficient of the original test, and v is the ratio of the length of the predicted test to the length of the original test. Obviously, v can be any real number greater than zero.

Cronbach's (1951) alpha is undeniably one of the most widely recognized multipart reliability coefficients, assuming essentially tau-equivalent part-tests.¹ The formula is given by

$${}_aR(X) = \left(\frac{n}{n-1} \right) \frac{\sigma^2(X) - \sum \sigma^2(X_i)}{\sigma^2(X)}, \quad (12)$$

where $\sigma^2(X_i)$ is the variance of each part-test, $X_i (i = 1, \dots, n)$. Note that the multiplier $n/(n-1)$ has nothing to do with correcting for bias. Notably, coefficient alpha is algebraically equal to Kuder and Richardson's (1937) KR20 coefficient if each item is treated as a part-test, and all items are scored dichotomously (i.e., 0 or 1). Kuder and Richardson's KR21 is a special case of KR20 when items are all equally difficult. However, because of the unrealistic assumption of equal item difficulty, the practical utility of KR21 is limited.² Another well-known property of ${}_aR(X)$ is that it equals the average of all possible split-half reliability coefficients computed using ${}_{FGR}R(X)$ in Equation 8. As a special case, when $n = 2$ in Equation 12, ${}_aR(X) = {}_{FGR}R(X)$.

Reporting coefficient alpha is prevalent and nearly a standard practice in the measurement and assessment literature. However, it is also true that alpha is frequently misused and/or misunderstood. One example of improper use of coefficient alpha is to assess the dimensionality of items in a test. Nothing in the derivation of alpha requires unidimensionality—alpha is not based on a latent trait model. In his reflection on coefficient alpha 50 years later, Cronbach (2004) stated, "I particularly cleared the air by getting rid of the assumption that the items of a test were unidimensional" (p. 397).

Another widely cited but potentially misleading characteristic of alpha is the phrase that alpha is a lower limit to reliability (Lord & Novick, 1968). While the mathematical proof is valid under a particular set of assumptions, it is hardly generalizable to other measurement circumstances for which the sources of error are different from those involved in alpha. For example, if the investigator intends to generalize over different testing occasions in addition to different forms, coefficient alpha computed based on data from a single occasion will likely be an overestimate (Brennan, 2001b, 2010). As mentioned earlier, the crux of the matter is whether the data used for estimation reflect the effects of error sources to be consistent with the investigator's conceptualization of replications. Cronbach (2004) also stated, "I no longer regard the alpha formula as the most appropriate way to examine most data" (p. 403). In theory, depending on the investigator's conceptualization, there can be many reliability coefficients for any set of test scores, and Cronbach incorporated this notion into the development of GT.

Another coefficient for essentially tau-equivalent parts, developed by Guttman (1945), is coefficient λ_2 , which is one of Guttman's series of lower bounds for reliability referred to as λ_1 through λ_6 . Guttman's λ_2 is always greater than or equal to λ_3 , which is the same quantity as alpha, but is lower than "the" reliability. In this sense, λ_2 is often considered a "better" lower bound than alpha. However, again, the conceptual

definition of reliability with respect to sources of error for replications should take precedence over any statistical justification for lower bounds.

If the stringent assumptions of essentially tau-equivalent parts are relaxed to be congeneric, part-tests are allowed to have heterogeneous error variances and true score variances, while maintaining a perfect correlation between true scores. The congeneric model is deemed suitable for cases in which observed part-test variances differ considerably, and one cannot solely attribute such variations to measurement error. For example, consider a test comprising several units (e.g., reading passages), each associated with a different number of items. If these units serve as part-tests in a reliability analysis, the observed part-test variances may well differ, and the differences are likely attributable not only to measurement error but also to variations in true score variances.

Under the congeneric assumptions, Raju (1977) extended his two-part coefficient (Raju, 1970) to multipart contexts, assuming the proportions of total test length for part-tests, l_i , are known:

$${}_R R(X) = \left[\frac{1}{1 - \sum l_i^2} \right] \left[\frac{\sigma^2(X) - \sum \sigma^2(X_i)}{\sigma^2(X)} \right] \quad (13)$$

which becomes identical to coefficient alpha if $l_i = 1/n$. For unknown part-test lengths, Feldt and Brennan (1989) provided a solution called Feldt's coefficient:

$${}_F R(X) = \frac{\sigma^2(X) [\sigma^2(X) - \sum \sigma^2(X_i)]}{[\sigma^2(X)]^2 - \sum [\sigma(X_i, X)]^2} \quad (14)$$

The derivation of Feldt's coefficient requires congeneric part-tests and an assumption that error variances follow dictates of CTT, meaning the error variance for each part-test equals l_i times the error variance for the total test—this model is often referred to as *classical congeneric*. The formula for Feldt's coefficient can also be obtained by using the effective test lengths, $l_i = \sigma(X_i, X) / \sigma^2(X)$, in Equation 13.

Other congeneric-model coefficients that are not discussed here in detail include Kristof's (1974) coefficient for tests that can be divided into three congeneric part-tests with unknown lengths. Additionally, Gilmer and Feldt (1983) presented a more general formula applicable to tests with more than three congeneric parts with unknown lengths—it is referred to as the Feldt–Gilmer coefficient in Feldt and Brennan (1989). A maximum likelihood approach is also available, as described by Jöreskog (1971), through the use of a computer program LISREL (Jöreskog & Sörbom, 2018).

The internal consistency coefficients discussed thus far are suitable for tests consisting of items or part-tests that largely conform to the requirements of the essential tau-equivalence or congeneric models. Consider, however, a test composed of multiple content categories (or clusters), each with a distinct set of items. While items within each content category may satisfy the assumptions of

the essential tau-equivalence or congeneric model, applying these assumptions to items across content categories may lead to violations. This is because some unique true score variance may be associated with each content category. The approach discussed in the next section employs a general framework for linear composites to address situations where parallel-form assumptions hold reasonably well within clusters but not across them.

Reliability of Linear Composites

A linear composite is defined as a weighted sum of scores from multiple constituent components: $Z = \sum_{m=1}^M w_m X_m$, where w_m is the weight associated with component m and M is the number of components. In this definition, weights are unconstrained—they can be positive, negative, or even zero. The general framework of linear composites considered in this section does not require that the constituent components in a composite are parallel in the classical sense of parallelism. In effect, a composite can be derived from any types of components. Consider the following examples: a gain score, which is the difference between pretest and posttest scores; battery composites, which are usually formed by averaging multiple subtest scores (e.g., English, math, reading, and science); predicted scores based on a multiple linear regression; and total test scores obtained by summing scores from several distinct item types.

Conceptually, for a linear composite, each instance of a replication would involve the same set of components with items within components that vary. Each individual component, X_m , may consist of a set of items that conform, more or less, to one of the CTT definitions of parallelism and is allowed to have its own true, error, and observed score variances and, consequently, reliability. If independent errors across components are assumed, the error variance for composite scores is simply a weighted sum of all component error variances: $\sigma^2(E_Z) = \sum w_m^2 \sigma^2(E_{X_m})$. This error variance for the composite is incorporated in the error-variance definition of reliability to yield a general-purpose reliability coefficient for a linear composite:

$$R(Z)_{EV} = 1 - \frac{\sigma^2(E_Z)}{\sigma^2(Z)} = 1 - \frac{\sum w_m^2 \sigma^2(E_{X_m})}{\sigma^2(Z)} = 1 - \frac{\sum w_m^2 \sigma^2(X_m)[1 - R(X_m)]}{\sigma^2(Z)}, \quad (15)$$

where $R(X_m)$ is the reliability coefficient for component m . Equation 15 is not only convenient to use as long as a reliability estimate is available for each component, but also serves as a basis for deriving a reliability coefficient for many different types of linear composites. One such example is discussed next.

Stratified coefficient alpha (Rajaratnam et al., 1965) is generally considered more appropriate than the unstratified version, ${}_aR(X)$, when a test is organized according to a table of content (or other type) specifications. The assumption of essential tau equivalence may be sensible within content categories (called “strata” more generally), but may be questionable across them because there is presumably some unique true

score variance associated with each category. For estimation purposes, stratum-level scores are computed even though they may never be reported. Then, as a special case of Equation 15, stratified coefficient alpha is given by

$${}_{\text{strat } \alpha} R(Z) = 1 - \frac{\sum \sigma^2(X_m)[1 - {}_{\alpha} R(X_m)]}{\sigma^2(Z)}. \quad (16)$$

The numerator in Equation 16 is the error variance in ${}_{\text{strat } \alpha} R(Z)$, which is the sum of error variances in the regular coefficient alpha associated with the strata. Occasionally, unstratified ${}_{\alpha} R(X)$ is applied to stratified data without explicitly taking into account stratification. Doing so will likely yield an underestimate of reliability, although the extent of the problem depends on the nature of strata. Stratification by content or item types often makes meaningful differences.

The formula presented in Equation 15 is “general” in the sense that it does not specify which reliability coefficient should be used for the constituent components. If ${}_{\alpha} R(X)$ is used for all components, the result is stratified alpha. In a similar vein, a stratified version of Feldt’s coefficient may be obtained if one is willing to assume a congeneric model for the components. However, as W. Lee et al. (2025) demonstrated, stratification makes little difference between the stratified and unstratified Feldt’s coefficients. As a final note, nothing in theory excludes the possibility of using different reliability coefficients for various components, although it is rarely done in practice.

RELIABILITY IN GT

It is undoubtedly true that the very simple model of CTT provides an accessible framework for addressing various measurement problems. However, a principal limitation of the simple model is the presence of only one error term (E), where all sources of measurement error are clumped together and cannot be disentangled. As an extension and liberalization of CTT (Brennan, 2001c; Cronbach et al., 1972; Feldt & Brennan, 1989), GT permits the explicit modeling of multiple sources of random error. This feature makes GT a powerful and flexible tool for studying reliability and related issues. The multifacet aspect of GT is achieved through the application of analysis of variance (ANOVA) procedures. Other important characteristics that distinguish GT from CTT include the following: (a) GT incorporates a conceptual framework that differentiates between the concepts of *universes of admissible observations* (and associated G studies) and *universes of generalization* (and associated D studies); (b) in GT, a single notion of *randomly parallel* forms replaces the multiple definitions of parallelism in CTT; (c) GT introduces a clear distinction between two different types of error—absolute error and relative error; and (d) multivariate GT provides an even broader framework for

mixed models, including both random and fixed facets, with multiple universes of generalization.

The first comprehensive exploration of GT was presented in the book titled *The Dependability of Behavioral Measurements: Theory of Generalizability for Scores and Profiles* by Cronbach et al. (1972). However, the application of ANOVA to measurement problems predates the formalization of GT by Cronbach's team. Earlier works by researchers such as Burt (1936, 1955), Ebel (1951), Hoyt (1941), and Lindquist (1953, chap. 16) had already introduced the idea. A more accessible exposition of the theory is provided by Shavelson and Webb (1991). Brennan's (2001c) book, titled *Generalizability Theory*, has been widely cited, serving as both a textbook and a resource for students and practitioners. For a comprehensive review of the history of GT up to the present, readers are directed to Brennan (2022) and the references therein.

We shall now delve into some fundamental concepts, definitions, and assumptions, primarily focusing on univariate GT. Following this, there will be a brief overview of multivariate GT, and the section will conclude with an introduction to extended multivariate GT. While a full treatment of GT is beyond the scope of this section, we will use a few hypothetical scenarios to elucidate some crucial concepts and methods.

Univariate GT

Univariate GT provides a framework to model and estimate distinct sources of random error separately. To draw a comparison with CTT, a tautological model for univariate GT can be expressed as

$$X_{pf} = \pi_p + (E_{pf1} + E_{pf2} + \cdots + E_{pfH}), \quad (17)$$

where π_p is the universe score for person p in the mean-score metric, which is analogous to the true score in CTT, and H is the number of sources of random error associated with "facets" (e.g., items, raters). The H error terms are closely tied to the investigator's intended universe of generalization (defined later), where replications ($f = 1, \dots, \infty$) are considered as comprising randomly parallel forms that differ with respect to the conditions of each facet. In this model, what constitutes error is a matter of definition and is emphatically under the control of the investigator.

Univariate GT is largely a two-step enterprise. The first step revolves around the notion of universes of admissible observations and generalizability studies (G studies), while the subsequent step considers the notion of universes of generalization and decision studies (D studies). These conceptual issues tend to be more challenging to grasp than the statistical issues concerning estimation of variance components and reliability statistics.

Universes of Admissible Observations and G Studies

Designing a measurement procedure begins with specifying a set of measurement conditions, known in GT as *facets*. To illustrate, consider a practical example of an English writing assessment. Among many possible considerations, one can identify facets of interest, such as writing prompts (denoted i) and raters (denoted r). Note that the investigator has full control over what and how many facets to consider given the specific purpose of the assessment. Both the numbers of potential writing prompts and the raters may be assumed to be indefinitely large, approaching infinity, at least theoretically. In this scenario, both facets are infinite in the *universe of admissible observations* (UAO), and the corresponding statistical model is called a random effects model, which is the primary focus of discussion in this section.³ Furthermore, if any prompt in the universe could be evaluated by any rater in the universe, the two facets in the UAO are crossed, denoted $i \times r$. Now suppose there is a target *population* of persons (p) for whom the writing assessment is intended. In this context, persons are the *objects of measurement* about whom decisions are drawn. If any prompt and any rater in their universes can be associated with any person in the population, it is symbolized as $p \times i \times r$, which characterizes any observable data for the population and universes.

A linear model associated with the $p \times i \times r$ structure that represents any observed score for a single person on a single prompt evaluated by a single rater is expressed as

$$X_{pir} = \mu + \nu_p + \nu_i + \nu_r + \nu_{pi} + \nu_{pr} + \nu_{ir} + \nu_{pir}, \quad (18)$$

where μ is the grand mean in the population and universes and the ν terms are mutually uncorrelated *effects*. The term ν_{pir} in Equation 18 represents a three-way interaction combined with all other residual effects. It follows that the variance of observed scores for a *single* condition of each facet can be decomposed into seven uncorrelated *variance components*:

$$\sigma^2(X_{pir}) = \sigma^2(p) + \sigma^2(i) + \sigma^2(r) + \sigma^2(pi) + \sigma^2(pr) + \sigma^2(ir) + \sigma^2(pir). \quad (19)$$

These variance components play a central role in all subsequent analyses. A study is conducted to collect data for the purpose of estimating these variance components for the UAO. Such a study is called a generalizability study, or more succinctly, a G study. One possible data collection design would involve a sample of n_p persons, each of whom responds to the same set of n_i prompts that are evaluated by the same set of n_r raters. This is called a $p \times i \times r$ G-study design, which is consistent with the structure of the UAO.

However, the UAO does not dictate a particular G-study design for collecting observed data. For example, if each of n_r raters provides ratings on the responses to two or more nonoverlapping prompts, this is a design symbolized as $p \times (i:r)$,

where prompts are “nested” within raters. While there is no definitive answer to which G-study design should be used, it is generally preferred to use a crossed design (i.e., $p \times i \times r$) when the UAO is crossed. Using a crossed design provides the benefit that all seven variance components in Equation 19 can be independently estimated, offering great flexibility in obtaining results for other nested designs as well as the crossed design. By contrast, using a nested G-study design, some variance components in Equation 19 are not separately estimable (i.e., confounded), and results can only be obtained for certain nested designs but not for the crossed design.

Based on the G-study data, estimates of variance components can be obtained using various methods, including the ANOVA procedure. This procedure essentially involves the explicit use of the expected mean-square equations for a given G-study design, setting them equal to the weighted sum of contributing variance components. The expected mean squares are substituted with observed mean squares in the equations, and they are then solved for each of the variance components in terms of the mean squares. Once estimates of the variance components are obtained, they can be used to estimate error variances and reliability-like coefficients in subsequent decision studies, as discussed next.

Universes of Generalization and D Studies

As indicated in Equation 19, the G-study variance components for the UAO pertain to scores on *single* conditions of each facet. These estimated G-study variance components can be used in designing efficient measurement procedures for operational purposes through various decision (D) studies. Conceivably, an operational measurement procedure might encompass a set of measurement conditions (e.g., four prompts and two raters) from the UAO, and decisions about objects of measurement (persons) will be based on their *mean* (i.e., average) scores over those measurement conditions. Moreover, there exists a large (presumably infinite) number of similar forms that can be selected from the infinite UAO, each form containing different samples of measurement conditions (i.e., different sets of four prompts and two raters). Such forms are referred to as *randomly parallel forms*, which embody the notion of replications in GT. Unlike the definitions of parallelism in CTT, no constraints such as equal means and variances are imposed on randomly parallel forms, which are essentially indistinguishable from one another according to the principle of random sampling.

The concept of replications tied to randomly parallel forms is intricately linked to the notion of *universe of generalization* (UG). Indeed, a UG constitutes the universe of randomly parallel forms to which the investigator intends to generalize the results based on a particular form. In essence, a UAO is a universe for single observations, whereas a UG is a test-level universe focusing on mean scores over sets of measurement conditions. In a similar vein, the G-study variance components are derived from single-observation data and are subsequently employed to obtain the D-study

variance components for mean scores over sets of conditions. The design structure of the D study may or may not mirror that of the G study. Furthermore, it is entirely legitimate for a UG to contain either all or a subset of conditions present in the UAO. These conceptual considerations are illustrated using the same example mentioned earlier.

Consider a scenario where the UAO is infinite with the $p \times i \times r$ structure, and G-study variance components have been estimated using the $p \times i \times r$ design with n_i prompts and n_r raters. Now, consider the following three different scenarios for D studies:

1. Same design and same universe as G study
 - Design: $p \times I \times R$
 - UG: both I and R are random (i.e., contains all the conditions in the UAO)
2. Same design but different universe
 - Design: $p \times I \times R$
 - UG: I is random, but R is a fixed facet (i.e., interest focuses on generalizing results over prompts only, but not raters)
3. Different design with same universe
 - Design: $p \times (I : R)$
 - UG: both I and R are random

Note that uppercase letters represent facets in D studies (i.e., I and R) to emphasize the use of *mean* scores over conditions, as opposed to the single prompt-rater scores in the G study. In addition, the D-study sample sizes for the prompts and raters can be user defined and may be the same as or different from the G-study sample sizes, denoted n'_i and n'_r .

It is particularly important to note that the specification of a UG and characterization of a D-study design bear resemblance to the *conceptualization-estimation* framework for reliability discussed in the section “Terms and Background.” To define a UG, an investigator needs to articulate or conceptualize what constitutes a replication of a measurement procedure, predominantly in terms of which facets are considered random and which are fixed. The features of a D-study design pertain to estimation of reliability statistics.

The linear model for the first D-study scenario (i.e., $p \times I \times R$ with both I and R random) representing a person's observed mean score over n'_i prompts and n'_r raters can be expressed as

$$X_{pIR} = \bar{X}_p = \mu + v_p + v_I + v_R + v_{pI} + v_{pR} + v_{IR} + v_{pIR}, \quad (20)$$

which is analogous to Equation 18 except for the use of uppercase subscripts, I and R . The D-study variance components for the score effects in Equation 20 can be obtained by dividing the corresponding G-study variance components by the user-defined D-study sample sizes. In this example, $\sigma^2(I) = \sigma^2(i)/n'_i$, $\sigma^2(R) = \sigma^2(r)/n'_r$,

$$\sigma^2(pI) = \sigma^2(pi)/n'_i, \quad \sigma^2(pR) = \sigma^2(pr)/n'_r, \quad \sigma^2(IR) = \sigma^2(ir)/n'_i n'_r, \quad \text{and} \\ \sigma^2(pIR) = \sigma^2(pir)/n'_i n'_r.$$

As noted earlier, GT employs the expected-value perspective on true score, which it refers to as *universe score*. That is, universe score is defined as the expected value of observed mean scores over all randomly parallel forms in the UG:

$$\pi_p \equiv \mu_p \equiv \mathcal{E}_T \mathcal{E}_R X_{pIR}. \quad (21)$$

The variance of universe scores over all persons in the population is defined as $\sigma^2(\pi) = \mathcal{E}_p (\mu_p - \mu)^2$. For the $p \times I \times R$ design with random I and R , the universe score variance is simply $\sigma^2(\pi) = \sigma^2(p)$.

The second scenario differs from the first in that its UG is more narrowly defined than the UAO by fixing the rater facet. In this case, every randomly parallel form consists of the exact same set of raters, eliminating generalization over raters. The net effect is that the variance component for the person-by-rater interaction effect contributes to universe score variance; specifically, $\sigma^2(\pi) = \sigma^2(p) + \sigma^2(pR)$.

For the third scenario with a $p \times (I : R)$ D-study design, the linear model is

$$X_{pIR} = \bar{X}_p = \mu + v_p + v_R + v_{I:R} + v_{pR} + v_{pI:R}. \quad (22)$$

This linear model has fewer score effects (and variance components) compared to the $p \times I \times R$ design shown in Equation 20. If the G-study variance components for the fully crossed $p \times i \times r$ design are available, another G study is not required to obtain the D-study variance components for the nested design. Instead, a nested effect can be expressed in terms of confounded effects from the crossed design; that is, $\sigma^2(i : r) = \sigma^2(i) + \sigma^2(ir)$ and $\sigma^2(pi : r) = \sigma^2(pi) + \sigma^2(pir)$. It follows that $\sigma^2(I : R) = [\sigma^2(i) + \sigma^2(ir)]/n'_i n'_r$ and $\sigma^2(pI : R) = [\sigma^2(pi) + \sigma^2(pir)]/n'_i n'_r$ — the other three variance components are the same for both designs. Although the design for the third scenario differs from the first one, universe score variance remains unchanged (i.e., $\sigma^2(p)$) because the UG is the same.

Error Variances and Coefficients

Reliability coefficients in CTT are fundamentally correlation-based, directly or indirectly focusing on the rank ordering of test takers. Consequently, error variance associated with CTT reliability coefficients is interpreted in relation to the performance of other persons in the group, making it inherently *relative*. By contrast, GT distinguishes between two types of error: absolute error and relative error, each with different interpretations and uses. Absolute error for a person is the difference between their observed mean score and the universe score:

$$\Delta_p \equiv \bar{X}_p - \mu_p. \quad (23)$$

The variance of Δ_p over persons is referred to as *absolute error variance*, denoted $\sigma^2(\Delta)$, which is more suitable for criterion-referenced interpretations of scores. On the contrary, relative error, akin to CTT, is the difference between observed deviation scores and universe deviation scores:

$$\delta_p \equiv (\bar{X}_p - \mathcal{E}_p \bar{X}_p) - (\mu_p - \mu). \quad (24)$$

Relative error variance, $\sigma^2(\delta)$, is the variance of Equation 24 over persons.

Each type of error variance has an associated reliability-like coefficient. A generalizability coefficient involves relative error variance as its error term, defined as

$$\mathcal{E}\rho^2 = \frac{\sigma^2(\pi)}{\sigma^2(\pi) + \sigma^2(\delta)}. \quad (25)$$

A different coefficient that involves absolute error variance is called a dependability coefficient, given by

$$\Phi = \frac{\sigma^2(\pi)}{\sigma^2(\pi) + \sigma^2(\Delta)}. \quad (26)$$

Results for error variances and coefficients depend on a specified UG, a D-study design, and corresponding D-study variance components. Relative error variance, $\sigma^2(\delta)$, and a generalizability coefficient, $\mathcal{E}\rho^2$, are analogous to error variance and a reliability coefficient, respectively, in CTT. For a simple $p \times I$ design, $\mathcal{E}\rho^2$ is equal to coefficient alpha (or KR20 for binary items) if $n'_i = n_i$; however, this equality does not extend to other UGs and/or D-study designs.

It can be shown that absolute error variance is the sum of all variance components except $\sigma^2(p)$ for a random model with a crossed design. In the first D-study scenario with the $p \times I \times R$ design (both I and R random),

$$\sigma^2(\Delta) = \sigma^2(I) + \sigma^2(R) + \sigma^2(pI) + \sigma^2(pR) + \sigma^2(IR) + \sigma^2(pIR).$$

Relative error variance, by contrast, contains all variance components for interaction effects that involve p :

$$\sigma^2(\delta) = \sigma^2(pI) + \sigma^2(pR) + \sigma^2(pIR).$$

Clearly, $\sigma^2(\delta)$ is smaller than $\sigma^2(\Delta)$, which, in turn, leads to $\mathcal{E}\rho^2$ that is larger than Φ .

In the second scenario with R fixed, $\sigma^2(pR)$ contributes to universe score variance, resulting in

$$\sigma^2(\Delta) = \sigma^2(I) + \sigma^2(pI) + \sigma^2(IR) + \sigma^2(pIR)$$

$$\sigma^2(\delta) = \sigma^2(pI) + \sigma^2(pIR).$$

Compared to the first scenario, this leads to larger universe score variance, smaller error variances, and larger coefficients. This outcome is a consequence of the reduced error in a restricted UG that limits the generalization of results.

For the third scenario, involving an infinite UG with a $p \times (I : R)$ design,

$$\begin{aligned}\sigma^2(\Delta) &= \sigma^2(R) + \sigma^2(I : R) + \sigma^2(pR) + \sigma^2(pI : R) \\ \sigma^2(\delta) &= \sigma^2(pR) + \sigma^2(pI : R).\end{aligned}$$

Results for this design are likely to differ from those of the first scenario with a fully crossed design, even if both share the same UG. This underscores the dependence of D-study results on both UG characteristics and D-study design structure.

The hypothetical scenarios with two-facet designs served as a vehicle to introduce key concepts, terminology, and statistical formulas in univariate GT. They also provided insight into the considerations necessary for establishing a well-defined measurement procedure. Perhaps the most critical consideration, after identifying all pertinent sources of error (i.e., facets), is determining which facets are random and which are fixed in the intended UG. Other factors demanding attention include the D-study design structure and D-study sample sizes. All these considerations affect D-study results, one way or another.

Multivariate GT

An early exploration of multivariate GT was presented by Rajaratnam et al. (1965), particularly in the context of introducing stratified alpha as a tool for estimating reliability for a composite. Considered as a precursor to multivariate GT, stratified alpha set the stage for later developments. Later, Cronbach et al. (1972) offered the first integrated treatment of multivariate GT, a framework further expanded by Brennan (2001c).

Expanding on the univariate model depicted in Equation 17, multivariate GT may be represented as

$$X_{pf} = (\pi_{p1} + \pi_{p2} + \cdots + \pi_{pM}) + (E_{pf1} + E_{pf2} + \cdots + E_{pfH}), \quad (27)$$

in which each person possesses M universe scores, each associated with one of M fixed conditions of measurement; and, as previously defined, the number of sources of error (i.e., facets), denoted by H , is typically the same across all M levels of a fixed facet—more intricate multivariate designs are considered in the section “Extended Multivariate GT.” While many fundamental principles of univariate GT still apply to multivariate GT, a key distinction lies in the presence of “multiple” univariate random effects models, each corresponding to each level of the fixed facet.

To apply multivariate GT, there must be at least one fixed facet and at least one random facet in the UAO and G-study data collection design. For illustration, let us consider a simple example based on the so-called table of specifications model

(Jarjoura & Brennan, 1982, 1983). In this model, each item in the UAO is associated with one of several specific content categories, making items (i) random and content categories (c) fixed. Suppose a G study is conducted to gather response data from a group of test takers (p) who respond to all items nested within each content category. This multivariate design is designated $p^{\bullet} \times i^{\circ}$, where the filled circle superscript indicates that the facet is crossed with the levels of the fixed facet, c , and the empty circle superscript signifies the facet nested within c .

For simplicity, suppose there are two content categories (i.e., $n_c=2$). Under the multivariate $p^{\bullet} \times i^{\circ}$ design, covariances exist for the object of measurement (persons) since the same persons respond to all items in both content categories. However, there are no covariances for items that are nested within c . The variance and covariance components for p , i , and pi are displayed in the following $n_c \times n_c$ matrices:

$$\Sigma_p = \begin{bmatrix} \sigma_1^2(p) & \sigma_{12}(p) \\ \sigma_{12}(p) & \sigma_2^2(p) \end{bmatrix}, \Sigma_i = \begin{bmatrix} \sigma_1^2(i) & \\ & \sigma_2^2(i) \end{bmatrix}, \text{ and } \Sigma_{pi} = \begin{bmatrix} \sigma_1^2(pi) & \\ & \sigma_2^2(pi) \end{bmatrix},$$

where the subscripts 1 and 2 denote the two content categories. Note that both Σ_i and Σ_{pi} are diagonal matrices with zero covariances. Since there is a univariate random $p \times i$ design for each content level, the variances reported in the first and second columns in the matrices represent the variance components for a $p \times i$ design based solely on data from the first and second content categories, respectively. Hence, the conventional ANOVA procedure can be used to estimate univariate variance components for each content category. The estimate of the covariance component in Σ_p , $\sigma_{12}(p)$, is simply the covariance between persons' observed scores on the two categories. For more complex designs, interested readers can refer to Brennan (2001c, chaps. 9 and 11) for procedures on estimating covariance components.

Now, consider a subsequent D study that involves n'_{i1} items for Category 1 and n'_{i2} items for Category 2 with the same design structure as the G study. In this case, the two diagonal elements in the variance-covariance component matrix for I , Σ_I , are $\sigma_1^2(I) = \sigma_1^2(i)/n'_{i1}$ and $\sigma_2^2(I) = \sigma_2^2(i)/n'_{i2}$. Likewise, Σ_{pI} contains the following diagonal elements: $\sigma_1^2(pI) = \sigma_1^2(pi)/n'_{i1}$ and $\sigma_2^2(pI) = \sigma_2^2(pi)/n'_{i2}$. It follows that the matrices for universe score, relative error, and absolute error, respectively, are $\Sigma_{\pi} = \Sigma_p$; $\Sigma_{\delta} = \Sigma_{pi}$; and Σ_{Δ} with diagonal elements of $\sigma_1^2(\Delta) = \sigma_1^2(I) + \sigma_1^2(pI)$ and $\sigma_2^2(\Delta) = \sigma_2^2(I) + \sigma_2^2(pI)$. Note that for this design, Σ_{Δ} and Σ_{δ} are diagonal matrices.

In practical applications, decisions about test takers are often based on their composite scores over all levels of content categories. A composite based on two content categories can be expressed as a weighted sum of two mean scores: $\bar{Z} = w_1\bar{X}_1 + w_2\bar{X}_2$, where the bar above Z denotes the mean-score metric, and weights are typically

proportional to the number of items in each category (i.e., $w_1 = n'_{i1} / (n'_{i1} + n'_{i2})$ and $w_2 = n'_{i2} / (n'_{i1} + n'_{i2})$). Similarly, the composite universe score for a person is defined as $\pi_{p\bar{z}} = w_1\pi_{p1} + w_2\pi_{p2}$. Since $\Sigma_{\pi} = \Sigma_p$, composite universe score variance $\sigma_{\bar{z}}^2(\pi)$ is the sum of all of the elements in Σ_p with associated weights: $\sigma_{\bar{z}}^2(\pi) = w_1^2\sigma_1^2(p) + w_2^2\sigma_2^2(p) + 2w_1w_2\sigma_{12}(p)$. Relative error variance and absolute error variance for the composite scores, respectively, are weighted sums of diagonal elements of their corresponding matrices, as follows: $\sigma_{\bar{z}}^2(\delta) = w_1^2\sigma_1^2(\delta) + w_2^2\sigma_2^2(\delta)$ and $\sigma_{\bar{z}}^2(\Delta) = w_1^2\sigma_1^2(\Delta) + w_2^2\sigma_2^2(\Delta)$. These error variances, when combined with composite universe score variance, provide reliability-like coefficients for the composite scores. A multivariate generalizability coefficient and a multivariate dependability coefficient for the composite are defined similarly to Equations 25 and 26, respectively.

The typical computational procedures for multivariate GT designs have been demonstrated using a simple $p^{\bullet} \times i^{\circ}$ design so far. Applying these procedures to multifacet situations and/or different design structures is straightforward as long as the multivariate design is properly identified. For example, consider a scenario with two types (c) of short free-response items (i) that are evaluated by raters (r), where each rater scores test takers' (p) responses to a *different* subset of items for both types. This constitutes a multivariate $p^{\bullet} \times (i^{\circ} : r^{\bullet})$ design with c serving as a multivariate fixed facet. Items are nested within both r and c , and for each level of c , there is a univariate random $p \times (i : r)$ design. Some effects (p , r , and pr) will have full matrices with nonzero covariance terms, while other effects ($i : r$ and $pi : r$) will have diagonal matrices with zero covariances. D-study variance and covariance components, along with various D-study statistics, can then be computed using the procedures delineated in the preceding discussion of the simplest design.

The procedures discussed thus far are generally sufficient for most applications with a "single" multivariate design where the same univariate design structure applies to all levels of the fixed facet. Nonetheless, more complex designs can arise in practical situations, necessitating special treatment, as discussed in the following section.

Extended Multivariate GT

The extant literature on GT offers limited guidance on handling a mixture of different design structures in a multivariate design. One such example is a mixed-format exam that contains both multiple-choice (MC) items and free-response (FR) items involving raters for scoring. Here, the item type represents a multivariate fixed facet with two levels, MC and FR. Moses and Kim (2015) were the first to consider combining two distinct designs in multivariate GT, and Brennan et al. (2022) later provided a more extensive treatment, referring to it as *extended* multivariate GT.

The model representation for conventional multivariate GT shown in Equation 27 may be further expanded to characterize extended multivariate GT. Specifically,

$$X_{pf} = [\pi_{p1} + (E_{pf1} + \cdots + E_{pfH_1})] + \cdots + [\pi_{pM} + (E_{pf1} + \cdots + E_{pfH_M})]. \quad (28)$$

This model suggests that there are M distinct levels of a fixed facet, each associated with its own sources of error (i.e., facets) signified by different subscripts to H , H_1 through H_M . Since this model has not been fully exploited in the literature, one of the examples reported by Brennan et al. (2022) is briefly introduced here.

To continue with the example of a mixed-format exam, the MC section involves items (i) as the primary measurement condition, while the FR section involves both items (i) and raters (r). For notational simplicity, the symbol i is used to represent both MC and FR items—however, it does not imply interchangeability between the two item types. Representing the combination of two universes, the UAO structure can be symbolized as $\{p^\bullet \times i^\circ\}\{p^\bullet \times i^\circ \times r^\circ\}$, where persons are crossed with both universes, as indicated by the closed circle superscript. Brennan et al. (2022) concisely represented this design as $p^\bullet \times [i^\circ \cup (i^\circ \times r^\circ)]$, where the symbol $\cup$ denotes the union of the MC and FR sections, and the first and second i° before and after $\cup$ are associated with the MC and FR sections, respectively.

Suppose G-study data were collected for the $p^\bullet \times [i^\circ \cup (i^\circ \times r^\circ)]$ design. The conventional univariate methods can be applied to estimate G-study variance components separately for the MC and FR sections based on a univariate $p \times i$ design for the MC section and a univariate $p \times i \times r$ design for the FR section. For the full multivariate design, the covariance component for p needs to be estimated. Given that p is the only linked facet in this design, an unbiased estimate of the covariance is simply the observed covariance between MC and FR scores.

The left side of Table 5.1 presents the G-study variance and covariance components for this multivariate design. Each matrix reports variance components for MC and FR (indicated by the subscripts 1 and 2) in the first and second columns, respectively. Notably, the MC section, analyzed with a $p \times i$ design, involves three relevant variance components (p , i , and pi). In contrast, the FR section, analyzed with a $p \times i \times r$ design, includes seven variance components (p , i , r , pi , pr , ir , and pir). Each of the seven matrices contains variance components corresponding to one of the seven effects for FR. However, only three matrices (Σ_p , Σ_i , and Σ_{pi}) report variance components for MC. This is because the other four matrices are not relevant to MC, as indicated by “NA.” Covariance components are present in Σ_p only.

On the right side of Table 5.1, the D-study variance and covariance components are presented. These components are obtained by dividing their corresponding G-study components by the user-defined D-study sample sizes, n'_{i1} , n'_{i2} , and n'_r . Composite universe score variance is calculated as the weighted sum of all the elements in Σ_p : $\sigma^2_{\bar{z}}(\pi) = w_1^2 \sigma_1^2(p) + w_2^2 \sigma_2^2(p) + 2w_1 w_2 \sigma_{12}(p)$. Since MC and FR involve different sources of error, both relative error variance and absolute error variance for the

Table 5.1 Variance and Covariance Components for the Extended Multivariate Design Example

G study $p^\bullet \times [i^\circ \cup (i^\circ \times r^\circ)]$		D study $p^\bullet \times [I^\circ \cup (I^\circ \times R^\circ)]$	
MC	FR	MC	FR
$\Sigma_p = \begin{bmatrix} \sigma_1^2(p) & \sigma_{12}(p) \\ \sigma_{12}(p) & \sigma_2^2(p) \end{bmatrix}$		$\Sigma_p = \begin{bmatrix} \sigma_1^2(p) & \sigma_{12}(p) \\ \sigma_{12}(p) & \sigma_2^2(p) \end{bmatrix}$	
$\Sigma_i = \begin{bmatrix} \sigma_1^2(i) & \\ & \sigma_2^2(i) \end{bmatrix}$		$\Sigma_I = \begin{bmatrix} \frac{\sigma_1^2(i)}{n'_{i1}} & \\ & \frac{\sigma_2^2(i)}{n'_{i2}} \end{bmatrix}$	
$\Sigma_r = \begin{bmatrix} \text{NA} & \\ & \sigma_2^2(r) \end{bmatrix}$		$\Sigma_R = \begin{bmatrix} \text{NA} & \\ & \frac{\sigma_2^2(r)}{n'_r} \end{bmatrix}$	
$\Sigma_{pi} = \begin{bmatrix} \sigma_1^2(pi) & \\ & \sigma_2^2(pi) \end{bmatrix}$		$\Sigma_{pI} = \begin{bmatrix} \frac{\sigma_1^2(pi)}{n'_{i1}} & \\ & \frac{\sigma_2^2(pi)}{n'_{i2}} \end{bmatrix}$	
$\Sigma_{pr} = \begin{bmatrix} \text{NA} & \\ & \sigma_2^2(pr) \end{bmatrix}$		$\Sigma_{pR} = \begin{bmatrix} \text{NA} & \\ & \frac{\sigma_2^2(pr)}{n'_r} \end{bmatrix}$	
$\Sigma_{ir} = \begin{bmatrix} \text{NA} & \\ & \sigma_2^2(ir) \end{bmatrix}$		$\Sigma_{IR} = \begin{bmatrix} \text{NA} & \\ & \frac{\sigma_2^2(ir)}{n'_{i2} n'_r} \end{bmatrix}$	

$\Sigma_{pir} = \begin{bmatrix} NA & \\ & \sigma_2^2(pir) \end{bmatrix}$	$\Sigma_{pIR} = \begin{bmatrix} NA & \\ & \frac{\sigma_2^2(pir)}{n'_{i2} n'_r} \end{bmatrix}$

Note. D study = decision study; FR = free response; G study = generalizability study; MC = multiple choice.

composite involve different variance and covariance components for the two sections, as follows:

$$\sigma_{\bar{Z}}^2(\delta) = w_1^2[\sigma_1^2(pI)] + w_2^2[\sigma_2^2(pI) + \sigma_2^2(pR) + \sigma_2^2(pIR)], \quad (29)$$

and

$$\begin{aligned} \sigma_{\bar{Z}}^2(\Delta) = & w_1^2[\sigma_1^2(I) + \sigma_1^2(pI)] + w_2^2[\sigma_2^2(I) + \sigma_2^2(R) + \sigma_2^2(IR) \\ & + \sigma_2^2(pI) + \sigma_2^2(pR) + \sigma_2^2(pIR)]. \end{aligned} \quad (30)$$

Finally, the reliability-like coefficients are obtained using these quantities for the composite in Equations 25 and 26.

The preceding discussion highlights that extended multivariate GT offers a useful framework for dealing with multivariate designs that are more complex than those commonly discussed in the current literature. However, the model needs to be studied further through more diversified applications of the model with various types of complex designs in real-world testing.

RELIABILITY IN IRT

In IRT, a test taker's response to an item is modeled as a function of an underlying proficiency variable denoted θ and item parameters. The proficiency for a test taker can be estimated using either the maximum likelihood (ML) or Bayesian estimation methods. An estimator, denoted $\hat{\theta}$, serves as the observed score in IRT. In this context, we primarily consider the ML and Bayesian expected a posteriori (EAP) estimators. Another Bayesian estimator, maximum a posteriori (MAP), is briefly discussed because it shares the same underlying framework with the EAP estimator.

The main focus of this section is to present various approaches to quantifying reliability within the framework of IRT. The mathematical formulations presented here are designed to be applicable and generalizable to many different IRT models, without making specific distinctions among those models. Throughout this section, unidimensional dichotomous IRT models are assumed, except in the last subsection where some procedures are discussed for a few specific multidimensional IRT (MIRT) models.

Results are presented for several score metrics, including ML estimates, EAP estimates, summed raw scores, transformed scale scores from summed raw scores, composite scores, and composite scale scores. The two classes of estimation methods (ML and EAP) are discussed separately because of their fundamental inconsistencies in terms of the model framework and assumptions.

Under the ML framework, the data at hand are viewed as a random sample from a distribution with known θ and item parameters. For a test taker with θ , the observed data over replications are conceptually obtained by administering test forms with the exact same item parameters repeatedly. These forms, with the same item parameters, are often called *strictly parallel* forms, or it can be said that the form is effectively fixed (W. Lee et al., 2000). Therefore, the source of error causing the variability in estimates over replications is best described as resulting from each item being sampled from a large pool of items with identical parameters.

Reliability statistics under the ML framework are conceptualized and computed by focusing on the distribution of proficiency estimates conditional on the parameter $f(\hat{\theta}|\theta)$. The standard deviation of $\hat{\theta}$ given θ is termed the conditional standard error of estimation (SEE). In IRT, the SEE plays a role similar to that of the SEM in CTT. However, these terms are often used interchangeably in the context of estimating reliability in IRT (e.g., B. F. Green et al., 1984; Lord, 1983). For the purposes of this chapter, no distinction is made between the two terms.

In contrast, the Bayesian framework is primarily concerned with obtaining the posterior distribution of parameters given observed data, $f(\theta|\mathbf{u})$, where parameters are considered random while data are fixed. Here, $\mathbf{u}$ is a vector of a test taker's item responses. The EAP estimate is the mean of the posterior distribution of θ for test takers with the same item responses. The standard deviation of the posterior distribution serves as the SEE for the EAP estimator. However, as demonstrated later, under this Bayesian framework, the concept of replications is obscure, at best, and thus the Bayes SEE is conceptually different from the SEE in the ML estimator and SEM in CTT.

Consider the following parameterization, similar to CTT:

$$\hat{\theta} = \theta + \varepsilon, \quad (31)$$

where a proficiency estimate $\hat{\theta}$ is decomposed into the latent proficiency θ and an error component, ε . For simplicity, subscripts indicating test takers and forms are omitted here. In contrast to CTT, where the true score for a test taker is equal to the expected value of observed scores, the proficiency estimators, both ML and EAP, provide biased estimates for θ (J. K. Kim & Nicewander, 1993; Lord, 1983; Warm, 1989). The ML estimator is unbiased only asymptotically as the test length approaches infinity. The bias in the ML estimates has significant consequences. Unlike the results in CTT, various expressions or definitions of the reliability coefficient for the ML estimator may not yield the same answer, a fact that is frequently overlooked.

Maximum Likelihood Proficiency Estimates

Let $\hat{\theta}$ denote the ML estimator of θ . As noted earlier, due to bias in $\hat{\theta}$, the expected value of $\hat{\theta}$ is not equal to θ ; namely, $\mathcal{E}(\hat{\theta}|\theta) \neq \theta$. The expected value of $\hat{\theta}$ is referred to here as *expected* proficiency, compared to *latent* proficiency θ . For $\hat{\theta}$, the following reliability coefficients are typically considered:

$$R(\hat{\theta})_{PF} \equiv \rho(\hat{\theta}, \hat{\theta}'); R(\hat{\theta})_{SC} \equiv \rho^2(\hat{\theta}, \theta); R(\hat{\theta})_{VR} \equiv \frac{\sigma^2(\theta)}{\sigma^2(\hat{\theta})};$$

$$R(\hat{\theta})_{EVR} \equiv \frac{\sigma^2[\mathcal{E}(\hat{\theta}|\theta)]}{\sigma^2(\hat{\theta})} = 1 - \frac{\mathcal{E}\sigma^2(\hat{\theta}|\theta)}{\sigma^2(\hat{\theta})}; \text{ and } R(\hat{\theta})_{MVR} \equiv \frac{\sigma^2(\theta)}{\sigma^2(\theta) + \mathcal{E}\sigma^2(\hat{\theta}|\theta)}.$$

In CTT, similar expressions of these reliability coefficients are all identical when derived under the assumptions of classically parallel forms. However, the equality does not hold for $\hat{\theta}$. The first definition $R(\hat{\theta})_{PF}$ is the parallel-forms coefficient, $R(\hat{\theta})_{SC}$ is the squared-correlation coefficient, and the last three represent the variance-ratio coefficients (indicated by subscripts including VR). These coefficients will likely produce different results primarily because they use different definitions of true proficiency and its variance. Hereinafter, $\sigma^2(\theta)$ in $R(\hat{\theta})_{VR}$ and $R(\hat{\theta})_{MVR}$ is referred to as *latent proficiency variance*, while the numerator of the first formula in $R(\hat{\theta})_{EVR}$, $\sigma^2[\mathcal{E}(\hat{\theta}|\theta)]$, is referred to as *expected proficiency variance*. The subscript *EVR* appended to $R(\hat{\theta})_{EVR}$ signifies the use of expected proficiency variance. Likewise, $\mathcal{E}\sigma^2(\hat{\theta}|\theta)$ in $R(\hat{\theta})_{EVR}$ and $R(\hat{\theta})_{MVR}$ is referred to here as *expected error variance*, which differs from either the error variance $\sigma^2(\varepsilon)$ (see Equation 31) or another quantity, $\sigma^2(\hat{\theta}) - \sigma^2(\theta)$. Recall that $\mathcal{E}\sigma^2(\hat{\theta}|\theta)$ quantifies the variability of $\hat{\theta} - \mathcal{E}\hat{\theta}$; by contrast, $\sigma^2(\varepsilon)$ is concerned about $\hat{\theta} - \theta$. The last three variance-ratio coefficients differ in terms of which types of variances are used in the numerators and denominators. In effect, $R(\hat{\theta})_{VR}$ involves latent proficiency variance in conjunction with $\sigma^2(\hat{\theta}) - \sigma^2(\theta)$ as its error variance; $R(\hat{\theta})_{EVR}$ contains expected variances in both the numerator and denominator; and $R(\hat{\theta})_{MVR}$ exploits an interesting mix of both types (note the letter *M* in the subscript).

For ease of explanation, let's first delve into the three variance-ratio coefficients, followed by $R(\hat{\theta})_{PF}$ and $R(\hat{\theta})_{SC}$. In the literature, $R(\hat{\theta})_{EVR}$ is often called marginal reliability (B. F. Green et al., 1984). S. Kim (2012) labeled $R(\hat{\theta})_{EVR}$ as the (squared) correlation ratio for predicting θ from $\hat{\theta}$, which might also be called an intraclass correlation coefficient based on the ANOVA identity, given by

$$\sigma^2(\hat{\theta}) = \sigma^2[\mathcal{E}(\hat{\theta}|\theta)] + \mathcal{E}\sigma^2(\hat{\theta}|\theta). \quad (32)$$

The intraclass correlation coefficient, $R(\hat{\theta})_{EVR}$, becomes identical to the squared Pearson correlation coefficient (i.e., $R(\hat{\theta})_{SC}$) if the relationship between $\hat{\theta}$ and θ is linear; however, if the relationship is not linear, $R(\hat{\theta})_{EVR} \geq R(\hat{\theta})_{SC}$.

Since $\hat{\theta}$ is a biased estimator, $\mathcal{E}(\hat{\theta}|\theta) = \theta + BIAS$. Bias is not constant and can be either positive or negative depending on the location of a proficiency parameter along the θ scale. An immediate consequence of the bias in $\hat{\theta}$ is that $\sigma^2[\mathcal{E}(\hat{\theta}|\theta)] \neq \sigma^2(\theta)$. Rather,

$$\sigma^2[\mathcal{E}(\hat{\theta}|\theta)] = \sigma^2(\theta + BIAS) = \sigma^2(\theta) + \sigma^2(BIAS) + 2\sigma(\theta, BIAS), \quad (33)$$

where the variance terms are always positive and the covariance between θ and $BIAS$ is usually positive although there is no theoretical justification or proof for that (Lord, 1983). Clearly, the expected proficiency variance, $\sigma^2[\mathcal{E}(\hat{\theta}|\theta)]$, is *not* equal to $\sigma^2(\theta)$ and the former usually is larger than the latter. From Equations 32 and 33, it follows that

$$\sigma^2(\hat{\theta}) = \sigma^2(\theta) + \sigma^2(BIAS) + 2\sigma(\theta, BIAS) + \mathcal{E}\sigma^2(\hat{\theta}|\theta). \quad (34)$$

As $\sigma(\theta, BIAS)$ typically is positive, $\sigma^2(\hat{\theta}) > \sigma^2(\theta)$.

Coefficient $R(\hat{\theta})_{EVR}$ uses the expected proficiency variance in the numerator and the expected error variance in the denominator because $\sigma^2(\hat{\theta}) - \sigma^2[\mathcal{E}(\hat{\theta}|\theta)] = \mathcal{E}\sigma^2(\hat{\theta}|\theta)$. Conceptually, $BIAS = \mathcal{E}(\hat{\theta}|\theta) - \theta$ is a constant for a given test taker with θ (i.e., systematic error), and thus its variance (and covariance) should contribute to the true proficiency variance, but not to the error variance. Equations 33 and 34 clearly show that the expected proficiency variance, $\sigma^2[\mathcal{E}(\hat{\theta}|\theta)]$, in $R(\hat{\theta})_{EVR}$ incorporates two additional terms related to bias, in addition to $\sigma^2(\theta)$, whereas the expected error variance does not encompass them.

To estimate $R(\hat{\theta})_{EVR} = 1 - [\mathcal{E}\sigma^2(\hat{\theta}|\theta)/\sigma^2(\hat{\theta})]$, the conditional error variance, $\sigma^2(\hat{\theta}|\theta)$, is often obtained by taking the reciprocal of the test information function as $\sigma^2(\hat{\theta}|\theta) = 1 / I(\theta, \hat{\theta})$. Thus, $R(\hat{\theta})_{EVR}$ can also be expressed as

$$R(\hat{\theta})_{EVR} = 1 - \frac{\mathcal{E}\sigma^2(\hat{\theta}|\theta)}{\sigma^2(\hat{\theta})} = 1 - \frac{\mathcal{E}[1/I(\theta, \hat{\theta})]}{\sigma^2(\hat{\theta})}. \quad (35)$$

Taking the three-parameter logistic IRT model as an example, the test information on an n -item test is simply the sum of the item information functions:

$$I(\theta, \hat{\theta}) = \sum_{i=1}^n I_i(\theta, \hat{\theta}) = \sum_{i=1}^n \left[\frac{[P'_i(\theta)]^2}{P_i(\theta)Q_i(\theta)} \right], \text{ where } I_i(\theta, \hat{\theta}) (i = 1, \dots, n)$$

is the item information functions, $P_i(\theta) = c_i + (1 - c_i) / \{1 + \exp[-1.7a_i(\theta - b_i)]\}$, and $Q_i(\theta) = 1 - P_i(\theta)$. The expectation in Equation 35 typically is taken over a set of discrete θ quadrature points and associated weights assuming a standard normal distribution.

Coefficient $R(\hat{\theta})_{VR}$ differs from $R(\hat{\theta})_{EVR}$ in its use of latent proficiency variance and a distinct form of error variance expressed as $\sigma^2(\hat{\theta}) - \sigma^2(\theta)$:

$$\sigma^2(\hat{\theta}) - \sigma^2(\theta) = \mathcal{E}\sigma^2(\hat{\theta}|\theta) + \sigma^2(BIAS) + 2\sigma(\theta, BIAS). \quad (36)$$

This “error variance” comprises the expected error variance plus two terms associated with systematic error, namely, bias. The bias-related terms, which contribute to the expected proficiency variance in $R(\hat{\theta})_{EVR}$, are integrated into the error variance in $R(\hat{\theta})_{VR}$, resulting in $R(\hat{\theta})_{EVR} \geq R(\hat{\theta})_{VR}$. This inclusion of bias terms in the error variance of $R(\hat{\theta})_{VR}$ raises concerns about the defensibility of this coefficient because systematic errors, in principle, should contribute to the true proficiency variance.

The final variance-ratio reliability coefficient, $R(\hat{\theta})_{MVR}$, is widely discussed and used in practice (e.g., Andersson & Xin, 2018; Cheng et al., 2012). Assuming the distribution of θ follows a standard normal distribution with a variance equal to 1, $R(\hat{\theta})_{MVR}$ can be expressed as $1/\{1 + \mathcal{E}[1/I(\theta, \hat{\theta})]\}$. The prevalent use of $R(\hat{\theta})_{MVR}$ relies on convenience—it does not require the use of sample estimates $\hat{\theta}$ s, assumes the variance of θ to be 1, and easily obtains the information function using standard normal quadrature points and weights. Coefficient $R(\hat{\theta})_{MVR}$ is an interesting statistic because it uses a mix of latent proficiency variance and expected error variance. Moreover, the sum of $\sigma^2(\theta)$ and $\mathcal{E}\sigma^2(\hat{\theta}|\theta)$ in the denominator is not equal to $\sigma^2(\hat{\theta})$, completely eliminating bias-related terms from the formula. Although it may be regarded as a more sensible coefficient than $R(\hat{\theta})_{VR}$, it has drawbacks because it engages the latent trait definition of proficiency, and the variance of actual proficiency estimates does not play any role.

It is interesting to note that $\sigma^2(\varepsilon)$ is never used as error variance for any of the variance-ratio reliability coefficients. According to the ANOVA identity, the overall error variance $\sigma^2(\varepsilon)$ can be formulated as (Lord, 1983):

$$\sigma^2(\varepsilon) = \sigma^2[\mathcal{E}(\varepsilon|\theta)] + \mathcal{E}\sigma^2(\varepsilon|\theta) = \sigma^2(BIAS) + \mathcal{E}\sigma^2(\hat{\theta}|\theta), \quad (37)$$

because $\mathcal{E}(\varepsilon|\theta) = \mathcal{E}(\hat{\theta} - \theta|\theta) = BIAS$ and $\sigma^2(\hat{\theta}|\theta) = \sigma^2(\varepsilon|\theta)$ for a single fixed test taker. Obviously, $\sigma^2(\varepsilon)$ includes both random error variance and variance attributable to bias, distinguishing it from the expected error variance $\mathcal{E}\sigma^2(\hat{\theta}|\theta)$ and the error variance defined in Equation 36.

Now, let us consider the parallel-forms coefficient, $R(\hat{\theta})_{PF} = \rho(\hat{\theta}, \hat{\theta}')$. This coefficient is, by definition, the Pearson correlation for a population between proficiency estimates obtained from two parallel forms. In cases where double testing is impractical, Lord (1983) derived a formula for $R(\hat{\theta})_{PF}$ that is expressed in terms of statistical quantities obtainable from a single administration of a test under the assumption of strictly parallel forms. Note that Samejima (1994) derived the same result as Lord (1983); however, she used the traditional assumptions of CTT, which may not hold exactly for $\hat{\theta}$. The parallel-forms reliability coefficient, $R(\hat{\theta})_{PF}$, is defined as

$$R(\hat{\theta})_{PF} \equiv \rho(\hat{\theta}, \hat{\theta}') = \frac{\sigma(\hat{\theta}, \hat{\theta}')}{\sigma(\hat{\theta})\sigma(\hat{\theta}')} = \frac{\sigma(\hat{\theta}, \hat{\theta}')}{\sigma^2(\hat{\theta})}, \quad (38)$$

where $\sigma(\hat{\theta}) = \sigma(\hat{\theta}')$ for strictly parallel forms. It can be shown that the asymptotically unbiased estimator of $\sigma(\hat{\theta}, \hat{\theta}')$ is

$$\sigma(\hat{\theta}, \hat{\theta}') = \sigma^2(\hat{\theta}) - \mathcal{E}\sigma^2(\hat{\theta}|\theta). \quad (39)$$

Therefore, the parallel-forms reliability coefficient of $\hat{\theta}$ becomes equal to $R(\hat{\theta})_{EVR}$:

$$\begin{aligned} R(\hat{\theta})_{PF} \equiv \rho(\hat{\theta}, \hat{\theta}') &= \frac{\sigma(\hat{\theta}, \hat{\theta}')}{\sigma^2(\hat{\theta})} = \frac{\sigma^2(\hat{\theta}) - \mathcal{E}\sigma^2(\hat{\theta}|\theta)}{\sigma^2(\hat{\theta})} \\ &= 1 - \frac{\mathcal{E}\sigma^2(\hat{\theta}|\theta)}{\sigma^2(\hat{\theta})} \equiv R(\hat{\theta})_{EVR}. \end{aligned} \quad (40)$$

The last coefficient to discuss is $R(\hat{\theta})_{SC}$, the squared-correlation reliability coefficient. S. Kim (2012) demonstrated that $R(\hat{\theta})_{SC}$ based on the linear regression of $\hat{\theta}$ on θ differs from $R(\hat{\theta})_{PF}$. Coefficient $R(\hat{\theta})_{SC}$ is defined as

$$R(\hat{\theta})_{SC} \equiv \rho^2(\hat{\theta}, \theta) = \frac{[\sigma(\hat{\theta}, \theta)]^2}{\sigma^2(\hat{\theta})\sigma^2(\theta)}, \quad (41)$$

where $\sigma(\hat{\theta}, \theta) = \sigma[\mathcal{E}(\hat{\theta}|\theta), \theta] + \mathcal{E}\sigma(\hat{\theta}, \theta|\theta) = \sigma^2(\theta) + \sigma(\theta, BIAS)$. Let $L(\varepsilon|\theta)$ denote the linear regression of ε on θ with the regression coefficient of $\beta(\varepsilon|\theta) = \sigma(\varepsilon, \theta)/\sigma^2(\theta) = \sigma(\theta, BIAS)/\sigma^2(\theta)$. It follows that

$$R(\hat{\theta})_{SC} = \frac{\sigma^2(\theta)}{\sigma^2(\hat{\theta})} [1 + \beta(\varepsilon|\theta)]^2 = R(\hat{\theta})_{VR} \times [1 + \beta(\varepsilon|\theta)]^2. \quad (42)$$

Because $\mathcal{E}(\varepsilon|\theta) = \mathcal{E}(\hat{\theta} - \theta|\theta) = BIAS \neq 0$, the slope of $L(\varepsilon|\theta)$, $\beta(\varepsilon|\theta)$, may not be zero. Then, it is clear from Equation 42 that $R(\hat{\theta})_{SC}$ and $R(\hat{\theta})_{VR}$ differ by a factor of $(1 + \beta_{\varepsilon|\theta})^2$. If $\sigma(BIAS, \theta)$ is positive, which usually is the case, $R(\hat{\theta})_{SC}$ will be larger than $R(\hat{\theta})_{VR}$. One way to estimate $R(\hat{\theta})_{SC}$ would be to use a mathematical expression for bias, which then can be used to estimate $\beta(\varepsilon|\theta)$. For example, Lord (1983) provided the bias function for $\hat{\theta}$ of θ under the three-parameter logistic model.

As evident from the formula itself, $R(\hat{\theta})_{SC}$ measures the extent to which proficiency estimates are associated with *latent* proficiencies. We can consider a similar (squared) correlation coefficient that involves *expected* proficiencies, denoted $\rho^2(\hat{\theta}, \mathcal{E}\hat{\theta})$. It is arguably more correct to refer to $\rho^2(\hat{\theta}, \mathcal{E}\hat{\theta})$ as a reliability coefficient, while $R(\hat{\theta})_{SC}$ can be seen as a squared validity coefficient. The key distinction lies in the fact that the two coefficients use definitions of true proficiency that differ by a constant *BIAS* for each test taker. If the bias is negligible, the distinction between the two will be trivial.

In many practical applications, $\hat{\theta}$ is often treated as an unbiased estimator, and the variance of the bias and its covariance with θ are neglected in estimating reliability. When the bias is negligibly small, such as for a long test, it may be argued that the expected variance terms are close to the variances associated with latent proficiencies: that is, $\sigma^2(\hat{\theta}) \cong \sigma^2(\theta) + \sigma^2(\varepsilon|\theta) \cong \sigma^2(\theta) + \mathcal{E}\sigma^2(\hat{\theta}|\theta) \cong \sigma^2[\mathcal{E}(\hat{\theta}|\theta)] + \mathcal{E}\sigma^2(\hat{\theta}|\theta)$.

Table 5.2 Variance-Ratio Reliability Coefficients for the Maximum Likelihood Estimator

Coefficient	Variance of Proficiency Estimates	True Proficiency Variance	Error Variance
$R(\hat{\theta})_{VR}$	$\sigma^2(\hat{\theta})$	$\sigma^2(\theta)$	$\mathcal{E}\sigma^2(\hat{\theta} \theta) + \sigma^2(BIAS) + 2\sigma(\theta, BIAS)$
$R(\hat{\theta})_{EVR} = R(\hat{\theta})_{PF}$	$\sigma^2(\hat{\theta})$	$\sigma^2[\mathcal{E}(\hat{\theta} \theta)] = \sigma^2(\theta) + \sigma^2(BIAS) + 2\sigma(\theta, BIAS)$	$\mathcal{E}\sigma^2(\hat{\theta} \theta)$
$R(\hat{\theta})_{MVR}$	$\sigma^2(\theta) + \mathcal{E}\sigma^2(\hat{\theta} \theta)$	$\sigma^2(\theta)$	$\mathcal{E}\sigma^2(\hat{\theta} \theta)$

Consequently, the three variance-ratio reliability coefficients will yield similar results:

$R(\hat{\theta})_{VR} \cong R(\hat{\theta})_{EVR} \cong R(\hat{\theta})_{MVR}$. The parallel-forms reliability coefficient, $R(\hat{\theta})_{PF}$, has been proven to be equal to $R(\hat{\theta})_{EVR}$. Coefficient $R(\hat{\theta})_{SC}$ is limited to the linear regression assumption, and from the well-known statistical properties, $R(\hat{\theta})_{EVR}$ is generally larger than $R(\hat{\theta})_{SC}$. The two coefficients, $R(\hat{\theta})_{SC}$ and $R(\hat{\theta})_{EVR}$, will be identical only if bias is zero.

As highlighted by previous researchers (e.g., S. Kim, 2012; Lord, 1983), these coefficients are *not* estimating the same parameter and thus are not interchangeable. In general, the following inequalities are likely to hold: $R(\hat{\theta})_{PF} = R(\hat{\theta})_{EVR} \geq R(\hat{\theta})_{SC} \neq R(\hat{\theta})_{MVR} \geq R(\hat{\theta})_{VR}$. The fundamental cause of these differences is the bias in $\hat{\theta}$, and the extent to which these coefficients yield different results largely depends on the amount of bias. If it is suspected that bias is not negligible, the use of $R(\hat{\theta})_{EVR}$ would be advisable. Table 5.2 summarizes the variance terms involved in each of the variance-ratio reliability coefficients.

The impact of bias in reliability coefficients can be alleviated by using modified ML estimators that adjust for the bias of $\hat{\theta}$. For example, Lord (1983) derived a bias-correction function for $\hat{\theta}$ under the three-parameter logistic model. Samejima (1993a, 1993b) expanded Lord's (1983) work to develop a bias function for any discrete item responses. Warm's (1989) weighted likelihood estimator is also known to reduce the bias of $\hat{\theta}$. However, in general, there is a dearth of literature focused on the effect of bias in reliability for various IRT models, including polytomous and multidimensional models. So, caution needs to be exercised when deciding which formula to use in practice.

Bayesian Proficiency Estimates

The Bayesian proficiency estimator of primary interest in this section is the EAP estimator denoted $\tilde{\theta}$. A crucial difference between the ML and EAP estimators in conceptualizing reliability lies in the use of different conditional distributions. The ML estimator focuses on the distribution of $f(\hat{\theta}|\theta)$, while the EAP estimator is concerned with $f(\theta|\tilde{\theta})$. The variance of $f(\theta|\tilde{\theta})$ serves as the conditional error variance for EAP estimates, denoted $\sigma^2(\theta|\tilde{\theta})$. The commonly discussed and utilized reliability coefficients for $\tilde{\theta}$ include:

$$\begin{aligned}
R(\tilde{\theta})_{SC} &\equiv \rho^2(\theta, \tilde{\theta}); \\
R(\tilde{\theta})_{VR} &\equiv \frac{\sigma^2(\tilde{\theta})}{\sigma^2(\theta)} = \frac{\sigma^2[\mathcal{E}(\theta|\tilde{\theta})]}{\sigma^2(\theta)} = 1 - \frac{\mathcal{E}\sigma^2(\theta|\tilde{\theta})}{\sigma^2(\theta)} = \frac{\sigma^2(\tilde{\theta})}{\sigma^2(\tilde{\theta}) + \mathcal{E}\sigma^2(\theta|\tilde{\theta})}; \text{ and} \\
R(\tilde{\theta})_{INF} &\equiv 1 - \frac{\mathcal{E}[1/(I(\theta, \tilde{\theta}) + 1)]}{\sigma^2(\theta)}.
\end{aligned}$$

The parallel-forms definition of reliability is *not* applicable to $\tilde{\theta}$ in the Bayesian framework because the obtained data are considered fixed. The squared-correlation definition of $R(\tilde{\theta})_{SC}$ resembles that of $R(\hat{\theta})_{SC}$ for the ML estimator, differing in that $R(\tilde{\theta})_{SC}$ is based on the linear regression of θ and $\tilde{\theta}$, $L(\theta|\tilde{\theta})$, while $R(\hat{\theta})_{SC}$ depends on $L(\hat{\theta}|\theta)$. Unlike the ML estimator, all variations of the variance-ratio coefficients associated with $R(\tilde{\theta})_{VR}$ are identical. Notably, the reversal of variances in true proficiencies and proficiency estimates in $R(\tilde{\theta})_{VR}$ compared to the ML estimator stems from the Bayesian framework's focus on predicting θ given $\tilde{\theta}$, as opposed to estimating $\hat{\theta}$ given θ under the ML framework. The last coefficient, $R(\tilde{\theta})_{INF}$, is proposed as an alternative reliability coefficient for $\tilde{\theta}$, approximating the relationship between the test information function (noted by the *INF* subscript) and the variance of the posterior distribution. As an approximation to $R(\tilde{\theta})_{VR}$, $R(\tilde{\theta})_{INF}$ offers the benefit of avoiding intricate computations of posterior variance while integrating the well-established concept of the test information function.

The EAP estimate for a test taker with item response data $\mathbf{u} = \{u_1, \dots, u_n\}$, by definition, is the mean of the posterior distribution, which is given by

$$\tilde{\theta} = \mathcal{E}(\theta|\mathbf{u}) = \frac{\int_{\theta} \theta \prod_{i=1}^n \Pr(U_i = u_i|\theta) f(\theta) d\theta}{\int_{\theta} \prod_{i=1}^n \Pr(U_i = u_i|\theta) f(\theta) d\theta}, \quad (43)$$

where $\Pr(U_i = u_i|\theta)$ is the item response function for a given IRT model and $f(\theta)$ is the prior distribution of θ , which often is assumed to be the same for all test takers. The variance of the posterior distribution (i.e., error variance) for a test taker with $\mathbf{u}$ is (Bock & Mislevy, 1982):

$$\sigma^2(\theta|\mathbf{u}) = \frac{\int_{\theta} (\theta - \tilde{\theta})^2 \prod_{i=1}^n \Pr(U_i = u_i|\theta) f(\theta) d\theta}{\int_{\theta} \prod_{i=1}^n \Pr(U_i = u_i|\theta) f(\theta) d\theta}. \quad (44)$$

The integrals in Equations 43 and 44 are replaced by summations using a discrete proficiency distribution for computational purposes.

Of note, one distinct property of $\tilde{\theta}$ is its one-to-one correspondence with $\mathbf{u}$, meaning that test takers with the same response pattern will have the same $\tilde{\theta}$. This property suggests that the conditional posterior distribution of θ is identical using either $\mathbf{u}$ or $\tilde{\theta}$

as the conditioning variable. As such, $\tilde{\theta} = \mathcal{E}(\theta|\mathbf{u}) = \mathcal{E}(\theta|\tilde{\theta})$ and $\sigma^2(\theta|\mathbf{u}) = \sigma^2(\theta|\tilde{\theta})$. In the context of predicting θ given $\tilde{\theta}$, the ANOVA identity suggests that

$$\sigma^2(\theta) = \sigma^2[\mathcal{E}(\theta | \tilde{\theta})] + \mathcal{E}\sigma^2(\theta | \tilde{\theta}). \quad (45)$$

Based on this equality, the intraclass correlation coefficient is $\sigma^2[\mathcal{E}(\theta|\tilde{\theta})]/\sigma^2(\theta) = 1 - [\mathcal{E}\sigma^2(\theta|\tilde{\theta})/\sigma^2(\theta)]$.

One appealing feature of the Bayesian framework is that the distinction of expected variance terms is no longer necessary. The first term in the right-hand side of Equation 45, $\sigma^2[\mathcal{E}(\theta | \tilde{\theta})]$, is equal to $\sigma^2(\tilde{\theta})$ because $\mathcal{E}(\theta | \tilde{\theta}) = \tilde{\theta}$. The equality of $\sigma^2[\mathcal{E}(\theta | \tilde{\theta})] = \sigma^2(\tilde{\theta})$ is sufficient to render the first three variance-ratio definitions in $R(\tilde{\theta})_{VR}$ identical. It can be further shown that $\sigma^2(\varepsilon) = \sigma^2[\mathcal{E}(\varepsilon|\tilde{\theta})] + \mathcal{E}\sigma^2(\varepsilon|\tilde{\theta})$, similar to Equation 37, and because $\sigma^2[\mathcal{E}(\varepsilon|\tilde{\theta})] = 0$, $\sigma^2(\varepsilon) = \mathcal{E}\sigma^2(\varepsilon|\tilde{\theta}) = \mathcal{E}\sigma^2(\theta|\tilde{\theta})$. As a result,

$$\sigma^2(\theta) = \sigma^2(\tilde{\theta}) + \sigma^2(\varepsilon) = \sigma^2(\tilde{\theta}) + \mathcal{E}\sigma^2(\varepsilon | \tilde{\theta}). \quad (46)$$

It follows that various variance-ratio definitions ascribed to $R(\tilde{\theta})_{VR}$ are all equal to one another.

Similar to Equation 42 for the ML estimator, the EAP version of the squared-correlation coefficient is given by

$$R(\tilde{\theta})_{SC} \equiv \frac{\sigma^2[L(\theta|\tilde{\theta})]}{\sigma^2(\theta)} = \frac{\sigma^2(\tilde{\theta})}{\sigma^2(\theta)}. \quad (47)$$

Equation 47 clearly suggests that $R(\tilde{\theta})_{SC} = R(\tilde{\theta})_{VR}$. So, for the EAP estimator, $R(\tilde{\theta})_{SC}$ and various alternative definitions associated with $R(\tilde{\theta})_{VR}$ are all equal. This equality occurs as a result of the following one-to-one correspondence: $\mathcal{E}(\theta|\mathbf{u}) = \mathcal{E}(\theta|\tilde{\theta}) = \tilde{\theta}$. If the one-to-one correspondence is absent for an estimator, the equality may not hold. For example, S. Kim (2012) cautioned that another Bayes estimator, MAP, does not necessarily exhibit the one-to-one correspondence with the one- or two-parameter logistic IRT models.

The coefficient $R(\tilde{\theta})_{INF}$ incorporates the concept of information, typically associated with the ML estimator, to estimate the conditional and overall error variances. The link between the information for $\tilde{\theta}$ and $\sigma^2(\theta|\tilde{\theta})$ is established by the argument that the information provided by the prior distribution of θ is equivalent to adding an item to which all test takers in the population respond identically (Ferrando & Lorenzo-Seva, 2007; Thissen & Orlando, 2001). If the prior distribution of θ follows the standard normal distribution, as is commonly assumed, its contribution to the test information function is a constant value equal to 1 because $1/\sigma^2(\theta) = 1$. Consequently,

$$\sigma_{INF}^2(\theta | \tilde{\theta}) \cong \frac{1}{I(\theta, \tilde{\theta}) + 1}, \quad (48)$$

where $I(\theta, \tilde{\theta})$ is the traditional test information for a given θ . Furthermore, $\mathcal{E}\sigma^2(\theta|\tilde{\theta})$ in $R(\tilde{\theta})_{VR}$ can be replaced with $\sigma_{INF}^2(\theta|\tilde{\theta})$ computed by Equation 48 to derive an alternative expression for the reliability coefficient for $\tilde{\theta}$:

$$R(\tilde{\theta})_{INF} = 1 - \frac{\mathcal{E}[1/(I(\theta, \hat{\theta}) + 1)]}{\sigma^2(\theta)}, \quad (49)$$

which can be further reduced to $R(\tilde{\theta})_{INF} = 1 - \mathcal{E}[1/(I(\theta, \hat{\theta}) + 1)]$ because $\sigma^2(\theta)$ is equal to 1.

It is fair to say that coefficient $R(\tilde{\theta})_{INF}$ is computationally more convenient and capitalizes on the useful concept of information concerning its error variance. However, $R(\tilde{\theta})_{INF}$ would function merely as an approximation to the more defensible coefficient $R(\tilde{\theta})_{VR}$. This is because the algebraic similarity in aggregate statistics does not necessarily imply that the interpretation of error variance and its relation to other variance terms, especially in terms of conditional statistics, remains unchanged.

Summed Raw Scores and Transformed Scale Scores

IRT can serve as an underlying psychometric framework for estimating reliability for both summed raw scores, denoted X , and transformed scale scores, denoted $S = t(X)$. The general procedures suggested in the literature on this topic are largely consistent, except for variations in presentation details (e.g., S. Kim & Feldt, 2010; Kolen et al., 1996; Lord, 1980). As a function of a proficiency distribution and item parameters, the probability distributions for all three components of a measurement model (i.e., observed, true, and error scores) can be modeled and used subsequently to form reliability statistics.

A general model for representing marginal observed scores is given by

$$f(x) = \Pr(X = x) = \int_{\theta} \Pr(X = x|\theta) f(\theta) d\theta, \quad (50)$$

where $\Pr(X = x | \theta)$ is the conditional raw-score distribution and $f(\theta)$ is the distribution of θ . The conditional distribution, $f(x|\theta) = \Pr(X = x|\theta)$, captures the score variability for a test taker with θ over repeated testing using the strictly parallel forms or a fixed form. It can be efficiently computed using a recursive formula (e.g., Hanson, 1994; Lord & Wingersky, 1984; Thissen et al., 1995). Assuming a specific θ distribution (e.g., standard normal), the marginal observed score distribution, $f(x)$, is obtained by integrating the conditional distributions. The resulting $f(x)$ is often called the fitted or model-based observed score distribution, which lends itself to many applications in measurement such as test score equating, model fit examination, score smoothing, and quantifying reliability statistics.

For a test taker with θ , the expected value of $f(x|\theta)$ is the IRT analogue of true score in CTT, denoted

$$\tau_{\theta} = \mathcal{E}(X|\theta) = \sum x \Pr(X = x|\theta), \quad (51)$$

where the summation is taken over all possible values of X . The IRT true score τ_{θ} , a monotone nonlinear transformation of θ , is also referred to as the TCC. The variance of $\Pr(X = x|\theta)$ is the conditional error variance, computed by

$$\sigma^2(X|\theta) = \sum x^2 \Pr(X = x|\theta) - \tau_{\theta}^2. \quad (52)$$

The expected value of $\sigma^2(X|\theta)$ over all test takers in the population is the overall error variance, that is, $\mathcal{E}\sigma^2(X|\theta) = \int_{\theta} \sigma^2(X|\theta) f(\theta) d\theta$.

The ANOVA decomposition of the observed score variance is given by

$$\sigma^2(X) = \sigma^2[\mathcal{E}(X|\theta)] + \mathcal{E}\sigma^2(X|\theta) = \sigma^2(\tau_{\theta}) + \mathcal{E}\sigma^2(X|\theta). \quad (53)$$

Based on this ANOVA identity, the most widely used reliability coefficient is the following intraclass correlation:

$$R(X)_{IRT} = \frac{\sigma^2(\tau_{\theta})}{\sigma^2(\tau_{\theta}) + \mathcal{E}\sigma^2(X|\theta)} = 1 - \frac{\mathcal{E}\sigma^2(X|\theta)}{\sigma^2(X)}. \quad (54)$$

S. Kim and Feldt (2010) referred to the first formula as the true score variance approach and the second formula as the observed score variance approach. Andersson and Xin (2018) called $R(X)_{IRT}$ the test reliability. The true score variance, $\sigma^2(\tau_{\theta})$, in Equation 54 can be obtained using

$$\sigma^2(\tau_{\theta}) = \int_{\theta} \tau_{\theta}^2 f(\theta) d\theta - (\mathcal{E}\tau_{\theta})^2, \quad (55)$$

where $\mathcal{E}\tau_{\theta} = \int_{\theta} \tau_{\theta} f(\theta) d\theta$. The second formula of $R(X)_{IRT}$ requires observed score variance, which is the variance of $f(x)$ in Equation 50. If the sample observed score variance, denoted $\hat{\sigma}^2(X)$, is used, the variance equality in Equation 53 is lost, and the two formulas of $R(X)_{IRT}$ are no longer exchangeable. The coefficient, $1 - [\mathcal{E}\sigma^2(X|\theta)/\hat{\sigma}^2(X)]$, might be best viewed as a sample estimate of $R(X)_{IRT}$, although there is no clear theoretical justification for doing so. The sample estimate may work well if the model fit is reasonably good and may sometimes be the only option when the model-based observed score variance cannot be computed easily (e.g., noninteger observed scores).

Note that there is a one-to-one correspondence between θ and τ_{θ} —that is, $\mathcal{E}(X|\theta) = \mathcal{E}[X|\tau_{\theta}] = \tau_{\theta}$. As a result, the squared-correlation coefficient $\rho^2(X, \tau)$ will be identical to $R(X)_{IRT}$.

Now let us consider scale scores, $S = t(X)$, that are transformed from raw scores. According to the well-known statistical property of correlation, a linear transformation of variables does not alter the value of correlation, assuming the direction of transformation for both variables is the same. This indicates that any linearly transformed scale scores will have the same reliability as that for raw scores. Thus, linear transformation is not discussed further in this section. By contrast, nonlinear transformation requires special treatment, as discussed next.

Suppose a conversion table contains all possible raw-score points, each corresponding to a scale-score point with a nonlinear relationship. The raw-to-scale score conversion table can be one-to-one or many-to-one and may contain integer or noninteger scale scores. Conceptually, over repeated measurements, the probability of a test taker receiving a certain scale score is the same as the probability of obtaining the corresponding

raw score—that is, $\Pr[t(x)|\theta] = \Pr(X = x|\theta)$. The expected value of scale scores over replications for a test taker with θ is called *true scale score* for the test taker and is given by

$$\xi_\theta = \mathcal{E}(S|\theta) = \sum t(x)\Pr(X = x|\theta), \quad (56)$$

where the summation is over the entire range of raw scores. Likewise, the variance of scale scores for given θ is defined as

$$\sigma^2(S|\theta) = \sum [t(x)]^2 \Pr(X = x|\theta) - \xi_\theta^2. \quad (57)$$

The square root of Equation 57 is the *conditional scale-score SEM*. A reliability coefficient for scale scores can be expressed as

$$R(S)_{IRT} = \frac{\sigma^2(\xi_\theta)}{\sigma^2(\xi_\theta) + \mathcal{E}\sigma^2(S|\theta)} = 1 - \frac{\mathcal{E}\sigma^2(S|\theta)}{\sigma^2(S)}, \quad (58)$$

where $\mathcal{E}\sigma^2(S|\theta) = \int \sigma^2(S|\theta)g(\theta)d\theta$ and $\sigma^2(\xi_\theta)$ can be obtained similarly to Equation 55.

Composite Scores and Composite Scale Scores

A composite score, as defined earlier, is a weighted sum of scores from multiple constituent components. The potential score points and range of the composite score depend on the combinations of component scores and weights. In practical applications, composite scores are often rounded to the nearest integer, especially when noninteger weights are employed. However, rounding is not obligatory as long as all possible composite scores can be accurately identified and modeled.

The framework presented in this section closely aligns with the work of W. Lee et al. (2020), and similar developments can be found in Kolen et al. (2012) and Kolen and Lee (2011). W. Lee et al. (2020) considered three underlying IRT frameworks: unidimensional IRT (UIRT), simple-structure MIRT (SS-MIRT), and bifactor MIRT (BF-MIRT) models, each addressing potential multidimensionality in different ways. While the assumption of unidimensionality may be somewhat violated for composite scores, UIRT models are still commonly used. In the SS-MIRT model, each item is assumed to measure a single construct (i.e., component) and constructs across multiple components can be correlated (Kolen et al., 2012; W. Lee et al., 2020). The BF-MIRT model (Gibbons & Hedeker, 1992; Gibbons et al., 2007) assumes that all items in the test measure the same general construct, and each item measures an additional construct specific to the associated component. The general and specific constructs are typically uncorrelated. Further information about BF-MIRT can be found in Cai et al. (2011) and DeMars (2006, 2013).

The modeling of marginal composite scores follows a structure similar to Equation 50, with the use of a vector θ as the conditioning variable:

$$f(z) = \Pr(Z = z) = \int_{\theta} \Pr(Z = z|\theta)f(\theta)d\theta. \quad (59)$$

The number of proficiency parameters in the vector θ depends on the model—for UIRT models, $\theta = \theta$; for the SS-MIRT model, $\theta = \{\theta_1, \dots, \theta_M\}$; and for the BF-MIRT model,

$\theta = \{\theta_G, \theta_1, \dots, \theta_M\}$, where θ_G indicates the general factor. Numerical integration can be carried out using a univariate standard normal distribution for UIRT or a multivariate normal density function for the MIRT models, with nonzero correlations between components for the SS-MIRT or zero correlations (typically) for the BF-MIRT.

Assuming conditional local independence, one way to compute the conditional composite score distribution, $f(z|\theta) = \Pr(Z = z|\theta)$, is

$$\Pr(Z = z|\theta) = \sum_{Z=w_1X_1+\dots+w_MX_M} \prod_{m=1}^M \Pr(X_m = x_m|\theta), \quad (60)$$

where the summation is taken over all possible combinations of weighted component scores that lead to the same composite score. The conditional distribution for each component can be computed using a recursion formula such as Lord and Wingersky's (1984) method. Note that not all elements of θ are used in computing the conditional distribution for each component. For example, for component m , only a single θ_m is involved for the SS-MIRT model, while both θ_G and θ_m are needed for the BF-MIRT model. The mean (i.e., true composite score) and variance of the conditional distribution, respectively, are

$$\zeta_\theta = \mathcal{E}(Z|\theta) = \sum z \Pr(Z = z|\theta), \quad (61)$$

and

$$\sigma^2(Z|\theta) = \sum z^2 \Pr(Z = z|\theta) - \zeta_\theta^2. \quad (62)$$

A reliability coefficient then is given by

$$R(Z)_{IRT} = \frac{\sigma^2(\zeta_\theta)}{\sigma^2(\zeta_\theta) + \mathcal{E}\sigma^2(Z|\theta)} = 1 - \frac{\mathcal{E}\sigma^2(Z|\theta)}{\sigma^2(Z)}. \quad (63)$$

Alternatively, $R(Z)_{IRT}$ can be expressed in the form of the general reliability-coefficient formula for linear composite scores (i.e., Equation 15), which involves error variances for individual components. That is,

$$R(Z)_{IRT^*} = 1 - \frac{\sum_{m=1}^M \mathcal{E}\sigma^2(X_m|\theta)}{\sigma^2(Z)}, \quad (64)$$

where $\mathcal{E}\sigma^2(X_m|\theta)$ is the overall error variance for each component and errors across components are assumed to be uncorrelated. Comparing $R(Z)_{IRT}$ and $R(Z)_{IRT^*}$, it is evident that computing each $\mathcal{E}\sigma^2(X_m|\theta)$ and adding them up is easier than computing $\mathcal{E}\sigma^2(Z|\theta)$, which relies on the computationally cumbersome conditional composite score distribution, $f(z|\theta)$. However, $\sigma^2(Z)$ in the denominator of both coefficients is based on $f(z)$ in Equation 59, which, in turn, requires the use of $f(z|\theta)$. Therefore, bypassing $f(z|\theta)$ in the computational process is not a viable option. If the sample composite score variance, $\hat{\sigma}^2(Z)$, is used in place of the model-based one

for $R(Z)_{IRT^*}$, some of the computational complexity will be alleviated. Doing so, however, will result in a reliability estimate that is best viewed as a sample estimate of $R(Z)_{IRT^*}$ (or $R(Z)_{IRT}$) and many desired features of the coherent psychometric framework will no longer be available. Yet, the computational simplicity might be very useful in practice.

Composite scores usually are further transformed nonlinearly to scale scores for reporting purposes. The results for composite scale scores, $S = t(Z)$, can be obtained in an analogous manner by noting that $\Pr[t(z)|\theta] = \Pr(Z = z|\theta)$ and $\Pr[t(z)] = \Pr(Z = z)$. Replacing Z with $t(z)$ in Equations 61, 62, and 63 yields the true score, conditional error variance, and reliability coefficient all on the composite scale score metric.

Scale Scores Transformed From Proficiency Estimates

In situations where IRT proficiency scoring is used, the proficiency estimates derived from ML or EAP estimation methods are commonly converted to scale scores for reporting purposes. Here, we are mainly concerned with nonlinear transformations. Let $t(\theta)$ be a monotone increasing transformation function that converts θ to scale scores. It is assumed that the transformation is applied to both true and estimated proficiencies such that $S = t(\hat{\theta})$ and $\mathcal{E}(S|\theta) = \xi_\theta = t(\theta)$. The transformation function is further assumed to be continuous and differentiable at every level of θ . In cases where a mathematical expression for a theta-to-scale score transformation is not available, a practical solution might involve employing a smoothing technique to obtain a smooth continuous conversion relationship, such as a high-degree polynomial.

Let us begin with the ML estimator. According to Lord (1980, p. 67), the test information of observed scale score, S , for making inferences about θ , is defined as

$$I(\theta, S) = \frac{\left[\frac{\partial}{\partial \theta} \mathcal{E}(S|\theta) \right]^2}{\sigma^2(S|\theta)} = \frac{\left[t'(\theta) \right]^2}{\sigma^2(S|\theta)}, \quad (65)$$

where $t'(\theta)$ is the first derivative function of $t(\theta)$ and

$$\sigma^2(S|\theta) \cong \left[t'(\theta) \right]^2 \sigma^2(\hat{\theta}|\theta). \quad (66)$$

Equation 66 assumes that $\hat{\theta}$ is an asymptotically unbiased estimator of θ and is known as the delta method approximation (Kendall & Stuart, 1977), which will be detailed in the next section. Equations 65 and 66 suggest that $I(\theta, S) = I(\theta, \hat{\theta})$. Furthermore, the monotone increasing relationship between θ and $\xi_\theta \equiv \mathcal{E}(S|\theta)$ implies that $\sigma^2(S|\theta) = \sigma^2(S|\xi_\theta)$. The overall scale-score error variance can be obtained by integrating $\sigma^2(S|\theta)$ over the proficiency distribution as

$$\mathcal{E}\sigma^2(S|\theta) \cong \mathcal{E} \left(\frac{\left[t'(\theta) \right]^2}{I(\theta, S)} \right) = \mathcal{E} \left(\frac{\left[t'(\theta) \right]^2}{I(\theta, \hat{\theta})} \right). \quad (67)$$

The variance of true scale scores is

$$\sigma^2(\xi_\theta) = \int_{\theta} \xi_\theta^2 f(\theta) d\theta - (\mathcal{E}\xi_\theta)^2, \quad (68)$$

which can be evaluated using numerical integration. The scale-score analogues of $R(\hat{\theta})_{VR}$, $R(\hat{\theta})_{EVR}$, and $R(\hat{\theta})_{MVR}$, respectively, are

$$R(S_{\hat{\theta}})_{VR} = \frac{\sigma^2(\xi_\theta)}{\sigma^2(S)}; \quad R(S_{\hat{\theta}})_{EVR} = 1 - \frac{\mathcal{E}\sigma^2(S|\theta)}{\sigma^2(S)}; \text{ and}$$

$$R(S_{\hat{\theta}})_{MVR} = \frac{\sigma^2(\xi_\theta)}{\sigma^2(\xi_\theta) + \mathcal{E}\sigma^2(S|\theta)}.$$

Similar to ML estimates, these three coefficients for scale scores do not necessarily yield the same result.

For the EAP estimator, the conditional error variance, $\sigma^2(\theta|\mathbf{u}) = \sigma^2(\theta|\tilde{\theta})$, is provided in Equation 44. The conditional error variance for scale scores can be found using the delta method approximation as

$$\sigma^2(\xi_\theta | \tilde{\theta}) \cong \left\{ t' [\mathcal{E}(\theta|\tilde{\theta})] \right\}^2 \sigma^2(\theta|\tilde{\theta}) = \left[t'(\tilde{\theta}) \right]^2 \sigma^2(\theta|\tilde{\theta}). \quad (69)$$

Note that, under the Bayesian framework, $\sigma^2(\xi_\theta | \tilde{\theta})$ is the variance of *true* scale scores conditional on $\tilde{\theta}$. It immediately follows that the overall scale-score error variance is $\mathcal{E}\sigma^2(\xi_\theta|\tilde{\theta}) \cong \mathcal{E} \left\{ \left[t'(\tilde{\theta}) \right]^2 \sigma^2(\theta|\tilde{\theta}) \right\}$, where the expectation (i.e., average) is taken over all persons in the data. A reliability coefficient for scale scores takes a form similar to $R(\tilde{\theta})_{VR}$:

$$R(S_{\hat{\theta}})_{VR} = \frac{\sigma^2(S)}{\sigma^2(\xi_\theta)} \cong 1 - \frac{\mathcal{E}\sigma^2(\xi_\theta|\tilde{\theta})}{\sigma^2(\xi_\theta)} \cong \frac{\sigma^2(S)}{\sigma^2(S) + \mathcal{E}\sigma^2(\xi|\tilde{\theta})}, \quad (70)$$

where the true scale-score variance, $\sigma^2(\xi_\theta)$, can be computed using Equation 68. Unlike the results for $\tilde{\theta}$, the three variations of $R(S_{\hat{\theta}})_{VR}$ may not yield the same results because of the use of the delta method approximation and possible rounding of reported scale scores.

As discussed earlier, the Bayesian conditional error variance can also be approximated using the test information function as $\sigma_{INF}^2(\theta | \tilde{\theta}) \cong 1 / [I(\theta, \theta) + 1]$. In this approximation, the conditioning variable becomes true θ and a discrete set of quadrature points can be used instead of individual $\tilde{\theta}$'s. Then, the conditional scale-score variance can be estimated using the delta method, which gives $\sigma^2(\xi_\theta|\theta) \cong \left[t'(\theta) \right]^2 \sigma_{INF}^2(\theta|\tilde{\theta})$, and the overall error variance is obtained by integrating $\sigma^2(\xi_\theta|\theta)$ over the θ quadrature distribution. Finally, the scale-score version of $R(\tilde{\theta})_{INF}$ is given by $R(S_{\hat{\theta}})_{INF} = 1 - \left[\mathcal{E}\sigma^2(\xi_\theta|\theta) / \sigma^2(\xi_\theta) \right]$.

ESTIMATORS OF CSEMs

Conceptually, SEM represents the standard deviation of test scores over repeated measurements for a person, assuming the measurement process does not alter their true score. In CTT, the SEM is commonly expressed as $\sigma(E) = \sigma(X)\sqrt{1-\rho(X, X')}$, referred to as the overall SEM. While this computation offers simplicity, an excessive focus on reliability coefficients may divert attention from actively considering whether the sources of error involved in the SEM closely align with the intended use and generalization of the test results. Additionally, applying the same SEM to all test takers when constructing confidence intervals overlooks variations in SEM magnitude as a function of true and observed scores. An arguably more defensible approach might involve starting with CSEMs, which can then be used to derive both the overall SEM [see Equation 6] and reliability coefficients, if needed.

Although direct estimation of CSEMs over many repeated measurements is practically unfeasible, collecting data from two replications may not be so unrealistic. This approach is similar to the data collection design used for estimating the test-retest and parallel-forms reliability coefficients. Using two sets of observed scores, X_1 and X_2 , an estimate of the CSEM for a single test taker can be computed directly as

$$CSEM_R = \frac{|X_1 - X_2|}{\sqrt{2}}. \quad (71)$$

Some benefits of Equation 71 were argued by Brennan (2001a), including that, by replicating the full-length measurement procedure twice, the investigator is forced to focus on the actual characteristics of replications to ensure that they are faithful reflections of the intended universe. In addition, Equation 71 provides a direct estimate of the CSEM without making any assumptions, applicable to various score types such as raw scores, scale scores, and composite scores. This is especially advantageous given that computing CSEMs for scale scores based on a single administration of a test can often be complicated (e.g., Kolen et al., 1992, 1996; W. Lee et al., 2000). Despite these potential benefits, Equation 71 is not widely used in practice, partly because of the questionable accuracy of estimation based on only two replications and the challenge of obtaining two full-length replications on adequate samples.

Similar to reliability coefficients, considerable effort has been invested in developing estimators for CSEMs based on a single test administration using various psychometric models and making assumptions that are often too strong or untestable. In theory, CSEM is the standard deviation of observed scores over repeated parallel (classically, randomly, etc.) measurements conditional on each person's true score: that is, $\sigma(X|\tau_p) = \sigma(E|\tau_p)$. (Note that the subscript p denotes a particular person but may be omitted for simplicity when context allows.) Estimators for CSEMs fall broadly into two categories: those that condition on observed scores and those that condition on true scores. The former category avoids assumptions about the true score distribution, employing each test taker's observed score as an estimator of their true score, $\hat{\tau}_p = x_p$, since true scores are unknown.

Lord (1984) and Woodruff (1990) noted, however, that considering CSEM as conditional on observed score is appropriate only when a test taker at a particular observed score is randomly selected. Nonetheless, the bias in estimated CSEMs using observed scores as a conditioning variable diminishes with increasing test reliability. Also, studies have found this bias to be practically minimal (Feldt et al., 1985; W. Lee et al., 2000; Woodruff et al., 2013).

The second type of procedures make certain assumptions to estimate the true score distribution and express CSEMs conditional on true score. Consequently, these procedures eliminate the bias issue and ambiguity of interpretation. However, if reporting the CSEM to each individual test taker is the goal, mapping observed scores to true scores used for CSEM computation becomes inevitable, which makes the practice essentially the same as using observed scores as a conditioning variable. Both types of procedures generally yield similar results, and no particular argument is made here for preferring one approach over the other. Rather, it is advised that the choice of method should depend on the characteristics of available data, reasonableness of assumptions underlying the psychometric model, and available computer resources.

Summed Raw Scores

Thorndike Method

Thorndike (1951) was one of the first investigators to examine CSEMs that vary as a function of observed scores based on split-half tests. Suppose the total test score X is split into two essentially tau-equivalent half test scores, $X_1 = (1/2)T + C_1 + E_1$ and $X_2 = (1/2)T + C_2 + E_2$, and $X = X_1 + X_2$. It can be shown that, under CTT assumptions, the variance of difference scores between half-test scores is equal to the error variance for the total test:

$$\sigma^2(X_1 - X_2) = \sigma^2(C_1 - C_2 + E_1 - E_2) = \sigma^2(E_1) + \sigma^2(E_2) = \sigma^2(E). \quad (72)$$

This implies that, for any group of test takers with total observed score x , the standard deviation of difference scores between X_1 and X_2 provides an estimate of the CSEM for that group:

$$CSEM(X)_{TH} = \sigma(X_1 - X_2 | x). \quad (73)$$

However, a limitation arises as CSEMs across the range of total scores can be erratic, particularly at extreme scores due to low test-taker frequencies. In practice, test takers can be grouped into short intervals based on their total scores, and the CSEM is computed for each interval (i.e., subgroup).

Mollenkopf Method

Mollenkopf (1949) developed an estimator for CSEMs based on split halves, often considered a refinement of Thorndike's method (Feldt & Qualls, 1996). Assuming tau equivalence of the two split-half tests, consider the following quantity for person p :

$$D_p = [(X_{p1} - X_{p2}) - (\bar{X}_1 - \bar{X}_2)]^2, \quad (74)$$

where $\bar{X}_1$ and $\bar{X}_2$ are group means on the two half-tests. For any subgroup of N test takers, the average of D_p values, by definition, is the variance of half-test difference scores, which is equal to the error variance for the full-length test:

$$\bar{D} = \frac{1}{N} \sum_{p=1}^N [(X_{p1} - X_{p2}) - (\bar{X}_1 - \bar{X}_2)]^2 = \sigma^2(X_1 - X_2) = \sigma^2(E). \quad (75)$$

The square root of $\bar{D}$ for a subgroup of test takers with an observed score x is the CSEM, which is identical to Thorndike's CSEM. Mollenkopf (1949) goes further to suggest using a polynomial regression with D_p in Equation 74 as a dependent variable and the total score X as an independent variable:

$$\hat{D} = \beta_0 + \beta_1 X + \beta_2 X^2 + \cdots + \beta_q X^q, \quad (76)$$

where the polynomial degree q is chosen by the investigator. If the regression model fits well, the resulting predicted values, $\hat{D}$, provide a better approximation of conditional means than $\bar{D}$. Once the polynomial regression coefficients are estimated with a chosen q , Mollenkopf's CSEM at observed score x is

$$CSEM(X)_{MO} = \sqrt{\hat{D}} = \sqrt{\beta_0 + \beta_1 x + \beta_2 x^2 + \cdots + \beta_q x^q}. \quad (77)$$

Although fitting a polynomial regression is cumbersome, $CSEM(X)_{MO}$ has the desirable characteristic of providing smoother patterns of CSEMs along the observed score scale.

Binomial Error Model

A notable drawback of $CSEM(X)_{TH}$ and $CSEM(X)_{MO}$ is that they require splitting the full test into two parallel halves, and there are various possibilities for obtaining such splits. Lord's (1955, 1957) seminal work on the binomial error model provided a substantially different perspective. In this framework, a test form with n dichotomously scored items is viewed as a random sample from a universe of such items (i.e., each item has an equal probability of being selected). Each test taker has a true proportion-correct score, $\pi_p = \tau_p/n$, such that the probability of answering each undifferentiable item correctly is π_p for test taker p . Measurement errors are conceptualized by the variation in observed scores across an infinite number of test forms, each containing a different set of randomly selected n items.

For a test taker with π_p , the distribution of observed scores from repeated measurements follows a binomial distribution with the parameter π_p , and the error variance for the test taker is $\sigma^2(E|\pi_p) = \sigma^2(X|\pi_p) = n\pi_p(1-\pi_p)$. Lord's CSEM, replacing the unknown parameter π_p with the observed proportion-correct score $\bar{x}_p = x_p/n$, is given by

$$CSEM(X)_{BN} = \hat{\sigma}(E|\bar{x}_p) = \sqrt{\frac{x_p(n-x_p)}{n-1}}. \quad (78)$$

This formula can compute CSEMs for raw-score points ranging from 0 to n without needing test-taker data. It has a quadratic form, ensuring the resulting CSEMs exhibit a smooth inverted-U shape with zero values at observed scores of zero and n .

Criticism of Lord's CSEM involves its failure to differentiate items, treating them as having equal difficulties under the binomial error model. In response, Keats (1957) proposed a correction, introducing a fuzzy factor of $(1 - KR20)/(1 - KR21)$ to multiply the squared values of Lord's CSEMs. This adjustment is intended to bring the overall error variance, when averaged, into alignment with the error variance in KR20. From the perspective of CTT, the criticism and Keats's adjustment find support. However, from the viewpoints of GT, Lord's model possesses valuable features that were not clearly identifiable at the time. The notion of random sampling of items over replications diverges from CTT definitions of parallelism but aligns with the key characteristic of GT—that is, the randomly parallel forms assumption. Moreover, Lord's error variance can be shown to be identical to the conditional *absolute* error variance for a single-facet design in GT. Lord's estimator indeed involves absolute error, a type of error not present in CTT. Therefore, Lord's binomial error model is sometimes considered a bridge between CTT and GT (Brennan, 2010).

Multinomial Error Model

Application of Lord's binomial error model is limited to items with binary score categories (i.e., right or wrong). W. Lee (2007) expanded Lord's model to cases where each item in an n -item test is scored polytomously with k possible score points, $a_1, a_2, \dots, a_k$. A set of n items in a test is viewed as a random sample from an undifferentiated universe of such items. For notational simplicity, the derivation is presented for a single test taker without the subscript p . Let $\eta = \{\eta_1, \eta_2, \dots, \eta_k\}$ indicate the true category-proportion scores for a test taker; namely, η_1 is the proportion of items in the universe for which the test taker would get a score of a_1 , η_2 for a_2 , and so on. The sum of the η values is equal to 1. Let $Y_1, Y_2, \dots, Y_k$ be random variables representing the observed numbers of items scored $a_1, a_2, \dots, a_k$, respectively, such that $Y_1 + Y_2 + \dots + Y_k = n$. It follows that the total raw score X is given as $X = a_1Y_1 + a_2Y_2 + \dots + a_kY_k$.

Due to the random sampling assumption, the category counts $Y_1, Y_2, \dots, Y_k$ will follow a multinomial distribution:

$$f(y_1, y_2, \dots, y_k | \eta) = \frac{n!}{y_1! y_2! \dots y_k!} \eta_1^{y_1} \eta_2^{y_2} \dots \eta_k^{y_k}. \quad (79)$$

The conditional distribution of X can then be obtained as

$$f(x | \eta) = \Pr(X = x | \eta) = \sum_{x=a_1y_1+\dots+a_ky_k} f(y_1, y_2, \dots, y_k | \eta), \quad (80)$$

where the summation is taken over all weighted combinations of $a_1y_1 + \dots + a_ky_k$ that sum to x .

Substituting $\hat{\eta}_i = y_i/n$ for η_i and applying a bias-correction factor, $\sqrt{n/(n-1)}$, an estimator of the CSEM for a test taker with observed category counts of $y_1, \dots, y_k$ is given by

$$CSEM(X)_{MN} = \sqrt{\frac{1}{n-1} \left[\sum_{i=1}^k a_i^2 y_i (n - y_i) - 2 \sum_{i < j} a_i a_j y_i y_j \right]}. \quad (81)$$

Of note, using the above formula results in different estimated CSEMs for test takers with the same total raw score but varying configurations of category scores. W. Lee (2007) observed that multinomial CSEMs often display a vertically scattered umbrella pattern when plotted against the total raw score. When item scoring is binary, the multinomial estimates become identical to Lord's estimates.

Univariate GT

A general approach to estimating CSEMs under the GT framework has been developed (Brennan, 1998, 2001c). In GT, a distinction between absolute error and relative error is made even for the CSEMs. Estimating absolute CSEMs is relatively straightforward, while computing relative CSEMs is usually complicated although a simplified formula is available under certain assumptions. In GT, analyses commonly use the *mean* score metric rather than the total score metric, and results expressed in one metric can be easily transformed into the other. As discussed earlier, absolute error for a single person p is defined as $\Delta_p = \bar{X}_p - \mu_p$, the difference between the person's observed mean score and universe score. The variance of Δ_p over randomly parallel instances of a measurement procedure is the absolute error variance for the person. In general, for any random effects design, the absolute CSEM for person p in the *mean* score metric is

$$CSEM(\bar{X})_{GTabs} = \sigma^2(\Delta_p). \quad (82)$$

For example, if the D-study design under consideration is $p \times (I : H)$, the design for an *individual person* is $I : H$. The variance components $\sigma^2(I : H)_p$ and $\sigma^2(H)_p$ are computed using data for each individual person, highlighted by the subscript p below each variance component. Then, the absolute CSEM for person p in the *mean* score metric is $\sigma(\Delta_p) = \sqrt{\sigma^2(h)_p/n'_h + \sigma^2(i : h)_p/n'_i n'_h}$. Multiplying this result by $n'_i n'_h$ gives $\sigma(\Delta_p)$ in the total score metric.

Estimating *relative* CSEMs in GT is much more complicated, largely because of some nonzero covariance terms that are difficult to estimate (see Jarjoura, 1986). For practical purposes, Brennan (2001c) offered an approximate estimator for any random effects designs in the *mean* score metric as

$$CSEM(\bar{X})_{GTrel} = \sigma(\delta_p) \cong \sqrt{\sigma^2(\Delta_p) - [\sigma^2(\Delta) - \sigma^2(\delta)]}. \quad (83)$$

Estimating the relative CSEM using Equation 83 is a two-step process: (a) computing the absolute CSEM using Equation 82 and (b) making an adjustment to it by the difference between the absolute and relative *overall* error variances. Clearly, the adjustment to $\hat{\sigma}^2(\Delta_p)$ is a constant for all persons.

UIRT Proficiency Estimates

In the context of ML estimation, the item and test information functions are frequently used as a measure of conditional accuracy of estimation. If item parameters are known, the information functions do not depend on the group of test takers being tested. The conditional variance of ML estimates is inversely related to the test information function as $\sigma^2(\hat{\theta}|\theta) = 1/I(\theta, \hat{\theta})$ (Lord, 1980). Thus, $CSEM(\hat{\theta}) = \sqrt{1/I(\theta, \hat{\theta})}$. The concept of a test information function and its inverse to define error variance holds numerous convenient properties. A limitation, however, is that there is no general conceptual framework or statistical procedure for incorporating multiple sources of error in the estimation of error variance. An exception is the work by Bock et al. (2002), who proposed an approach to incorporating multiple ratings in IRT aiming for correcting for the bias in the standard error of proficiency estimates. Nevertheless, this approach is considered somewhat ad hoc, lacking a robust substantiation of the notion of replications (e.g., distinction between random and fixed facets) (Brennan, 2001a). Their approach certainly deserves further research.

Error variance in the Bayesian framework is defined as the variance of the posterior distribution of θ for a test taker with item response data $\mathbf{u}$, and its standard deviation is the CSEM for the test taker. Since there is a one-to-one correspondence between the EAP estimator $\tilde{\theta}$ and $\mathbf{u}$, test takers with identical item responses will share the same CSEM. The variance form of CSEM for $\tilde{\theta}$ was presented in Equation 44. Under this framework, the notion of replications plays no explicit role in conceptualizing the variability of θ 's in the posterior distribution. To explicitly incorporate errors due to replications in estimating CSEMs and other reliability statistics, one approach is to apply the estimation procedure to at least two independent administrations of the test on the same group of test takers, preferably using different sets of items from the same domain. While this empirical approach is more feasible with computerized adaptive testing, a comprehensive theoretical framework has not been developed to seamlessly integrate the Bayesian definition of error based on the posterior distribution with one fixed set of data and the errors from actual replications involving more than one data set.

One well-known property of IRT proficiency estimates is that CSEMs tend to be smallest in the middle range of the proficiency scale and increase at both extremes. This phenomenon is not inherent to IRT but is a direct consequence of using the θ scale. As argued by Lord (1980), there is no unique virtue of the θ scale for measuring proficiency, and in general, there is no obvious reason to prefer θ over any other monotonic transformation of it. If θ is transformed to the (true) raw-score metric, the resulting CSEMs will exhibit a reversed pattern compared to that for the θ CSEMs. Nonlinear transformations from one metric to another not only change

the magnitude of CSEMs but also alter their general pattern along the score scale, as discussed next.

Scale Scores

The current *Standards* (AERA et al., 2014) and its predecessors recommend (a) reporting standard errors at different score levels (i.e., conditional) and (b) expressing them in units of a reported score scale. Most reliability statistics, including CSEMs, rely on the specific score scale used for reporting. Two main approaches exist for estimating CSEMs for nonlinearly transformed scale scores. The first utilizes the delta method, a general statistical technique for estimating the variance of a statistic that is a function of another statistic with a known variance (Kendall & Stuart, 1977). The second approach involves computing the conditional distribution for scale scores under assumed psychometric models.

The Delta Method Approximation

To demonstrate how scale transformation affects CSEMs, we begin with the discussion of linear transformation. Let $S = t(X)$ be a linear transformation function of scores X to scale scores S such that $S = B + A(X)$, where A and B are the slope and intercept of the linear function, respectively. It follows that $\sigma^2(S) = A^2 \sigma^2(X)$. This relationship also holds for conditional observed score (i.e., error) variances. That is, denoting E_X and E_S as error scores on the metrics of X and S , respectively, $\sigma^2(E_S | \tau) = A^2 \sigma^2(E_X | \tau)$. This suggests that the scale-score CSEM can be expressed by multiplying the CSEM for scores X by the slope of the transformation function. Thus, for linear transformations, computations are straightforward if CSEM estimates for the original score scale, X , are available.

When dealing with nonlinear transformations, where the slope of the transformation is not constant across score levels, complexities arise. The delta method provides a useful approximation to address this issue. Consider a continuous, differentiable function, $S = t(X)$, where X can represent raw scores, IRT proficiency estimates, or composite scores. The variance of S can be approximated using the delta method as

$$\sigma^2(S) = \left(\frac{dt}{dX}(\mathcal{E}X) \right)^2 \sigma^2(X), \quad (84)$$

where $dt/dX = t'(X)$ is the first derivative function of $t(X)$ with respect to X , which is evaluated at the mean of X . In essence, the delta method approximates the variance of scale scores as a function of both the variance of X and the first derivative (i.e., slope) of the transformation function.

In real-world applications, $S = t(X)$ is rarely a continuous function with a concrete mathematical expression. More frequently, a conversion table contains a discrete set of values for X and corresponding scale-score points, usually rounded to integers. To attain a differentiable mathematical function, Feldt and Qualls (1998) proposed fitting a high-degree polynomial function to the discrete conversion table as

$$t(X) \cong \beta_0 + \beta_1 x + \beta_2 x^2 + \cdots + \beta_q x^q, \quad (85)$$

where the polynomial degree q can be determined based on visual inspection of the fit, incremental R -square statistics, or other relevant criteria. The first derivative of the polynomial function at $X = x$ is

$$t'(x) \cong \beta_1 + 2\beta_2 x + \cdots + q\beta_q x^{q-1}. \quad (86)$$

Once the first derivative function is computed using Equation 86, the scale-score CSEM can be approximated using any CSEM estimators for X . In general, the scale-score CSEM is estimated using this polynomial procedure as

$$CSEM(S)_{PN} = \sigma(E_S | \tau) = \sigma(S | \tau) \cong t'(\mathcal{E}X | \tau) \sigma(X | \tau). \quad (87)$$

For example, consider a nonlinear transformation of IRT θ to a certain type of scale scores with scoring performed using the EAP estimator. The first step is to fit a polynomial regression on the conversion relationship and find the first derivative function as in Equation 86. Then, an approximate value of the scale-score CSEM for a test taker with $\tilde{\theta}$ is $\sigma(S | \tilde{\theta}) \cong t'(\tilde{\theta}) \sigma(\theta | \tilde{\theta})$ because $E(\theta | \tilde{\theta}) = \tilde{\theta}$. The polynomial procedure, as an approximation to the delta method, is versatile because it can be combined with any CSEM estimates for the original untransformed scores. However, a limitation is the somewhat subjective decision on the degree of the polynomial, and the estimated conditional slope based on the fitted function is still an approximation. The subsequent estimation procedures discussed do not necessitate such a slope-estimation process and utilize the entire distribution for scale scores.

Strong True Score Models

Kolen et al. (1992) extended Lord's (1965) strong true score theory to estimating scale-score CSEMs for tests scored number correct. Letting π denote the proportion-correct true score, the general expression for strong true score theory is given by

$$f(x) = \Pr(X = x) = \int_{\pi} \Pr(X = x | \pi) f(\pi) d\pi, \quad (88)$$

where the conditional distribution, $f(x | \pi) = \Pr(X = x | \pi)$, can be modeled using either a binomial or a two-term approximation to the compound binomial distribution; the marginal true score distribution, $f(\pi)$, is assumed to follow either a two-parameter or a four-parameter beta distribution; and $f(x)$ is the resulting marginal observed score distribution. Kolen et al. (1992) considered the most complex four-parameter beta compound binomial model.

The CSEM on the raw-score metric is expressed as

$$CSEM(X)_{ST} = \sigma(X | \pi) = \sqrt{\sum_{x=0}^n x^2 \Pr(X = x | \pi) - \left[\sum_{x=0}^n x \Pr(X = x | \pi) \right]^2}. \quad (89)$$

For a given discrete raw-to-scale score conversion table, the probability for earning a particular raw score is identical to the probability for earning the corresponding scale score—that is, $f[t(x)|\pi] = f(x|\pi)$. This allows replacing X with $S = t(X)$ in Equation 89 to obtain the scale-score CSEM:

$$CSEM(S)_{ST} = \sigma(S|\pi) = \sqrt{\sum_{x=0}^n [t(x)]^2 \Pr(X = x | \pi) - \left[\sum_{x=0}^n t(x) \Pr(X = x | \pi) \right]^2}. \quad (90)$$

Equation 90 provides unambiguous estimates of scale-score CSEMs no matter whether a conversion table is one-to-one or many-to-one (i.e., multiple raw-score points convert to a single scale-score point). If desired, the conditional scale-score distribution based on a many-to-one conversion table can be attained by summing the probabilities associated with all raw scores converting to a particular scale-score point. Doing this for all unique scale-score values will give a distribution for scale scores.

Binomial Procedure

For a test with dichotomous items, Brennan and Lee (1999) derived results for scale-score CSEMs, seen as a scale-score analogue of Lord's CSEM. The assumptions underlying this approach align with Lord's binomial error model. Since the binomial error model does not assume a specific true score distribution, the CSEM is estimated for each individual or uses observed score as a conditioning variable.

The conditional observed score distribution for an individual with a proportion-correct observed score $\bar{x} = \hat{\pi}$ follows a binomial distribution as

$$\Pr(X = x | \hat{\pi}) = \binom{n}{x} \hat{\pi}^x (1 - \hat{\pi})^{n-x}. \quad (91)$$

Lord's CSEM is the square root of the unbiased estimate of variance of the binomial distribution, as shown in Equation 78: $\sqrt{n/(n-1)} \sqrt{[x(n-x)]/n}$, where $\sqrt{n/(n-1)}$ is a bias-correction factor. Lord's CSEM formula can be re-expressed as

$$\sigma(X | \hat{\pi}) = \sqrt{\frac{n}{n-1}} \sqrt{\sum_{x=0}^n x^2 \Pr(X = x | \hat{\pi}) - \left[\sum_{x=0}^n x \Pr(X = x | \hat{\pi}) \right]^2}, \quad (92)$$

where the squared term inside the square root is the mean of the conditional distribution. By replacing raw score x with $t(x)$, the scale-score version of Lord's CSEM is

$$CSEM(S)_{BN} = \sqrt{\frac{n}{n-1}} \sqrt{\sum_{x=0}^n [t(x)]^2 \Pr(X = x | \hat{\pi}) - \left[\sum_{x=0}^n t(x) \Pr(X = x | \hat{\pi}) \right]^2}. \quad (93)$$

Brennan and Lee (1999) discovered that the overall pattern and magnitude of scale-score CSEMs estimated based on the binomial procedure closely aligned with results from the polynomial-delta method.

Other Procedures

The expression for scale-score CSEMs in UIRT can be obtained by the square root of Equation 57. The derivation of scale-score CSEMs for the multinomial error model is outlined by W. Lee (2007), which is virtually the same as the process used for the binomial procedure. It involves using the fact that $f[t(x)|\eta] = f(x|\eta)$ (see Equation 80) and computing the standard deviation of the scale-score distribution.

Composite Scores

Compound Binomial and Compound Multinomial Error Models

The binomial error model has been extended to cases in which a test consists of multiple strata or components, known as the compound binomial model (Feldt, 1984). Let the number of items in each of M components be $n_1, n_2, \dots, n_M$ and $X_1, X_2, \dots, X_M$ represent the component scores. In this model, it is assumed that each item belongs to one of M distinct universes of items, errors follow a binomial distribution within each component, and errors are uncorrelated across components. Due to the uncorrelated-error assumption, the composite error variance is a simple weighted sum of Lord's (1957) error variances for the components. For a test taker with observed component scores $x_1, x_2, \dots, x_M$, the estimated CSEM (often called Feldt's SEM) is

$$CSEM(Z)_{CB} = \sqrt{\sum_{m=1}^M w_m^2 \left[\frac{x_m(n_m - x_m)}{n_m - 1} \right]}. \quad (94)$$

Similarly, the extension of the multinomial error model to composite scores is provided by W. Lee (2007). The composite CSEM is the square root of a weighted sum of multinomial error variances for the various components, each of which is estimated using Equation 81. A constraint for the compound multinomial model is that the number of score categories must be the same for all items within a component.

Multivariate GT

As an extension of univariate GT, multivariate GT provides a framework for estimating CSEMs for composite scores. From the multivariate GT perspective, the foregoing treatment of composite scores is nothing more than a multivariate $p^\bullet \times i^\circ$ design. Let us define the composite score in the *mean* score metric as $\bar{Z} = \sum_{m=1}^M w_m \bar{X}_m$. Under the multivariate $p^\bullet \times i^\circ$ design, the within-person design for each person is simply i° ; that is, items are nested within a set of fixed content categories. In such a case, the absolute CSEM for a person is the square root of a weighted sum of squared absolute CSEMs over the content categories: $\sigma(\Delta_{p\bar{Z}}) = \sqrt{\sum_m w_m^2 \sigma_m^2(\Delta_p)} = \sqrt{\sum_m w_m^2 \sigma_m^2(i) / n'_{im}}$. This result, when transformed to the total score metric, will be identical to the result based on the compound binomial model presented in Equation 94. Similarly, the relative composite score CSEM for a person is $\sigma(\delta_{p\bar{Z}}) = \sqrt{\sum_m w_m^2 \sigma_m^2(\delta_p)}$, where the relative CSEM for each category is computed using Equation 83.

The application of multivariate GT in the estimation of composite score CSEMs is not limited to the $p^\bullet \times i^\circ$ design and can be further extended to many multivariate designs that other competing approaches may not be able to handle properly. For example, consider an assessment that consists of two components, speaking and listening, each consisting of different performance tasks (i), and test takers' responses to both types of tasks are evaluated by the same set of human raters (r). Here, the two content components act as the fixed multivariate variable and the multivariate design is $p^\bullet \times i^\circ \times r^\bullet$. The within-person design is $i^\circ \times r^\bullet$ and the absolute error variance–covariance matrix

is $\begin{bmatrix} \sigma_1^2(\Delta_p) & \sigma_{12}(\Delta_p) \\ \sigma_{12}(\Delta_p) & \sigma_2^2(\Delta_p) \end{bmatrix}$, where the subscripts 1 and 2 indicate the two components,

and the variances and covariances are derived from the variance–covariance component matrices of Σ_i , Σ_r , and Σ_{ir} . Note that errors are allowed to be correlated here, which is unique to multivariate GT compared to other approaches that often assume uncorrelated errors.

A general formula for computing absolute error composite score CSEMs is given by

$$CSEM(\bar{Z})_{MGTab_s} = \sigma_{\bar{Z}}(\Delta_p) = \sqrt{\sum_m w_m^2 \sigma_m^2(\Delta_p) + \sum_{m \neq m'} w_m w_{m'} \sigma_{mm'}(\Delta_p)}. \quad (95)$$

Similar to Equation 83 for the univariate case, the relative error composite score CSEMs can be approximated as

$$CSEM(\bar{Z})_{MGTr_{el}} = \sigma_{\bar{Z}}(\delta_p) \cong \sqrt{\sigma_Z^2(\Delta_p) - [\sigma_Z^2(\Delta) - \sigma_Z^2(\delta)]}, \quad (96)$$

where the correction to $\sigma_Z^2(\Delta_p)$ is the difference between the overall absolute and relative error variances for the composite scores.

MIRT

As previously discussed, the conditional composite score distribution, $\Pr(Z = z | \theta)$, can be obtained using Equation 60 under either the UIRT or the MIRT framework. The standard deviation of the conditional distribution is the CSEM for the composite, which is equal to the square root of Equation 62. For graphical representation of composite-score CSEMs, especially under MIRT, it is common to use the true composite score, ζ_θ , as the conditioning variable. However, the relationship between θ and ζ_θ in MIRT is not strictly one-to-one, leading to challenges in visualization. This is because of the infinite possible combinations of component θ 's that yield the same composite true score. Thus, multiple CSEM estimates can be associated with each true composite score. To address this issue, various strategies can be employed, such as computing the arithmetic mean for each true composite score or applying a polynomial regression to obtain single-valued smoothed estimates.

A MIRT model typically provides better fit than a UIRT model when a test is composed of multiple subdimensions such as content areas. Oftentimes, however, a UIRT model is judged to be robust to a moderate violation of the unidimensionality assumption and more feasible to use in practice because of its computational simplicity and unambiguous interpretation of results. When applied to mixed-format tests, W. Lee et al. (2020) observed that the UIRT and MIRT models generally agreed closely in terms of the patterns of CSEMs; however, when aggregated to obtain the overall SEM and reliability, results tended to be quite different as the data became more multidimensional.

Summary and Other Issues

The procedures discussed in this section are summarized in Table 5.3, categorized based on their respective model, score types, assumptions about replications, and item format. Not covered in the preceding section are methods for estimating CSEMs for scale scores converted from composite scores. Composite scale-score CSEMs can be derived using the compound binomial model (Brennan & Lee, 1999), compound multinomial model (W. Lee, 2007), or MIRT (W. Lee et al., 2020).

When raw scores or IRT proficiency estimates are the primary focus, estimating CSEMs is relatively straightforward, and the general shapes of these CSEMs are highly predictable. However, in many cases, raw scores or IRT proficiency estimates are transformed into scale scores for reporting. In such cases, expressing CSEMs on the metric of a reported score scale provides more informative results. Previous research suggests that the overall pattern of scale-score CSEMs along the score scale tends to follow the changes in the slope (or first derivative) of a transformation function (Brennan & Lee, 1999; Feldt & Qualls, 1998; Kolen & Lee, 2011; W. Lee et al., 2000, 2020). A steeper slope at a raw-score point corresponds to a wider range of adjacent raw scores converting to a broader range of scale scores, leading to greater variability of scale scores over repeated measurements. Conversely, a flatter slope is associated with a wide range of raw scores converting to a smaller range of scale scores, resulting in less variability of scale scores over replications. It is advisable in practice that the relative magnitude of scale-score CSEMs be examined, especially near the score points that are critical for decision-making, such as cut scores for licensure and certification exams.

The delta method approximation can serve as a general procedure for estimating scale-score CSEMs because it can be used jointly with almost any estimates of raw-score CSEMs. In most applications in educational testing contexts, the delta method requires an approximation of the first derivative function through a *fitted* conversion table to obtain a continuous, differentiable function. A high-degree polynomial model is often chosen due to its flexibility and ease of differentiation. However, the performance of the delta method with polynomial approximation may be contingent on the characteristics of a conversion table. For example, if a conversion table is characterized as many-to-one, the polynomial approximation of slope may

Table 5.3 Estimators of Conditional Standard Errors of Measurement Based on a Single Test Administration

Procedure/Model	Score Type	Item Type	Assumption
Thorndike	Raw score	Both	Essential tau-equivalent split halves
Mollenkopf	Raw score	Both	Essential tau-equivalent split halves
Binomial error model	Raw score Scale score	DI	Randomly parallel
Compound binomial error model	Composite score Composite scale score	DI	Stratified randomly parallel
Multinomial error model	Raw score Scale score	PO	Randomly parallel
Compound multinomial error model	Composite score Composite scale score	PO	Stratified randomly parallel
Univariate GT	Raw score: Absolute error Relative error	Both	Randomly parallel
Multivariate GT	Composite score: Absolute error Relative error	Both	Stratified randomly parallel
Strong true score model	Raw score Scale score	DI	Randomly parallel
Unidimensional IRT	Raw score Scale score ML estimator	Both	Strictly parallel
Unidimensional IRT	EAP estimator	Both	Undefined
Multidimensional IRT	Composite score Composite scale score	Both	Stratified strictly parallel
Delta-polynomial method	Scale score Composite scale score	Both	

Note. DI = dichotomous item type; PO = polytomous item type.

be questionable. In that case, estimation procedures that leverage the conditional scale-score distribution may be deemed preferable, although further research is needed to substantiate this preference.

Virtually all estimation procedures for scale-score CSEMs discussed in this section assume a *constant* raw-to-scale score conversion table across hypothetically replicated parallel forms and for every test taker in the population. In real-world testing situations where multiple alternate forms of a test are developed and used, the concern is centered around the interchangeability of scores across these forms, which may vary in difficulty. Equating plays an important role in this context, and an

outcome of such equating is a raw-to-scale score conversion table *specific* to each test form. The resulting scale scores are considered interchangeable across different forms if equating is trustworthy.

The need for equating to generate different conversion tables for each hypothetical replication in estimating scale-score CSEMs has not yet been systematically investigated in the literature. Obviously, the assumption of strictly parallel forms for the IRT procedures does not require equating because forms are effectively fixed, and any score differences are solely attributable to random error. In contrast, the assumption of randomly parallel forms in binomial and multinomial procedures, at least in the context of estimating CSEMs, does not require every test taker to take the same set of items on each replication. This implies that a test form, as a collection of specific items, is not clearly defined under this conception. If an additional restriction is imposed to allow for the same random sample of items to be used for all test takers in each replication, the resulting forms will have equivalent difficulty levels because all items selected for each replication are of equal difficulty for any given test taker. Therefore, under the randomly parallel forms assumption, equating is deemed either impossible or unnecessary. Further exploration of this issue may be warranted.

While the overall and conditional SEMs by themselves provide useful information about the amount of error in test scores, they are frequently used in conjunction with intervals. The *Standards* (AERA et al., 2014), especially Standard 6.10, recommend that score precision be depicted by error bands using the SEM. There is a voluminous literature on various types of interval estimation procedures in relation to different types of scores. Space does not permit any systematic review of the topic, but the following two principles merit consideration. First, the CSEM is usually favored over the overall SEM when constructing intervals for each individual test taker. Second, the endpoints of an interval should preferably be on the score metric used for reporting (e.g., scale scores). For example, W. Lee et al. (2006) recommended using CSEMs rather than the overall SEM based on a simulation study. They also proposed an endpoints conversion method for constructing intervals for nonlinearly transformed scale scores from raw scores, demonstrating superior performance compared to a normal approximation method.

As a final note, if a test has a multidimensional structure by design, such as a table of content specifications or mixed item formats, it is strongly recommended that the CSEMs for the total scores be estimated using one of the composite score models. Ignoring the fact that domains are stratified and fitting noncomposite models to the total scores could introduce bias in the estimated CSEMs, with larger bias as data become more multidimensional (W. Lee et al., 2000).

RELIABILITY OF CLASSIFICATION CATEGORY SCORES

When using a test score or composite score for categorical classification decisions (e.g., pass/fail), the *Standards* (AERA et al., 2014) recommend estimating the consistency of classifications across two replications of the same measurement procedure.

Classification errors occur when decisions are based on test takers' observed scores, which contain measurement error. In this context, the interpretation of test scores primarily considers each test taker's observed score relative to a standard or cut score, rather than the performance of other test takers. Since Glaser (1963) introduced the notion of criterion-referenced interpretation of test scores, extensive research has been devoted to developments of indices for measuring the precision of classifications. Berk (1980) provided a comprehensive summary of the measures developed until 1980, and since then, new methods have emerged as a result of increased use of IRT and complex assessment types.

This section reviews procedures based on threshold-error loss for assessing consistency of classifications. These methods primarily focus on the extent of consistent classifications with respect to the cut score, treating all false classifications as equally serious. By contrast, squared-error loss methods, such as those proposed by Livingston (1972), Brennan and Kane (1977a, 1977b), and Kane and Brennan (1980), consider misclassifying test takers with scores far from the cut score as more serious than misclassifying those with scores near the cut score. While both approaches offer meaningful insights into classification consistency, they address different aspects of the classification problem. Another group of procedures, not reviewed in this section, includes methods involving dividing the test into two parallel halves and stepping up the result to what might be expected for the full-length test (e.g., Breyer & Lewis, 1994; Woodruff & Sawyer, 1989).

The precision, or lack thereof, of classifications is often described in terms of classification consistency and accuracy in the literature. *Classification consistency* measures the degree to which test takers are classified in the same performance category based on two independent replications of the same (or similar) measurement procedure. A double administration procedure (Hambleton & Novick, 1973) using two parallel forms involves tallying the proportion of test takers assigned to each classification category on both administrations. By contrast, single-administration procedures rely on two expected (i.e., model-predicted) observed score distributions from two hypothetical replications of the test. The concept of replications, whether actual or hypothetical, leads to the perception of classification consistency as the reliability of classifications (W. Lee et al., 2002).

Classification accuracy assesses the agreement between classifications based on test takers' observed scores and classifications based on test takers' true scores (W. Lee et al., 2002; Livingston & Lewis, 1995). Unlike classification consistency, which compares two observed classifications, classification accuracy relates observed classifications to true classifications. In this sense, classification accuracy is sometimes referred to as decision validity (Berk, 1980; Hambleton, 1980).

Classification Consistency and Accuracy Indices

Suppose that test takers are classified into H mutually exclusive performance categories based on a set of $H - 1$ cut scores on the raw-score metric, $c_1, c_2, \dots, c_{H-1}$. For notational

convenience, let c_0 and c_H denote the lowest and highest possible scores, respectively. The first performance category contains scores ranging from c_0 to $c_1 - 1$; the second category contains scores from c_1 to $c_2 - 1$; and so forth. Let $P_1, P_2, \dots, P_H$ denote the observed performance categories in which each test taker is classified by comparison of their observed scores to cut scores. Further, let X_1 and X_2 be the random variables for observed scores on two administrations of the test that are independent and identically distributed.

The two most frequently discussed classification consistency indices are the agreement index ϕ and Cohen's (1960) kappa (κ) coefficient. The marginal agreement index ϕ is the percentage of test takers consistently classified in the same category on two independent replications:

$$\phi = \sum_{h=1}^H \Pr(X_1 \in P_h, X_2 \in P_h). \quad (97)$$

More specifically, the ϕ coefficient is the sum of diagonal elements of an $H \times H$ contingency table composed of joint probabilities or percentages of observed category classifications on two replications, denoted $\Pr(X_1 \in P_i, X_2 \in P_j)$. The κ coefficient adjusts for agreement occurring by chance and is given by

$$\kappa = \frac{\phi - \phi_c}{1 - \phi_c}, \quad (98)$$

where ϕ_c is the chance agreement: $\phi_c = \sum_{h=1}^H \Pr(X_1 \in P_h) \Pr(X_2 \in P_h) = \sum_{h=1}^H [\Pr(X_1 \in P_h)]^2$ because X_1 and X_2 are identically distributed.

Classification accuracy relies on a bivariate distribution of observed and true classifications. True classification involves determining a test taker's true categorical status based on their true score relative to cut scores expressed on the true score metric, $\lambda_1, \lambda_2, \dots, \lambda_{H-1}$, with λ_0 and λ_H being the lowest and highest possible true scores, respectively. These true cut scores typically are set to be the same as the observed cut scores, but theory does not require doing so. Because test takers' true scores are unknown, individual true scores can be estimated, or an entire true score distribution for a population can be estimated or assumed. Let $\Gamma_h (h = 1, 2, \dots, H)$ denote the true category of a test taker with true score τ such that $\lambda_{h-1} \leq \tau < \lambda_h$. An $H \times H$ contingency table can be generated, containing the joint probabilities of observed and true classifications, $\Pr(\tau \in \Gamma_i, X \in P_j)$. This contingency table is asymmetric. The marginal classification accuracy index, denoted γ , is defined as the sum of the diagonal elements in the contingency table:

$$\gamma = \sum_{h=1}^H \Pr(\tau \in \Gamma_h, X \in P_h). \quad (99)$$

If the rows represent true categories and columns represent observed categories, the sum of the upper diagonal elements indicates the percentage of test takers classified in observed categories higher than their true category, known as the marginal false-positive error rate, symbolically expressed as

$$\gamma^+ = \sum_{i=1}^{H-1} \sum_{j=i+1}^H \Pr(\tau \in \Gamma_i, X \in P_j). \quad (100)$$

Conversely, the marginal false-negative error rate represents the percentage of test takers whose observed categories are lower than their true categories and is defined as the sum of the lower diagonal elements of the contingency table:

$$\gamma^- = \sum_{i=2}^H \sum_{j=1}^{i-1} \Pr(\tau \in \Gamma_i, X \in P_j). \quad (101)$$

In essence, all estimation procedures discussed next involve, one way or another, constructing $H \times H$ contingency tables for consistency and accuracy. Nevertheless, they differ with respect to underlying assumptions ascribed to various models and applicable item types (dichotomous vs. polytomous) and score types (raw, composite, or theta estimates).

For most estimation methods, it is more convenient and informative to begin with estimating classification indices for each individual test taker or conditional on each level of true score. These conditional indices are then aggregated or averaged to derive the marginal indices. The subsequent sections primarily concentrate on the ϕ and γ coefficients to simplify matters.

Strong True Score Models

The first procedure is grounded in strong true score models. Huynh (1976) introduced an estimation procedure based on the beta-binomial model, the simplest form of a family of strong true score models. Later, Hanson and Brennan (1990) extended Huynh's approach to more general strong true score models. The conditional raw-score distribution, $f(x|\pi)$, can be modeled using either a binomial or a two-term approximation to the compound binomial model. The distribution of π for a population is either a two-parameter beta or a four-parameter beta distribution.

Let $f(x_1|\pi)$ and $f(x_2|\pi)$ represent the identically distributed conditional raw-score distributions on two replications of a measurement procedure. The conditional probability of being classified in the h th observed category P_h is

$$\Pr(X_1 \in P_h | \pi) = \Pr(X_2 \in P_h | \pi) = \sum_{x_1=c_{h-1}}^{c_h-1} f(x_1|\pi). \quad (102)$$

Due to the local independence assumption, the conditional joint distribution of X_1 and X_2 is

$$f(x_1, x_2 | \pi) = f(x_1 | \pi) f(x_2 | \pi). \quad (103)$$

Given a set of $H - 1$ cut scores, a *conditional* $H \times H$ contingency table can be generated based on the conditional joint probabilities. The probability of falling in the same h th category on two replications (i.e., diagonal elements) can be computed as

$$\Pr(X_1 \in P_h, X_2 \in P_h | \pi) = \sum_{x_1=c_{h-1}}^{c_h-1} f(x_1 | \pi) \sum_{x_2=c_{h-1}}^{c_h-1} f(x_2 | \pi) = \left[\sum_{x_1=c_{h-1}}^{c_h-1} f(x_1 | \pi) \right]^2. \quad (104)$$

It follows that the conditional probability of consistent classifications is

$$\phi(\pi) = \sum_{h=1}^H \Pr(X_1 \in P_h, X_2 \in P_h | \pi), \quad (105)$$

which is referred to as the conditional agreement index. The marginal agreement index is obtained by integrating $\phi(\pi)$ over the entire distribution of π :

$$\phi = \int_{\pi} \phi(\pi) f(\pi) d\pi, \quad (106)$$

where integration is performed numerically using a set of quadrature points from an estimated true score distribution (e.g., beta).

Now, let us suppose that a true score (or a quadrature point) belongs to the h th performance level, $\pi \in \Gamma_h$. An accurate classification occurs when, based on observed scores, a test taker is classified in a performance category that is the same as the test taker's true performance category. Therefore, the conditional accuracy index is simply

$$\gamma(\pi) = \Pr(X \in P_h | \pi \in \Gamma_h), \quad (107)$$

which can be computed using Equation 102. The marginal accuracy index is then given by

$$\gamma = \int_{\pi} \gamma(\pi) f(\pi) d\pi. \quad (108)$$

The conditional and marginal false-positive and -negative error rates can be derived in a similar manner.

Normal Approximation Procedure

The normal approximation procedure (Peng & Subkoviak, 1980) was initially proposed as a simplification of Huynh's (1976) beta-binomial procedure. Research suggests, however, that this relatively simple procedure performs adequately across various situations and can accommodate different types of scores (e.g., S. Y. Kim & Lee, 2019, 2020; Wan et al., 2007). The crucial assumption of this procedure is that the observed scores from two replications follow a bivariate normal distribution with a correlation equal to test reliability.

Let $z(c_h)$ denote a z -score corresponding to each cut score c_h ($h = 1, 2, \dots, H$). This standardization enables us to use the convenient properties of z scores. The marginal

percentages of test takers who are classified in the same h th performance category on two replications, $\Pr(X_1 \in P_h, X_2 \in P_h)$, can be determined using a cumulative standard bivariate normal distribution. The marginal agreement index ϕ is a sum of $\Pr(X_1 \in P_h, X_2 \in P_h)$ over all performance categories, as follows:

$$\begin{aligned}\phi &= \sum_{h=1}^H \Pr(X_1 \in P_h, X_2 \in P_h) \\ &= \sum_{h=1}^H \int_{z(c_{h-1})}^{z(c_h)} \int_{z(c_{h-1})}^{z(c_h)} \frac{1}{2\pi\sqrt{1-R(X)^2}} \exp\left[-\frac{x_1^2 - 2R(X)x_1x_2 + x_2^2}{2[1-R(X)^2]}\right] dx_1 dx_2, \quad (109)\end{aligned}$$

where $R(X)$ is an estimate of reliability. Based on the fact that the marginal distribution of X_1 (or X_2) is univariate normal, the marginal category probabilities of $\Pr(X_1 \in P_h)$ and $\Pr(X_2 \in P_h)$ can be computed using a cumulative univariate standard normal distribution. The chance agreement and kappa coefficient can be computed accordingly.

Classification accuracy was not considered explicitly by Peng and Subkoviak (1980). Later researchers adopted the normality-based framework for estimating classification accuracy indices (e.g., S. Y. Kim & Lee, 2019). The assumption is that the marginal joint distribution of the observed and true scores follows a bivariate normal distribution. Since both observed and true classifications are involved, the true cut scores as well as the observed cut scores need to be standardized. For summed raw scores, $\mu(X) = \mu(T)$ and $\sigma(T) = \sigma(X)\sqrt{R(X)}$ in CTT. Thus, true cut scores are standardized as $z(\lambda_h) = [\lambda_h - \mu(X)] / \sigma(X)\sqrt{R(X)}$. The correlation of this bivariate distribution is $\sqrt{R(X)}$ because $\rho(X, T) = \sqrt{R(X)}$. The marginal accuracy index is given by

$$\begin{aligned}\gamma &= \sum_{h=1}^H \Pr(X \in P_h \mid \tau \in \Gamma_h) \\ &= \sum_{h=1}^H \int_{z(c_{h-1})}^{z(c_h)} \int_{z(\lambda_{h-1})}^{z(\lambda_h)} \frac{1}{2\pi\sqrt{1-R(X)}} \exp\left[-\frac{\tau^2 - 2\sqrt{R(X)}\tau x + x^2}{2[1-R(X)]}\right] d\tau dx. \quad (110)\end{aligned}$$

A cumulative univariate standard normal distribution for each of the true and observed scores can be used to obtain the marginal category probabilities of $\Pr(\tau \in \Gamma_h)$ and $\Pr(X \in P_h)$, which then are used to fill the off-diagonal cells of the marginal $H \times H$ contingency table, $\Pr(\tau \in \Gamma_i, X \in P_j)$, for computing false-positive and -negative error rates.

The assumption of bivariate normality for the normal approximation method may not fully hold in reality. However, research suggests that this approach is quite robust to violations of the normality assumption (e.g., S. Y. Kim & Lee, 2020; Wan et al., 2007). Regarding the choice of reliability coefficient in Equations 109 and 110, it is generally preferred to use reliability coefficients that involve absolute error variance because the

focus in classification contexts is on the discrepancy between test takers' scores and cut scores rather than their ranking. Peng and Subkoviak (1980) used KR21 with the normal approximation method, and Huynh (1976) also employed KR21 in the beta-binomial model framework, following Lord and Novick (1968), who demonstrated that reliability for the beta-binomial model is indeed KR21. Although the choice of reliability coefficient may have minimal practical impact, it is prudent to select one that is defensible for a particular application, especially paying close attention to the score type of interest.

Livingston and Lewis Procedure

The strong true score models (Hanson & Brennan, 1990; Lord, 1965) assume that n items are dichotomously scored and equally weighted. The Livingston and Lewis (1995) procedure is intended to extend the strong true score models to other complex types of test scores such as scores from polytomous items, composite scores, and even scale scores. For this somewhat ad hoc extension, they introduced the concept of *effective test length*, denoted here as $\tilde{n}$, which represents the pseudo number of equally difficult dichotomous items required to achieve the same reliability as the actual reported scores. (Note that the term effective test length carries a different interpretation compared to its usage in Equation 9). Letting X denote the actual test scores, the effective test length is computed as

$$\tilde{n} = \frac{[\hat{\mu}(X) - \min(X)][\max(X) - \hat{\mu}(X)] - R(X)\hat{\sigma}^2(X)}{\hat{\sigma}^2(X)[1 - R(X)]}, \quad (111)$$

where $R(X)$ is a reliability coefficient for the original score type, and $\min(X)$ and $\max(X)$ indicate the minimum and maximum possible scores, respectively. Since $\tilde{n}$ can be a noninteger value, it is often rounded to the nearest integer. One of the strong true score models can be applied to this pseudo dichotomous data to compute classification indices as outlined in the section "Strong True Score Models."

The flexibility of the Livingston and Lewis procedure makes it one of the most frequently cited and used procedures in practice. Many comparison studies have found that results for the Livingston and Lewis procedure are comparable to those for other methodologies (e.g., S. Y. Kim & Lee, 2020; W. Lee et al., 2009; Wan et al., 2007).

Binomial and Multinomial Models

Subkoviak (1976) proposed a procedure for estimating classification consistency for a group of test takers under the assumption of dichotomously scored items. Unlike Huynh (1976), who utilizes the full feature of the beta-binomial model, Subkoviak's procedure does not entail estimating the true score distribution, although it assumes a binomial distribution for the conditional observed score distribution, $f(x|\pi)$. Instead of estimating the entire true score distribution, Subkoviak's procedure uses an estimated true score for each individual test taker. Subkoviak (1976) suggests using either a test

taker's observed proportion-correct score or Kelley's (1947) regressed score estimate. The procedure computes the conditional agreement index for each person and then obtains the marginal agreement index by averaging the conditional results over all persons in the data set.

W. Lee (2005) and W. Lee et al. (2009) extended Subkoviak's procedure by: (a) proposing a procedure based on the multinomial error model (W. Lee, 2007) for polytomous items; (b) applying the compound multinomial model (W. Lee, 2007) to composite scores; and (c) considering classification accuracy, which was not addressed in Subkoviak (1976). The multinomial procedure, briefly introduced below, reduces to Subkoviak's model if items are dichotomously scored.

As previously defined in the section "Multinomial Error Model", for a person with $\eta = \{\eta_1, \eta_2, \dots, \eta_k\}$, the random variables, $Y_1, Y_2, \dots, Y_k$, represent the numbers of items scored $a_1, a_2, \dots, a_k$, respectively, which follow a multinomial distribution. The total raw score is $X = \sum_{i=1}^k a_i Y_i$. The conditional total score distribution given η is provided in Equation 80. The probability of being in the h th performance level is given by

$$\Pr(X \in P_h | \eta) = \sum_{x=c_{h-1}}^{c_h-1} f(x|\eta). \quad (112)$$

For a person with $\hat{\eta}_i = y_i/n$, the conditional agreement index, $\phi(\hat{\eta})_p$, is computed using Equations 104 and 105. These conditional agreement indices for all N persons are averaged to obtain the marginal agreement index:

$$\phi = \sum_{p=1}^N \phi(\hat{\eta})_p. \quad (113)$$

Using observed score x as an estimate of true score, each person's true performance level is determined by comparing x to true cut scores. For a person with observed $\hat{\eta}$ and $\lambda_{h-1} \leq \hat{\tau} = x = \sum_{i=1}^k a_i y_i < \lambda_h$, the probability of accurate classifications is simply the probability of being classified into the h th performance category:

$$\gamma(\hat{\eta})_p = \Pr(X \in P_h | \hat{\tau} \in \Gamma_h), \quad (114)$$

which is computed using $\hat{\eta}$ in place of η in Equation 112. The gamma coefficient for a group of test takers is

$$\gamma = \sum_{p=1}^N \gamma(\hat{\eta})_p. \quad (115)$$

The methodology discussed above can be extended to cases where the score type of interest is a composite score. The key difference is to model errors according to the compound binomial model, as discussed in detail by W. Lee (2005, 2007) and W. Lee

et al. (2009). Brennan and Lee (2008) considered correcting for bias in classification consistency indices by proposing an estimator of true score that has the same variance as true scores.

IRT Procedures

Several procedures exist for computing classification indices under the IRT framework. For example, Huynh (1990) considered the Rasch model for classification consistency, with subsequent extensions to accommodate other UIRT models (W. Lee, 2010; W. Lee et al., 2002; Schulz et al., 1999; T. Wang et al., 2000). S. Y. Kim and Lee (2019) and W. Lee et al. (2020) further expanded the UIRT procedures to handle composite scores using assumptions of SS-MIRT and BF-MIRT models. While these procedures were primarily designed for tests based on summed scoring, those developed by Rudner (2001, 2005) and Guo (2006) are geared toward ML proficiency estimates. We first review Rudner's proficiency-based procedure, followed by methods tailored for summed scoring.

ML Proficiency Estimates

Rudner's procedure operates under the assumption that, for person p with an ML estimate $\hat{\theta}_p$, errors are asymptotically normal with a mean of $\hat{\theta}_p$ and standard deviation of $\hat{\sigma}_p = \sqrt{1 / \hat{I}(\hat{\theta}, \hat{\theta})}$, where $\hat{I}(\hat{\theta}, \hat{\theta})$ is a sample estimate of the test information function evaluated at $\hat{\theta}_p$. The expected probability of falling in the h th category is expressed as

$$\Pr(\hat{\theta} \in P_h \mid \hat{\theta}_p) = \Phi(\hat{\theta}_p, \hat{\sigma}_p, c_h) - \Phi(\hat{\theta}_p, \hat{\sigma}_p, c_{h-1}), \quad (116)$$

where $\Phi(\hat{\theta}_p, \hat{\sigma}_p, cut)$ is the cumulative probability below the theta cut score, cut , based on the normal distribution, $N(\hat{\theta}_p, \hat{\sigma}_p)$. Assuming errors are identically distributed for two replications, the probability of consistent classifications for each person is calculated as

$$\phi(\hat{\theta})_p = \sum_{h=1}^H \Pr(\hat{\theta}_1 \in P_h, \hat{\theta}_2 \in P_h \mid \hat{\theta}_p) = \sum_{h=1}^H \left[\Pr(\hat{\theta} \in P_h \mid \hat{\theta}_p) \right]^2. \quad (117)$$

For a test taker with $\lambda_{h-1} \leq \hat{\theta}_p < \lambda_h$, the probability of accurate classifications is equal to the probability of being placed in the h th category:

$$\gamma(\hat{\theta})_p = \Pr(\hat{\theta} \in P_h \mid \hat{\theta}_p \in \Gamma_h). \quad (118)$$

The marginal indices of ϕ and γ for a group of persons are computed by averaging conditional indices as in Equations 113 and 115.

Guo (2006) proposed a modification of Rudner's procedure that relaxes the normality assumption. Instead of using the ML point estimate of θ and its standard error, Guo's approach utilizes the likelihood function of a test taker's item responses

given item parameters to compute probabilities of classifications. Research has shown that both Rudner's and Guo's procedures tend to yield similar results (Guo, 2006; Wyse & Hao, 2012).

Summed Scoring

The formulation of IRT summed-score procedures is virtually the same as, or similar to, that of other procedures, particularly the strong true score models. However, there are two main distinctions: (a) the models used to derive the conditional observed score distribution (i.e., errors) and (b) the conditioning variables. For example, conditional distributions are defined for a UIRT model in Equation 50 or a MIRT model for composite scores in Equation 60. Subsequently, the steps outlined in Equations 102 through 108 can be applied to compute classification indices by replacing π with either θ or θ depending on the model used.

Aggregation Methods

Estimating marginal classification indices requires a distribution of θ (or θ) for a population of test takers. While a discrete quadrature distribution is typically employed for a UIRT model, computational complexity grows exponentially with a MIRT model as the number of dimensions increases. To address this challenge, W. Lee et al. (2020) suggested alternative approaches for aggregating conditional indices. These include using: (a) quadrature distributions (D method), (b) individual proficiency estimates (P method), and (c) Monte Carlo simulation (M method). These three marginalization methods can also be applied to estimating CSEMs and reliability coefficients (see W. Lee et al., 2020).

The D method involves specifying a discrete set of combinations of quadrature points and associated weights for θ , often using a multivariate standard normal distribution. For example, with four dimensions and 21 quadrature points per dimension, there are $21^4 = 194,481$ possible combinations of quadrature points. Conditional agreement indices, $\phi(\theta)$, are computed for each combination and aggregated over the entire θ distribution to obtain the marginal index: $\phi = \sum_q \phi(\theta)w_q$, where the sum is taken over all combinations of theta values and w_q is the weight associated with quadrature combination q .

In contrast, the P method utilizes proficiency estimates as the conditioning variable for each person. Conditional indices are computed for each person with $\hat{\theta}$, and a marginal index is obtained by averaging the conditional indices over the number of persons in the group: $\phi = \sum \phi(\hat{\theta})_p / N$. The P method is typically computationally less intensive than the D method; however, results may be subject to the chosen proficiency estimator. The P method would be most useful when the purpose is to quantify classification errors for each individual test taker.

The M method combines elements of the D and P methods. Similar to the D method, it begins with an assumed distribution of θ , from which a large number of random

deviates are drawn. For example, $N_r = 100,000$ combinations of theta values could be drawn from a multivariate standard normal distribution. Conditional results are estimated for each of the $N_r = 100,000$ simulated test takers. Then, similar to the P method, marginal results are computed by averaging the conditional results over the N_r test takers: $\phi = \sum \phi(\theta) / N_r$.

While these methods typically produce similar results (W. Lee, 2010; W. Lee et al., 2020), the M method is often preferred for MIRT models. It offers computational efficiency, eliminates unrealistic theta combinations, and yields conditional estimates—such as classification errors and SEMs—that are visually more interpretable when plotted.

Other Issues

The foregoing discussion on classification errors is restricted to cut scores established on untransformed score metrics. However, in many large-scale educational testing programs, cut scores are often set on reported score scales. Once a score scale is established for the initial test form, it is maintained across subsequent forms through test equating (Kolen & Brennan, 2014). In this scenario, there are at least two ways to estimate classification indices for scores on each test form. The easiest method would be to use the operational raw-to-scale score conversion table, in which the raw-score points that correspond to the cut scores on the scale-score metric could be identified. Alternatively, the conditional distribution of scale scores can be computed, as discussed in the section “Estimators of CSEMs.” Then, the processes of constructing category probabilities and computing conditional and marginal indices, outlined in the section “Reliability of Classification Category Scores,” can be applied.

The marginal classification indices provide useful information about the overall precision of classifying a group of test takers. However, they do not provide information about the precision of classifications at different score or proficiency levels. For this purpose, conditional indices along the score scale can be examined. Studies have consistently shown that classification errors tend to be larger near cut scores, as one might expect. Examples of exploring conditional classification indices are found in W. Lee (2010), W. Lee et al. (2002, 2020), and Wyse and Hao (2012). Wainer et al. (2005) considered a Bayesian method, involving the Markov Chain Monte Carlo procedure to produce samples from the posterior distribution of a test taker’s proficiency estimate. The probability of passing, what they call the posterior probability of passing curve, is determined by counting the number of sampled proficiency values that exceed the cut score.

Most research to date on classification consistency and accuracy has focused on measurement errors that are attributable to items or forms. It seems natural to consider an extension of the current theories and methodologies to broader measurement situations. For example, classification decisions could be made based on test takers’ responses to a set of essay prompts scored by raters. In such cases, an effective

procedure should allow measurement errors attributable to essay prompts and raters to be modeled separately in constructing performance category probabilities. GT might prove to be a useful tool for developing such estimation models in classification contexts.

OTHER MODELS, AGGREGATION, AND PRECISION ISSUES

There are many additional aspects of reliability this chapter can only touch on.

Other Models and Assessment Types

Diagnostic Classification Models

With diagnostic classification models (DCMs), the latent traits are assumed to be categorical. This implies, typically, that there is a more limited range of possible latent values (e.g., master and nonmaster) than actual score values (raw scores, IRT proficiency estimates, or scale scores). In DCMs, the error variance and the latent trait variance are not independent, causing some complications in estimating reliability.

Using a replication definition of reliability, simulations are used to administer an assessment (the same form, a parallel form, or M. S. Johnson and Sinharay's (2018) definition of multiple assessments with an identical Q matrix and item parameters) repeatedly. What category test takers were assigned to each time was observed. Several authors have investigated different methods of estimating precision in DCMs, including M. S. Johnson and Sinharay (2018), who noted that simply reporting the estimated probability that an individual test taker is correctly classified may be misleading without considering the distribution of the categorical trait in the population. For instance, if 95% of a population are "masters," simply classifying every test taker as a master will result in 100% of the masters being correctly classified and 100% of the nonmasters being incorrectly classified.

Templin and Bradshaw (2013) introduced a measure of DCM reliability and compared it to an IRT measure. Replications for the DCM method can be obtained by repeated sampling from test takers' posterior distributions. For the IRT model estimate, the observed item responses provide an estimate of the latent trait, the standard error of which can be calculated using the test information function. Resampling via simulation can be used to obtain the distribution of the latent variable across the test-taker population, and the correlation computed between scores from two administrations can be used as an IRT reliability estimate. Comparing reliability estimates over the hypothetically repeated administrations, Templin and Bradshaw illustrated both theoretically and through the simulations that DCMs exhibited greater precision than IRT model-based estimates. Thompson et al. (2019) looked at DCM results for an operational assessment system reporting information, including reliability, at five levels and also found that the DCM reliabilities based on

simulations approximating replications of testing were higher than those for CTT or IRT methods.

Structural Equation Models

Structural equation models allow for comparing various models for assessment data, which aids in the determination of an appropriate reliability coefficient in situations where one is uncertain about the dimensionality, tau equivalency, and other aspects of the data. Graham (2006) provided a hierarchy of models to estimate reliability, using structural equation models to test model fit to data, lamenting that

many students and researchers in education and psychology are unaware of many of the assumptions required by a given statistical procedure, are unaware of how to test those assumptions, or are unaware of acceptable alternatives should those assumptions not be met. (p. 942)

Bacon et al. (1995) looked at the underestimation of reliability using coefficient alpha and omega across different conditions, advocating for weighted omega. Hancock and An (2018) provided an introduction to scale reliability within the context of confirmatory factor analysis and structural equation models, endorsing the use of McDonald's ω instead of Cronbach's alpha. S. B. Green and Yang (2008) derived a nonlinear structural equation model method to compute reliability for ordered categorical items. Raykov and Shrout (2002) presented a method to compute point and bootstrapped confidence interval estimates of reliability for weighted and unweighted composites with a general structure. Karimi (2015) illustrated structural equation models in estimating model-based reliability, including applications for the bifactor and mixed reflective-formative models, as well as covariate-dependent and covariate-free reliability.

Raykov and Penev (2010) outlined a latent variable analysis approach to provide both point and confidence interval estimates of reliability of group means, the overall reliability of group means, and conditional reliability for conditional and unconditional two-level models. Kano and Azuma (2003) discussed both the essential tau equivalence and the independence assumptions in a structural equation model environment for coefficient alpha, stating, "the independence assumption is more important than the essential τ equivalence assumption because dependency among unique factors can cause overestimation of the true reliability" (p. 147).

Oberski and Satorra (2013) addressed the "usual practice" of using error variances from an independent study as population variances in subsequent structural equation model analyses, showing how this may make the structural parameters' standard error too small. They provided an adjustment factor, illustrating its use with simulations and empirical data. Structural equation modeling continues to be a productive area of research related to precision coefficients.

Reliability Related to Longitudinal Data and Growth Models

Examining trends, such as an individual's scores over time or pretest and posttest scores to examine the effectiveness of a treatment, involves additional precision issues. Rogosa and Willett (1983) observed that when test takers have similar true growth changes, difference scores cannot adequately distinguish the amounts of true change among test takers. However, if the test takers differ in the amount of true growth, difference scores may indeed be adequate in distinguishing among test takers. Kane (1996) noted,

The precision of change scores will depend on the intended interpretation of the change scores, in particular, on whether the interpretation focuses on the absolute magnitude of change for each individual or on the change for each individual compared with the average change in some reference group. (p. 368)

Thomas and Zumbo (2012) provided some support for the use of difference scores.

Raudenbush and Jean (2012) looked at reliability in the context of using value-added scores to examine teacher effectiveness, endorsing the use of confidence intervals over point estimates, and discussing multiple issues related to the use of value-added scores. Brennan et al. (2003) discussed various univariate and multivariate GT approaches to examine the reliability of group mean difference scores based on longitudinal data, from both norm-referenced and criterion-referenced perspectives, viewing the difference score as a composite score (the difference) of the two individual assessment scores.

Geldhof et al. (2014) examined reliability for data based on multistage sampling, concluding that level-specific calculations are appropriate when using multilevel data. Marcoulides (2019) examined reliability estimation in longitudinal studies, specifying the need to ensure that the approach used to model growth and measurement error aligned with the data being analyzed. Boyd et al. (2013) proposed an approach for estimating measurement error when students were administered three or more assessments, such as state assessments in consecutive grades. Their model allows for changes (increases or decreases) in knowledge and skills between administrations, as well as for the assessments to be neither parallel nor vertically scaled and to vary in their degree of measurement error.

Some research has examined change, difference, or growth scores in more complicated settings. Schuurman and Hamaker (2019) provided a preliminary model for some types of measurement error within the framework of autoregressive time series modeling, discussing how it could be relevant to both within-person and between-person precision. Tisak and Tisak (1996) used a latent curve approach to look at longitudinal models of reliability (see also Brandmaier et al., 2018).

DCMs have advanced to accommodate longitudinal data, examining how test takers' status changes over time. Madison (2019) defined and evaluated two reliability measures for longitudinal DCMs. The first measure is based on the idea of administering the same test repeatedly; the second is focused on the consistency of attribute mastery transitions, calculating the average most likely transition probability. Madison used both simulations and an empirical data set to study the two reliability metrics compared to a longitudinal IRT model. Consistent with the results of Templin and Bradshaw (2013),

the longitudinal DCMs had higher reliability than the longitudinal IRT models and were easier to interpret.

Brennan et al. (2003) focused on longitudinal difference scores for matched students. In practice, schools likely have three groups of test takers when looking at growth across grades: students present (and tested) in both grades, students present in only the lower grade, and students present in only the higher grade. For the test takers having assessment scores in both grades, their scores tend to be positively correlated, which tends to decrease the standard error associated with the mean difference scores, whereas this is not the case when the test takers in the lower and higher grade samples do not overlap. In addition to larger error, conceptually using independent samples to look at differences across grades makes drawing conclusions about instructional effectiveness questionable (Brennan et al., 2003), a reminder that the data collection design needs to be considered in terms of the questions one wishes to consider.

These more complex designs and analyses tend to introduce additional sources of error that need to be considered in addressing precision issues, some of which may not be estimable. Haertel (2013) discussed many issues to consider related to teacher value-added scores, and Kane (2017) laid out issues related to using residualized student gain scores for value-added models, including bias in the individual student residual gain scores and the impact of this bias when averaging across students to obtain estimates of a teacher- or school-level effect. A discussion of possible “corrections” is provided, but with the caution that estimates reflecting “all sources of random error in the prior scores” (Kane, 2017, p. 10) are typically not available.

Adaptive Testing

Computerized adaptive tests (CATs) differ from other assessments in that the items a test taker is administered depend on the test taker’s estimated proficiency. Multi-stage tests (MST) are typically of a fixed length, meaning a predetermined number of stages (and items) are administered to each test taker. Item or passage CATs generally stop after a set number of items are administered or after a fixed precision is reached. Although the standard errors of the proficiency estimates for each test taker can be used to obtain an approximate estimate of reliability, the standard errors will typically differ across test takers based on augmented stopping rules, such as stopping testing after a maximum test length is reached, regardless of the standard error of the current proficiency estimate.

A salient issue in adaptive testing is that basing which item or set of items a test taker sees next on how they responded to previous items suggests a violation of the item independence assumption, which IRT methods tend to rely on. The majority of methods used to estimate reliability for adaptive assessments use IRT methodology, though Divgi (1989) presented two methods to estimate reliability for a CAT without invoking IRT, and S. Kim and Livingston (2017) investigated a CTT-based procedure to estimate reliability for a MST, finding through their simulation that the method produced accurate results.

B. F. Green et al. (1984) stated, “Many psychometricians feel that devising a reliability coefficient for an adaptive test is inappropriate and misguided” (p. 352), but provided two alternatives, one being similar to an information function and the other using marginals. The authors suggested getting empirical reliability through test–retest designs. Beiser et al. (2016) computed test–retest reliability on an adaptive assessment of depression, concluding that the assessment provided “reliable screening.” Haley et al. (2010) reported a study where test–retest reliability was computed using intraclass correlations across four CATs.

The *Standards* (AERA et al., 2014) suggest estimating reliability and precision information through simulations. Thissen (2000, p. 166) concurs, stating that

because the entire system is used, including the item pool, the item selection algorithm, and the item exposure control system, such simulations may be expected to give accurate predictions about the performance of the CAT. . . . Simulation is the only situation in which the “real reliability” or “theoretical reliability” of a test can be determined.

Nicewander and Thomasson (1999) presented three test information–based reliability estimates for the Bayes modal estimate (i.e., MAP) and the ML estimate of proficiencies derived from direct definition, harmonic means, and Jensen’s inequality, demonstrating that the latter two estimates were upper bounds for the true reliability. The results of multiple simulations found that ML and MAP provided nearly identical true reliabilities in all data sets and that all reliability estimates were within .02 of the true reliabilities. Segall (2001) introduced two methods designed to improve measurement precision of “a general test factor,” one using a MIRT proficiency estimate and the other adaptively choosing items to maximize precision of a general proficiency score. Both methods were found to improve precision.

Nicewander (2018) transformed a reliability index to provide precision information for individuals, subgroups, and cut scores (conditional reliability coefficients), applying them to number-correct scores and theta estimates computed from number-correct scores, as well as theta estimates used as CAT scores. Seo and Jung (2018) compared three observed standard error marginalization methods (arithmetic mean, harmonic mean, and Jensen equality) in estimating empirical CAT reliabilities, finding that the Jensen equality method provided better accuracy and easy computation. Park et al. (2017) introduced a new method to obtain an analytic derivation of MST information.

Jodoin et al. (2006) studied test–retest and alternate forms reliability coefficients for several designs, including two- and three-stage MSTs, speculating that they would obtain higher coefficient values if there were more separations between their modules (i.e., if the medium module would have been less similar to the easy and difficult modules). Zhang et al. (2006) compared two IRT-based procedures for computing an aggregate reliability estimate using data from an MST assessment consisting of both MC and performance

tasks. One procedure used an empirical ability distribution to estimate score variance, whereas the other assumed a normal distribution. The authors concluded that the two methods tended to produce similar results. The authors raised the issue that if the two methods provide quite different estimates, the question to consider is “whether reliability estimation in IRT scored tests, especially adaptive tests, should be sample-driven or sample-free” (Zhang et al., 2006, p. 13).

One issue to keep in mind in MST is that test takers are routed to a subset of items, so computing precision information over all items in a panel falsely inflates precision because each test taker is administered only the items included in a single path, not all possible items included over all paths.

C. Wang (2014) combined adaptive testing with hierarchical latent trait estimation, in hopes of increasing the reliability of hierarchical latent trait estimation. Two item selection methods were proposed, and both improved measurement precision over a unidimensional item selection method, particularly for short tests and when the correlation between dimensions was high.

Schmitt et al. (2010) investigated how speededness affected the reliability of proficiency estimation in a CAT, using simulation and two item pools, one “real” and one “ideal.” The proficiency estimates became increasingly negatively biased as the CAT became more speeded in the real pool; these results were not replicated with the ideal pool.

Future precision research in adaptive testing will likely incorporate more complex IRT models, scoring with plausible values, and more complex assessment situations involving gaming and other simulations, where routing may be based on factors in addition to ability estimation.

Reliability Issues Related to Speeded Assessments

Operationally, some assessments are untimed, some are generously timed or partially speeded for at least some test takers, and still others have time limits imposed for practical reasons, such as when a test is administered in a school cafeteria and needs to be finished in time for lunch (for issues related to timing, see Margolis & Feinberg, 2020).

Estimating reliability for pure speed assessments from a single administration has been discredited for some time, with a consensus that administering two or more forms of an assessment to a group of test takers is the appropriate way to investigate precision (Anastasi & Drake, 1954; Cronbach & Warrington, 1951; Gulliksen, 1950), though attempts have been made to develop improved methods because of practical difficulties in obtaining data on two or more forms for a group of test takers (see Gulliksen, 1950). Cronbach and Warrington (1951) listed three conditions that result in inaccurate split-half or coefficient alpha reliabilities based on a single form when the assessment is speeded, including small variability in the number of items test takers have answered, when test takers have responded to all items they are likely to answer correctly within the time limit, and when the variation in the number of

items responded to from form/occasion to form/occasion is small compared to the number of items responded to across test takers. According to these authors, if data from an assessment with a time limit do not meet one or more of these conditions, a split-half reliability estimate from a single administration might be usable.

In achievement and licensure/certification testing, relatively few assessments are pure speed tests, meaning there is not an expectation that lack of time is the sole, or even primary, reason for test takers not answering every item correctly. According to Cronbach and Warrington (1951), speededness is a factor to consider when a test taker's position in a group of test takers would change if the test taker were given additional time to respond to the assessment. Speededness violates the assumption of local independence of items, in that for those items a test taker does not have time to answer, the lack of time affects the test taker not answering the item correctly more than other characteristics, such as item difficulty, thus impacting the assumptions both GT and IRT methods make about local item independence for estimating coefficients.

Attali (2005) used simulations to illustrate the impact of speededness on reliability, assuming that test takers who were running out of time would engage in rapid guessing on their remaining items as opposed to leaving them unanswered, which tends to lower reliability because some items are answered correctly by chance, which is unlikely to be consistent across multiple test forms. Whether the speed at which a test taker works is consistent across alternate forms is another consideration.

The salient point is to what degree the test taker differences in scores are due to speed, or what proportion of total score variance is "speed" variance (Attali, 2005; Anastasi & Drake, 1954). When assessments are slightly speeded, or only a small portion of total variance is due to speed factors, internal consistency coefficients may not be too misleading. However, with the increase in computerized testing and the collecting of timing information, such as the amount of time a test taker spends responding to each item, more sophisticated methods of addressing speededness are possible, such as explicitly including timing information in estimating proficiency. Petscher et al. (2015) used a conditional item response model that incorporates response time as an item parameter in the context of a reading fluency assessment. Their model subsumes the idea of independence at the individual level, but incorporates a joint relation between speed and accuracy at the population level. The authors found their model improved the precision of student scores by an average of 5%. The increase was not uniform, however, having the most improvement for higher proficiency students. Other models, such as those introduced by van der Linden (2009) that incorporate latency, could also be used.

Aggregation Issues

Reliability of Group Means

The reliability coefficients dealt with in this chapter have concentrated on individual test takers and precision related to normative or criterion-referenced issues related to individuals. There are, however, instances where the unit of interest is at the aggregate

level, for example, looking at a classroom. Examining trends, such as a cohorts' set of scores over time, or change scores, such as pretest and posttest scores to examine the effectiveness of a treatment, involves additional precision issues. Geldhof et al. (2014) examined level-specific (e.g., individual and group) reliability using three estimates and simulated and real multilevel data, finding support for the use of level-specific reliability estimates.

It is well known that the variability of, for example, individual fifth graders' assessment scores in a school district is generally greater than the variability of the average scores of the fifth-grade classrooms. Brennan (1995) used GT to illustrate, however, that the error variance for individuals could be less than the error variance for groups under certain conditions, depending on whether one considered persons and items random or fixed in terms of the universe of generalization. According to Brennan (1995), "Aggregation may well lead to a sizable decrease in error variance, but this can be very misleading if an investigator fails to take into account the corresponding decrease in true (or universe) score variance" (p. 395).

Reliability Generalization

Reliability is not a constant property of an assessment, but may vary based on context, such as a particular sample of test takers or number of raters, and the definition of a replication. Reliability generalization (RG) is basically a meta-analysis of reliability coefficient estimates across different studies, with the goal of estimating an average reliability across studies, as well as investigating the variability in the reported estimates and identifying factors that seem to be influencing the reliability estimates.

The importance of RG studies is that many researchers do not provide reliability estimates based on their particular context, but instead rely on, perhaps, a publisher's technical documentation for their reported reliability information, even though their context may differ in ways likely to affect precision. Although not as ideal as having precision information calculated on their particular data, RG analyses may provide some information on whether "borrowing" reliability information from one context and assuming it applies in another is likely to be reasonable (see Vacha-Haase et al., 2002, and Whittington, 1998).

There are different ways to implement an RG study and different factors to consider as possible influencers on estimated coefficient values. Holland (2015) examined 107 peer-reviewed RG studies, finding most analyzed coefficient alpha coefficients. He provided a set of guidelines for both conducting and reporting RG studies. Sánchez-Meca et al. (2019) also developed a checklist to assist researchers in reporting reliability generalization results. Henchy (2013) examined 64 RG studies, comparing the recommendations around such studies to how they were actually conducted, finding that some recommendations, such as conducting a priori power analyses, were not followed. Those conducting RG studies need to attend to issues such as whether to weight study results by test-taker sample size and how to treat a possible lack of

independence of reliability estimates where a given study has reliability estimates from various subgroups, subscales, or multiple methodologies.

Precision Issues Related to Raters

Rater Reliability

When the scoring of a test taker's responses is impacted by who does the scoring, this source of variability should be incorporated when computing reliability. Rater impact is often a matter of degree and encompasses various situations, such as a teacher and a teacher's aide interpreting penmanship differently to various trained raters scoring constructed response items using an elaborate rubric on a statewide accountability assessment. The more likely different raters are to assign the same score to a test taker's response, and the more likely the same rater is to assign the same score to the same response, the less rater variability contributes to error variance. Good rater training, well-defined scoring rubrics, and monitoring to ensure raters are interpreting the rubrics and responses the same way help increase rater consistency.

GT is frequently used to model the variability of raters, as well as to estimate precision information over various features, such as the number of raters and the number of prompts or tasks administered. However, it is not always clear how well the results of these studies generalize to a particular context. Studies done by publishers during the initial administration of an assessment may include expert raters, training materials that are still under development, and prompts and rubrics that are still being tweaked, as well as administration conditions, such as time limits, that are still being determined, and they may or may not include test takers who are motivated. All of these factors can impact the GT precision information and make it less relevant for a later context. In addition, under operational conditions, raters are likely not all at the expert level, and raters may not be assigned randomly but rather by convenience, such as which raters happen to be available for a particular shift when a particular set of responses are available for grading. For local GT analyses, existing data are often searched for a small subset of data that align with a standard GT design, such as a fully crossed rater by test taker nested within prompt design, to gather precision information, including rater effects.

Rater scores are often compared through either a rank ordering of responses (correlation between rater scores over a group of test-taker responses) or a match of actual assigned scores (often contingency tables focusing on exact or adjacent matched scores, frequently corrected for chance agreement). Rater severity and leniency; the tendency of a rater to assign high or low scores, respectively; and proclivity of a rater to use the whole range of scores or not are perhaps the most frequently cited rater effects. The scoring process logistics, such as scoring all responses to a single prompt versus scoring all responses by a single test taker, can mitigate some rater issues, such as the halo effect.

Studies should account for variability within and across raters. Models incorporating rater effects include IRT models (Linacre, 1989; Lunz et al., 1990; Verhelst & Verstralen,

2001), a hierarchical rater model (Patz et al., 2002), a signal detection theory model (DeCarlo, 2010; DeCarlo et al., 2011), Yao's rater model (Z. Wang & Yao, 2013), and Longford's (1994) model-based approach for multiple raters of essays. Recent research includes that of Zapf et al. (2016), who investigated confidence intervals for nominal data and Fleiss's kappa and Krippendorff's α for interrater reliability in multiple scenarios, finding that bootstrapped confidence intervals provided coverage probability close to the theoretical ones. Choi and Wilson (2018) proposed a generalized linear latent and mixed model approach, combining IRT and GT, which allows ML estimation of individual random effects and variance components for generalizability coefficients. Gianinazzi et al. (2015) asked the same raters to rate the same responses at two points in time, looking at both intrarater and interrater reliability. Abdalla (2019) looked at the scoring of prompts reused over time under different conditions of rater drift, looking at the percentage of exact agreement and Cohen's kappa as interrater agreement measures, and the paired t test and Stuart's Q as marginal homogeneity measures, under two data frameworks: the generalized partial credit model and latent-class signal detection theory model.

Haertel (2006) discussed several rater issues, including what is the true score of test takers on a prompt where raters score responses. Is it the average score across replications of raters? Or across a test taker's repeated responses to the prompt, if the test taker could be repeatedly administered the same prompt? Or is it based on the rubric and not on rater's assigned score? Haertel (2006) also mentioned issues related to scoring with a finite rubric, such as 0 to 3, and the implications for test takers with true scores at the extremes. For example, a test taker with a true score of zero can only have measurement errors in one direction. Haertel (2006) stated, "Unless all raters assign the identical score, the mean observed score over raters is a biased estimator of the essay's true score. Thus, from this perspective, true score cannot be equal to the expected value of observed score" (p. 102). Haertel emphasized the need for precisely specifying the definition of true score and error, as well as the model being proposed, to minimize ambiguity and determine the appropriateness for a particular context.

Haertel (2006) also raised the issue of what score is assigned when multiple raters score the same response. Typically, multiple scores are averaged only if the scores are identical or fall within some predetermined range of each other; for example, adjacent scores may be averaged, but scores that are not identical or adjacent may be sent to resolution. Resolution may involve ignoring the previous rater scores and using only a score assigned by a more expert rater. Other rules may involve keeping the original rater score that most aligns with an expert score, discarding the more disparate original rater score. It is also the case that any averaging of ratings is likely to result in fractional scores that do not directly align with the scoring rubric. Both fractional scores and resolution scores impact variability due to raters. Haertel (2006) suggested that additional research on how to incorporate these cases into a rater model is warranted.

Variability across raters can be examined by assigning multiple raters to score the same responses. Variability within a rater is somewhat more difficult. A rater may

remember seeing a particular response previously, so having a rater score a single response multiple times as independent scores may be challenging, as well as resource intensive. Examining how consistently a rater scores “essentially identical” responses might provide some insight, though the issue then becomes what is essentially identical and under what conditions (time of day, position in a stack of responses, before or after a higher or lower scoring response, length of time between scorings, etc.). Though raters are typically not the largest source of error in the precision of rater-scored responses, lagging behind task/prompt variability, rater variability is still a source of unreliability to minimize.

Automated Scoring Issues

Machine scoring, or artificial intelligence (AI) scoring, involves training a computer, through natural language processing or other methodology, to score essay/constructed responses by machine, rather than human raters. AI scoring is appealing because, in theory at least, it is more efficient and returns scores faster and more cost-effectively than human raters. Note, however, that current AI engines tend to require some training on each individual prompt, so the benefit in efficiency is largely manifest at scale when large numbers of test takers respond to the same prompt. (See, however, Attali, 2011 and Foltz et al., 2013 for a generic model; Foltz et al., 2013 reported the generic AI rater as having about 10% lower reliability than the prompt-specific rater). Although most of the research literature in AI seems to focus on essay scoring, there have been studies on other types of constructed response items (see Shermis, 2015, who looked at machine scoring short-answer items).

Whether assessment responses are scored solely by a single AI engine, multiple AI engines, or a combination of an AI engine and one or more human raters, precision coefficients are impacted. The most common way AI scores are currently evaluated is to look at the consistency between scores assigned by human raters to a group of test-taker responses correlated with the scores an AI engine assigns, where the AI engine scoring is typically trained to maximally predict the human scores based on features that may or may not resemble the human scoring rubrics. Various coefficients, including Pearson correlations between the two sets of scores, exact and adjacent agreement, and kappa, have been used (see, for example, Attali, 2013, who examined correlations between AI and human scoring across multiple studies, typically comparing human–human correlations to AI–human correlations). Attali (2015) examined different weights applied to AI features to find the optimal weights for reliability and validity, as opposed to the traditional use of predicting scores human raters would assign, reporting that the feature weights that predicted human rater scores were different from those that emphasized reliability coefficients.

Attali and Burstein (2006) discussed issues related to using human rater and AI agreement as reliability, including when data on only a single prompt are used. While a human rater may or may not assign the same score to a test-taker response presented twice, an AI engine would be expected to return the same score, assuming that no

intervening tweaking or training of the engine occurred, suggesting it may be preferable to compare scores across multiple prompts rather than a single prompt.

Attali et al. (2013) looked at increasing the reliability of combined human and AI scores, both by decreasing the overlap in the features rated and by increasing the reliability of the human scores. Both methods proved effective. Attali (2011) reported that a test–retest reliability for a single human rater was .53, while that of a generic AI rater was .80. However, in the same way that all prompts, rubrics, administration conditions, samples, human rater training protocols, and so on vary, so do different AI engines, so while these results may be informative, they may not generalize to other contexts.

One question that arises in considering AI scoring is what actually constitutes a replication. Sending a specific response through the same AI scoring engine twice does not reflect the same variability as sending the same response through human scoring twice, with either the same or a different rater. The same test taker could be administered the same prompt or form twice and both responses could be sent through the AI engine, but this is not really a replication to investigate the AI engine because the within-person variability confounds the interpretation. Perhaps training the AI engine twice on two separate sets of training or calibration papers and then running a new set of responses through both engines and comparing the paired scores would be informative, but still would not really align with the typical human rater analyses.

Reliability of Behavioral Observations

Another setting where raters are involved is in observations of behavior, such as observers in a classroom setting looking for incidences of certain behaviors, the absence or presence of which on the part of teachers and/or students is recorded. Individual rater errors consist of recording an occurrence when it is not manifest and not recording an occurrence when one is manifest. Issues in this context involve rater consistency (one rater observes a behavior and one does not) and rater accuracy (either the behavior did or did not occur, so both raters observing the same incident are not correct), and representativeness—if one wishes to make inferences about behaviors based on the observed/rated sample, how representative is the observation period? For example, is an observed teacher demonstrating typical behavior, or is the fact of being observed leading a teacher to be more likely to demonstrate a desired behavior?

Gwet (2012) discussed issues around interrater reliability in medical settings, raising the issue of whether two raters whose ratings correlate highly are “interchangeable” and to what extent we can extrapolate from raters in a study rating particular subjects to a broader context, emphasizing the importance of gathering precision information using raters similar to those that will be used operationally. Gwet (2014) also discussed ordinal measurement issues, when the distinction of whether raters agree or disagree may be a matter of degree as opposed to absolute, offering the illustration,

Two raters A and B who rate the same patient as “Certain Multiple Sclerosis” and “Probable Multiple Sclerosis” are not quite in total agreement. But are they in disagreement? Maybe to some extent only. That is, with ordinal scales, a disagreement is sometimes seen as a different degree of agreement. (p. 16)

This suggests that a rank ordering of test takers, rather than a contingency table, might be preferred to examine consistency.

The reader is referred to Haertel (2006) for additional information on issues related to precision with behavioral observations, particularly his treatment of Rogosa and Ghandour (1991) and their framework for considerations of score accuracy.

Error in Reliability Estimates

Reliability coefficients are used to provide an indication of the uncertainty in measurements (see Frank, 2002, for the use of reliability coefficients to correct effect sizes), but reliability estimates also contain error. In the examples provided in W. Lee et al. (2025), coefficient values across the two contrived forms can be used as a measure of consistency, but in practice, it is uncommon for more than one administration to occur, and simulations or resampling procedures are often used to estimate standard errors and confidence intervals. While this information can be informative, some sources of error, such as test-taker consistency across alternate forms or separate administrations, are not fully considered.

Several researchers have investigated issues around error in reliability and precision estimates. Andersson and Xin (2018) derived asymptotic variances for IRT marginal and test reliability coefficient estimates for both dichotomous and polytomous IRT models and demonstrated through simulations that the resulting confidence intervals had “good coverage” under several conditions studied, with the marginal reliability coefficient having somewhat lower sampling variability and larger bias than the test reliability coefficient.

Feldt (1990) provided methodology to create confidence intervals for the intra-class reliability coefficient, used when there is a single rater for individual responses, based on sampling theory. Ogasawara (2009) derived asymptotic distributions of several sample coefficients with and without stratification under nonnormality. Terry and Kelly (2012) focused on estimating the sample size needed to obtain narrow confidence intervals for composite coefficients. Bujang et al. (2018) looked at sample sizes relative to hypothesis tests for Cronbach’s alpha coefficient. Zapf et al. (2016) looked at confidence intervals for interrater reliability estimates for nominal data.

When using an estimate of precision, particularly to inform a high-stakes decision, it is important to consider the precision of the estimate as well. This is likely to be of particular concern in GT where variance component estimates may be based on a sampling of very few levels from an infinite population (see Brennan, 2001c).

Practical Guidelines

What Reliability Computations Are Most Appropriate for What Context?

As has been discussed throughout this chapter, there are a variety of methodologies that can be used to compute precision information. According to the *Standards* (AERA et al., 2014), the reliability methodology selected for use in a particular context should “be consistent with the structure” of the assessment, providing the example that an assessment with considerable multidimensionality would indicate that a composite score reliability be used. It is also recommended that precision information be computed for the scores on which decisions are going to be made. For example, if equated and rounded scale scores are used for placing students into their first-year college math class, precision information provided on equated and rounded scale scores will be more appropriate than internal consistency information on raw scores.

E. Haertel (personal communication, March 8, 2019) advocated framing the issue of which reliability computations are most important by first considering what the intended use of the data is and what sources of error should be considered (“begin with a substantive definition of the intended universe of generalization”). This is then followed with selecting a data collection design that would populate the appropriate model. GT can often be extremely helpful here by explicitly identifying what factors one wishes to generalize over calculations (see Revelle & Condon, 2019). It is not always possible to collect the desired data, for example, administering the same assessment over and over to the same test takers. However, knowing what is desired can be helpful in choosing what available methodology to substitute.

To explore the various reliability statistics that can be used to represent consistency and inconsistency of scores, two large-scale examples are provided by W. Lee et al. (2025). For each of the examples, multiple reliability coefficients, CSEMs, and classification consistency and accuracy coefficients are provided. In addition, results are provided for number-correct raw score, IRT proficiency, and scale-score metrics for various statistics and indices. The purpose of providing these examples is to illustrate similarities and differences in values across multiple reliability statistics and to reinforce the importance of identifying details about how a reliability estimate was computed, instead of simply reporting “the reliability was [some value].”

W. Lee et al. (2025) demonstrated through examples that different reliability coefficients calculated on a single set of data yield different values. This is largely because the different coefficients make different assumptions. Simply running a multitude of analyses and choosing to report the highest values is counterproductive. Woodruff and Wu (2012), in a paper comparing coefficient alpha with multiple other coefficients, reminded us to remember what each reliability coefficient indicates and that we should be reporting the coefficient that best aligns with the inferences we plan to make.

How Do I Increase Reliability and How Much Do I Need?

The *Standards* (AERA et al., 2014) do not provide criteria for minimally acceptable reliability coefficients. Occasionally a request for proposal, a government organization, or an author (see Dimitrov et al., 1999) may specify a particular value of reliability that should or must be achieved, but there is rarely any rationale provided for the chosen value or any criteria for the conditions under which the value must be achieved (such as test-taker sample size, whether under operational or special study conditions, or the metric or type of coefficient). Reliability coefficients appearing in technical manuals may provide some indication of the magnitude thought acceptable, but typically these are lacking in detail about the data collection, and there is no evidence that these values are “adequate” other than that the test publisher thought they were sufficient to publish the assessment. Ellis (2013) commented, “The absence of such standards is a serious gap in existing behavioral research methods and leads one to ask why reliabilities are routinely computed if their acceptable values are unknown” (p. 16). Wainer and Thissen (1996) brought up the related issue of the practical impact of small differences in reliability coefficients.

Kane (1996) advocated judging how adequate a precision level is for one’s intended use by considering the measurement error in relation to the “tolerance for error” in a specific situation:

The level of error that is tolerable in a particular context is determined by the interpretations to be applied to the measurements and the uses to be made of the measurements. To the extent that errors do not interfere with intended interpretations or uses, they are not a serious problem. (p. 356)

This leads to reframing the question “How much reliability do I need?” to “How much error (uncertainty) can I tolerate in the decisions I need to make with these data?” Practitioners may not be concerned with relatively large CSEMs occurring far away from a cut score. However, when using an assessment as a component in a decision, such as a test score, a grade point average, or soft skill measures in determining college admissions, it may be much more difficult to articulate the amount of “tolerance for error” in a component.

Different factors impact different precision calculations differently, again depending on what the specific calculations account for. For example, differences in test specifications across test forms have no impact on computing a reliability coefficient based on only one administration of a single form, but would have an impact on a coefficient involving parallel forms or on analyses involving different forms over time. Alternate forms reliabilities will tend to increase as the forms are more similar.

Internal consistency measures increase as the items within an assessment have higher discrimination values. To rank order test takers according to some characteristic or trait, items that all test takers or no test takers answer correctly provide no information. Jodoin et al. (2006) reported that higher coefficient values for MST tests would be obtained if there was more separation between the easy, medium, and difficult modules.

The more objectively an assessment or item is scored, the more likely the reported scores are to be consistent and the less the scoring process is likely to contribute to error variance. The way an assessment is scored can affect reliability; Pugh and Brunza (1975) stated that the reliability of a test increased from .57 to .85 when comparing traditional number-correct scoring to a confidence scoring method. In addition, when multiple components are used to form a composite score, giving more weight to the more reliable components tends to increase reliability of the composite. Kane and Case (2004), for example, addressed how to weight two components of a composite score to maximize correlation with desired true score (defined as a specified weighted composite of component true scores) when the observed component scores have different reliabilities.

Another factor that can impact reliability coefficients is the metric used, as shown in tables associated with the two examples reported by W. Lee et al. (2025). There are multiple ways in which scale scores, theta scores, and cut scores could be set, which would also potentially influence precision calculations.

One factor that seems to be generally accepted is that longer assessments have more precision than shorter assessments because they provide a larger sample of tasks or items. However, there are caveats to keep in mind. One is that increases in precision due to increasing assessment length is likely most effective when the initial test is short. Adding 30 items to a 10-item test typically will increase reliability more than adding 30 items to a 200-item test, other things being equal. “Other things being equal” is an important caveat. Adding poor items (where “poor” may indicate inferior statistically, or in terms of alignment to a test blueprint, or items of such novel format that test takers are confused, or items that make the test so long fatigue and lack of motivation become issues) are more likely to lower precision than increase it. As Thorndike (1951) stated, “It has been shown that the reliability of many tests could actually be increased by omitting a number of items on the test” (p. 602).

In addition to increasing the number of items, the length of a multiple-choice assessment may also be considered in terms of increasing the number of options per item, again assuming the additional options are viable and of equivalent quality. The relationship of item sets to reliability may be somewhat more complex because of local dependence. Adding additional items per item set, where all items refer to the same set of stimulus material, is unlikely to have the same impact on reliability as adding additional item sets. According to Livingston (2018), “A test taker who has difficulties with that particular stimulus will have trouble with all the questions about it. To improve alternate-forms reliability, we need to increase the number of item sets” (p. 16).

Wainer and Thissen (1996) provided an example for which a test of shorter passage sets needed 43% additional items and a test of longer passages need 65% more items for each to obtain the reliability of a test of 40 stand-alone items. Lawrence (1995) also looked at the issues of local item dependence and the effect on reliability, finding that item sets effectively reduced test length: “The effect of item sets is revealed by a systematic discrepancy between the internal consistency estimates, which treats items based

on the same passage as independent, and the parallel-form estimates” (p. 13). Passage sets may be an excellent way to assess certain content, but the introduction of item dependence affects some precision coefficients through a violation of assumptions.

When scores involve raters, adding additional independent raters tends to increase precision, again assuming the additional raters are of similar quality as the original raters. The question of whether adding additional prompts/items or additional raters would be most likely to improve reliability in a particular setting requires the total design to be considered. GT studies allow one to estimate the influence different factors would have on certain types of reliability coefficients, such as whether adding additional items or prompts, raters, clusters of students per school or more schools, and so on would provide a better return on investment in a particular context (see Sun et al., 1997). The design implemented for data collection impacts precision, especially from the standpoint of the intended universe of generalization. Whether a particular set of raters or prompts is considered fixed or random may have a substantial impact on the coefficient values. However, the goal is not to choose a design, such as assuming that raters are fixed, to raise a coefficient value, but to have the design reflect the context one is interested in.

Different data models, as well as different precision estimates, have different assumptions and incorporate different sources of variability into their definition of error. Therefore, selecting a coefficient because it is larger is not recommend. Coefficients should be selected to fit one’s desired use and to align with the data collection design one implements.

Inappropriate administration conditions for an assessment can lower precision estimates by adding in additional error. These factors can range from inappropriate time limits, use of unfamiliar item formats or technology, inadequate motivation on the part of test takers to score their best, inadequate test directions, sloppy scoring, and a myriad of other conditions. Adequate instructions and practice exercises to ensure test takers understand what they are being asked to do tends to increase precision (see Thorndike, 1951).

For some consistency measures, the test-taker sample on which they are computed is a factor with large influence on the calculated value of the coefficient, such as the distribution of masters/nonmasters for a classification consistency measure or the overall distribution of test takers, such as how bunched or spread out the test takers are in terms of the underlying trait one is trying to estimate. The issue of restriction of range, when the possible value range is truncated through self-selection (for example, when only previously failing candidates are administered a retest or only high-proficiency candidates self-select to take an assessment) has been studied by various researchers. Sackett et al. (2002) examined the effect of different scenarios of range restriction on reliability coefficients, finding that the different scenarios resulted in different underestimates of criterion reliability. Fife et al. (2012) also looked at various selection ratios in relation to several reliability coefficients, including KR20 and test–retest, corrected and uncorrected, under varying selection ratios. These estimators were examined in

terms of bias and precision, with test–retest reliability usually being the best estimator of reliability across conditions.

Improving precision has multiple perspectives. Deliberately testing a sample with an extreme range of ability may result in a larger calculated value of a coefficient for, say, technical documentation, but doing so influences only that particular administration, whereas adding additional items to the test will likely improve precision for every future administration. Similarly, narrowing the desired universe of generalization, from a GT perspective, by considering, for example, raters fixed may raise a value, but is inappropriate if those raters will not be scoring future responses. Knowing what factors may influence a particular reliability coefficient facilitates comparing values across assessments by considering the context under which each coefficient was calculated.

Effective Ways to Communicate Reliability Information

Once reliability information has been estimated, these values need to be communicated to those wanting to make decisions based on the scores. The statement “The reliability of Assessment A is .80” is virtually meaningless in terms of helping a user know how much confidence to place in the scores of interest. Without additional information, one cannot even be sure that a value of “.80” is better than a value of “.70” but not as good as a value of “.90,” because one does not know whether the three values are for the same type of coefficient (or what sources of error were incorporated), or what sample of test takers was used in each instance, or other details, such as administration conditions, scoring, and so on. When presenting precision information, the relevant context must also be presented, so in addition to information about the actual coefficients computed, information on the assessment, the administration, the test-taker sample, the scoring, the reported score metric, and other pertinent details should be included. An internal consistency coefficient of a released practice form given under lax conditions with no stakes to students reported on number-correct scores and an alternate-forms coefficient under high-stakes standardized conditions to a self-selected sample reported on a scale score metric might be interpreted quite differently by someone planning to incorporate the assessment into a composite for decision-making, even if the coefficient values were similar.

Given there is sufficient detail to understand the context of the design and the coefficient calculations used, “uncertainty” needs to be communicated in a manner that facilitates understanding. A statement such as “A coefficient value of .75 suggests that 75% of the variance in scores is due to actual differences in ability while the remaining 25% is attributable to measurement error” is unlikely to be helpful to a lay audience. S. Johnson and Johnson (2009, p. 51) stated,

If the public is to be educated about technical issues in assessment, and if reliability information is to be routinely published alongside examination results, then we need to decide which form of reliability measure would be the most appropriate one to use. There are basically two choices: a variance ratio (reliability coefficient), and a standard error of measurement.

According to C. Wang (2014, p. 454), “reliability has the advantage of being a compact measure of precision that has a fixed metric (bounded between 0 and 1) that is widely understood.” Cronbach (2004) asserted that the SEM should take precedence as the most important piece of information to report, rather than a reliability coefficient. Patterson (1955), in an article dedicated to interpreting SEMs, discussed problems in making statements about SEM concerning true scores using the standard error of observed scores.

Walsh et al. (2014) illustrated reporting information graphically rather than as a single number. Raudenbush and Jean (2012) advocated the use of confidence intervals for value-added scores for teachers; they also discussed issues around interpretation, such as shorter intervals (e.g., 75% versus 95% confidence intervals) and the different interpretations one might make (such as “Where do I as a teacher stand among all teachers?” versus an administrator wanting to identify a lower group of teachers for training or a higher group for recognition).

Regardless of one’s view on what measure of precision to report, illustrations and examples can help practitioners understand abstract concepts around uncertainty. For example, statements suggesting how many masters/nonmasters are likely to be misclassified, or how a test taker is likely to score if given the assessment a second time, or illustrating through simulation the distribution of obtained scores a test taker (simulee) of a given true proficiency achieves on two different CAT designs may be more impactful than simply reporting a coefficient value. Providing a comparison can also be useful to aid in interpretation, as Wood (2020) illustrated:

When possible, documentation should include agreement statistics for two independent human raters and for a human rater with automated scoring. The public may be surprised if a scoring engine agrees with a human 65% of the time but may not be so surprised if two independent humans agree only 67% of the time on the same prompt. (p. 144)

FUTURE DIRECTIONS

In the years since the fourth edition of *Educational Measurement* was released, there has been progress in addressing reliability issues with more complex data models, with incorporating additional sources of error in coefficients, and with the development of new methodologies and coefficients. There has also been increased emphasis on the use of CSEMs over reliability coefficients, which this chapter hopefully reinforces.

As computing power and the integration of computer science and data analytics into measurement approaches continue to advance, more complicated simulation methods are available to examine reliability across more complex assessment models. As our models and assessments become more complex, so do our methods of estimating reliability. From fixed forms to adaptive tests to game-based assessment experiences, the concept of replication becomes more challenging. It may be relatively easy to imagine a test taker taking the same fixed form (or a randomly parallel or tau-equivalent form) a second time.

However, when it comes to adaptive testing and game-based assessment, with various possible paths involving the same or different pools, the scenario becomes more complex.

Simulations have become more necessary to estimate reliability, such as running the same simulees through alternate CAT pools multiple times. These simulations rest in part on having realistic models to generate test-taker responses, and we are not there yet. Too many simulations are conducted with models with too small of a random (or even some systematic) error component. We need new models of data generation along the lines of those used by Kolen and Harris (1987) and Davey et al. (1997) to more accurately reflect actual test-taker behavior if we are going to rely on the generated data for reliability information.

The previous editions of *Educational Measurement* have primarily focused on the reliability of summed scores from a single point in time (Haertel, 2006). This chapter extends its focus to include additional metrics such as IRT proficiency estimates and scale scores, recognizing the importance of reliability information aligned with the specific metric used for decision-making. In the future, additional metrics will likely become more prevalent in operational use, requiring further advancements in reliability estimation. Although the adopted definition of reliability in this chapter is replication based, the focus remains on discrete points in time rather than the continuous testing model mentioned by Haertel (2006). These types of assessment models, familiar to some as ongoing formative assessments, still require additional development in terms of reliability information across all previously collected data, the definition of what a replication consists of in a model continually adding additional assessment information, as well as what we are attempting to make inferences about (and when) in an ongoing data stream.

Additional considerations warrant attention, including the exploration of whether automated item generation and item cloning can accurately predict item parameters or characteristics to a sufficient extent for computing CSEMs prior to administering an assessment. Moreover, evaluating reliability around test takers using plausible values, imputed item scores, automated scoring, and scoring that incorporates additional information from item latencies or item clicks is essential. It is particularly important to define the relevant error components and determine the composition of a replication in these scenarios.

Additional ways to communicate what different levels of reliability and CSEM translate to in practice are needed. For example, under classification consistency/accuracy, informing users of the likely percentage of test takers being misclassified either at a cut score or overall helps a user interpret what a difference in classification consistency/accuracy might mean in practice. Similar ways of translating or illustrating the impact of different levels of reliability for a particular inference would be beneficial. Because settings differ widely in the type of decisions one is making, for example, whether to have a student do additional work with finding common denominators prior to moving on to subtraction involving mixed fractions versus licensing an applicant to practice in medicine or law, having one-size-fits-all requirements on the level of reliability needed is inappropriate. However, providing guidelines on presenting reliability information to

enhance users' understanding of what a particular level of reliability means in a specific context would be helpful. In addition, more guidance on which types of coefficients on which metrics ought to be reported in different contexts would seem appropriate.

Cronbach stated in 2004,

I am convinced that the standard error of measurement . . . is the most important single piece of information to report regarding an instrument, and not a coefficient. The standard error, which is a report on the uncertainty associated with each score, is easily understood not only by professional test interpreters but also by educators and other persons unschooled in statistical theory, and also to lay persons to whom scores are reported. (p. 413)

Cronbach's plea warrants serious attention.

Since the fourth edition of *Educational Measurement*, there has been relatively little literature published on the integration of IRT, GT, and CTT, despite Haertel (2006) and others encouraging it. Hopefully, this chapter is a meaningful response to that goal, though there is still plenty of room for additional progress. Also, while there has been some progress on integrating the concepts of reliability and validity, to echo Haertel (2006), much remains to be done.

ACKNOWLEDGMENTS

The authors express gratitude to Edward H. Haertel at Stanford University, Seonghoon Kim at Hanyang University, and Feifei Ye at RAND for their invaluable contributions as reviewers, providing excellent and thorough reviews. They also extend thanks to Robert L. Brennan at the University of Iowa and Stella Y. Kim at the University of North Carolina at Charlotte for their valuable comments on the initial draft. Special appreciation is given to Huan Liu and Kuo-Feng Chang, graduate students at the University of Iowa, for their assistance with the literature review and data analysis.

NOTES

1. Coefficient alpha can also be derived under the assumption of randomly parallel forms. It can be shown that alpha is equal to the generalizability coefficient of a $p \times I$ design in GT.
2. Refer to Brennan and Lee (2006) for some other perspectives on KR21, especially its relation to absolute error variance.
3. General procedures are available for the UAO consisting of a mixture of infinite and finite universes—that is, a mixed effects model. However, a univariate mixed model is often viewed as a special case of a multivariate model, in which there is a random effects model within each condition of a fixed facet.

Fairness in Educational Measurement

Theory and Concepts

Rebecca Zwick

ETS (Retired), University of California (Emerita)

Nearly 50 years after the publication of Lee Cronbach's landmark paper *Five Decades of Public Controversy Over Mental Testing* (1975) and a quarter century after Robert Linn's *A Century of Standardized Testing* (2001), test fairness continues to be very much in the public eye. The coronavirus pandemic that began in 2020 led to widespread cancellation of accountability testing in U.S. public schools and impelled many undergraduate and graduate institutions to eliminate admissions test requirements, in some cases permanently. A parallel development has been the initiation of large-scale remote testing programs, in which test takers respond to assessments in their homes or workplaces, often with human or electronic monitoring. These changes have been accompanied by a wholesale reconsideration of the fairness of standardized tests, a re-examination that has been further fueled by an increasing awareness of systemic racism in U.S. society and the role that test scores can have in limiting educational and occupational opportunities. Recent challenges to standardized testing have focused on the use of achievement tests as part of K–12 accountability programs, the fairness of college and graduate school admissions tests, and, more generally, the pervasive performance differences among socioeconomic and ethnic groups.

In striving to understand test fairness issues in the early 21st century, it is useful to briefly examine some key developments in the history of assessment. Although we tend to think of institutionalized testing programs and their attendant fairness and validity concerns as purely modern-day phenomena, the civil service examinations administered in imperial China provide a vivid counterexample. To qualify for a position, candidates had to take several rounds of exams in history, philosophy, painting, calligraphy, and poetry. Competition for the highest posts took place in Beijing every 3 years. Because these tests were the key to income and prestige, candidates' families often invested in years of special tutoring. Determined to pass at any cost, some candidates hired substitute test takers or purchased crib sheets ahead of time; others cheated by wearing special garments inscribed with prepared essays or by smuggling miniature books into the testing venue (Miyazaki, 1976; Webber, 1989).

Although the imperial civil service examination program began nearly 1,500 years ago (Miyazaki, 1976),¹ many of the evident fairness and validity issues are essentially the same as those we encounter today—those of access, privilege, and opportunity to learn. The tests were viewed as a step toward equity because government positions that had previously been filled by members of the aristocracy were now filled by individuals who successfully completed examinations that were considered impartial (Miyazaki, 1976). However, although the tests were theoretically open to all candidates, this was not the case in practice. First, “all candidates” actually meant “all men.” Second, only the upper classes had the resources and leisure time needed to become literate and master the topics of the exam. The wealthier classes were also more able to pay for intensive tutoring for candidates and for tools used to cheat—issues that have a particular resonance today. In addition, traveling to the testing site could be particularly difficult for candidates living in isolated areas, far from the capital. Compounding this problem was the fact that passing the tests was the only path to civil service positions. There

were no alternative opportunities for candidates to demonstrate their competence. Contemporary educational and occupational tests are often challenged on similar grounds.

The imperial civil service tests ended in the early 20th century. During their lengthy existence, various other types of institutionalized testing began to develop, including college admissions testing. The earliest college admissions test may have been a Sorbonne entrance examination administered in the 13th century (Office of Technology Assessment, 1992), although there is some debate on this point. Most historians agree that in England and Germany, admissions tests had been instituted by the mid-19th century. In most European countries, university graduation tests predated admissions tests. In the early 19th century, for example, anyone who could afford it could attend Oxford or Cambridge. Whether they could graduate was determined by examination (Webber, 1989). A milestone in the development of college admissions tests in the United States was the formation in 1900 of the College Entrance Examination Board (now College Board) by the leaders of 12 northeastern colleges and universities. The board created a set of entrance examinations that were administered by the member institutions and then sent back to the board for scoring.

In 1904, the same year that the last imperial civil service exam took place (Miyazaki, 1976) and shortly after the formation of the College Board, Alfred Binet, director of the psychology laboratory at the Sorbonne, developed a set of tasks to measure reasoning skills. Having abandoned skull measurements and other “medical” methods for assessing intelligence, he was now determined to use a “psychological” approach (Gould, 1996). The tasks were ordered, and each was assigned an age level. Binet was opposed to strict hereditarian theories of intelligence. From his perspective, intelligence was not fixed; it could be augmented through education. The primary purpose of intelligence testing was to identify and help children who needed special education (Gould, 1996). Binet’s tasks later formed the basis for the Stanford–Binet intelligence test (Terman, 1916), which came to be interpreted and used in ways that Binet would not have supported.

A staunch proponent of intelligence tests was Carl Brigham, a Princeton University psychology professor who was firmly entrenched in the eugenics movement. Based on his assessments of World War I military personnel, Brigham concluded that immigrants, Black people, and Jews were deficient in intelligence and that their presence could lead to a deterioration of the nation’s intellectual capacity (Brigham, 1923). Although he later acknowledged that existing tests were not adequate for making comparisons of the kind that he had conducted (Brigham, 1930, p. 165), he did not retract his claims about group differences in intelligence (Saretzky, 1982). As an advisor to the College Entrance Examination Board, Brigham chaired the commission that developed the multiple-choice exam that was eventually dubbed the Scholastic Aptitude Test, first administered in 1926. Although today’s SAT (no longer an acronym) bears little resemblance to the 1926 version, the SAT’s ancestral link to intelligence tests and eugenics continues to be cited in present-day criticisms of the test (e.g., Atkinson, 2001; see also Camara, 2009).

During the early 20th century, standardized tests gradually made their way into the public school system in the United States. Assessments in the schools proceeded on two fronts—intelligence testing and achievement testing. The National Intelligence Tests, a group assessment intended for schoolchildren, was introduced in final form in 1920 (Office of Technology Assessment, 1992). The assessment was an adaptation of the Army Alpha, a test used for screening military personnel during World War I (Whipple, 1921). The Army Alpha, which formed the basis of Brigham's best-known work, *A Study of American Intelligence* (1923), had itself been influenced by early intelligence tests. To measure student achievement, the psychologist E. L. Thorndike and his students developed standardized tests in arithmetic, reading, and other areas. By 1918, more than 100 standardized achievement tests, created by different researchers, were available to measure the skills of elementary and secondary school students (Office of Technology Assessment, 1992).

More than a century later, testing in U.S. classrooms has expanded tremendously. The federal Every Student Succeeds Act, approved in 2015, requires that states must “establish college- and career ready standards and maintain high expectations when assessing all students against those standards” (U.S. Department of Education, 2017). Currently, classroom tests are used to evaluate teachers, principals, and schools, as well as students (see Brookhart & DePascale, this volume, for discussion of classroom tests, and Ho & Polikoff, this volume, for discussion of accountability tests).

Other tests that are widely used today are those required for admission to various levels of schooling, graduation tests, employment tests, licensing and certification tests, language tests, military personnel tests, large-scale surveys such as the National Assessment of Educational Progress and the Programme for International Student Assessment, and personality tests. Many of these types of assessments are discussed in later sections of this chapter.

CHAPTER OVERVIEW

The remaining five sections of this chapter are organized as follows. The section “Concepts of Fairness” begins with a consideration of the relationships among the concepts of test fairness, validity, and bias. The section also describes the fairness perspectives represented in the *Standards for Educational and Psychological Testing* (the *Standards*; American Educational Research Association [AERA] et al., 2014), addresses the misguided notion of fairness as equality of performance, and discusses aspects of test content and test administration that have implications for fairness. The key principle of opportunity to learn is presented as well. The section “Legal Perspectives on Test Fairness” highlights four landmark court cases involving test construction practices, test disclosure policies, the annotation of test scores resulting from nonstandard administrations, and the equitability of college admissions tests, respectively. The section “Statistical Perspectives on Test Fairness: Measurement, Prediction, and Linking Invariance” explains how investigations of invariance contribute to the assessment of

test fairness. To permit fair test-based inferences, key aspects of test functioning should be invariant across demographic groups. This section describes the types of statistical analyses currently used in these evaluations, including assessments of differential item functioning, differential prediction, and differential validity. Examples of invariance studies are provided. The section “Selection Fairness” describes various models that have been proposed to improve the fairness of selection procedures. The chapter ends with the “Summary and Conclusion.”

Elsewhere in this volume, Rodriguez and Thurlow discuss fair and valid test score interpretations and uses, focusing on issues of accessibility for all test takers, including individuals with disabilities and English learners. Other recent treatments of the fairness of educational tests include Zwick and Dorans (2016), which considers philosophical perspectives on fairness; Zwick (2019a), which addresses selection fairness; Sireci and Randall (2021), which describes the evolving notions of test fairness in the United States; and Zwick (2021), which addresses the fairness of IQ testing, admissions testing, and accountability testing, including the use of value-added modeling to assess teachers. Fairness issues in the assessment of personal characteristics (sometimes called noncognitive factors) are addressed by Kyllonen and Zu (this volume).

CONCEPTS OF FAIRNESS

This section first considers the interrelated concepts of validity, fairness, and bias. Next, the section describes the concepts of fairness as presented in the *Standards* (AERA et al., 2014) and then addresses the perception that fairness implies equality of performance. Subsequently, fairness issues in test content are considered. The issue of opportunity to learn is also discussed in this section. Next, fairness considerations involving test administration practices are described, including issues arising in remotely proctored testing, a mode of test administration that became widespread during the coronavirus epidemic. Finally, the importance of treating test takers respectfully is addressed.

Test Validity, Fairness, and Bias

According to current perspectives in the field of educational measurement, validity refers to the degree to which a particular use or interpretation of an assessment is supported by evidence. If a test is unfair in a certain context—for example, a math test in English that is found to underestimate the math skills of native Spanish speakers relative to those of native English speakers—it is, by definition, invalid for the population and purpose in question: The test cannot be counted on to provide an accurate conclusion about the math proficiency of native Spanish speakers. When we evaluate the fairness of tests for particular groups, we are, of course, making generalizations. In this example, we may declare the test to be unfair to native Spanish speakers even though we realize that some native Spanish speakers have excellent English skills and some native English speakers do not. In this example, the precise meaning of the declaration of unfairness is that (a) English language skills are not part of the construct that the math

test is intended to measure and (b), on average, the English language skills of native Spanish speakers are not as strong as those of native English speakers (given a particular level of math proficiency). (See Lane & Marion, this volume, for a further discussion of validity and validation.)

Clearly, fairness and validity are inextricably connected. As stated in the *Standards* (discussed further in the section “Representation of Fairness in the *Standards for Educational and Psychological Testing*”), “fairness is a fundamental validity issue” (AERA et al., 2014, p. 49).

Bias is another term that arises in discussions of test fairness and validity. The term lacks a clear and precise definition in the measurement setting, partly because its meanings in other contexts have led to confusion. In mathematical statistics, a biased estimator is a statistic whose *expectation* is not equal to the target parameter value.² In everyday speech, bias means “prejudice” or “partiality.” In the world of educational measurement, *bias* has been assigned at least two different meanings, which are distinct from the statistical and everyday definitions. As described in the section “Prediction Invariance,” Cleary (1968) defined test bias as a phenomenon that can occur when a test score is used to predict a criterion measure—say, subsequent grades—using regression analysis: If predictions are systematically too high or too low for some group of test takers, this constitutes test bias. (This phenomenon later came to be called *predictive bias*.) Cole and Moss (1989) defined bias much more broadly, as “differential validity of a given interpretation of a test score for any definable, relevant subgroup of test takers” (p. 205). The hypothetical math test described earlier would be a biased test of the math abilities of native Spanish speakers, according to Cole and Moss (1989). Whether it was biased in Cleary’s sense would need to be determined by further analyses.

In practice, most fairness evaluations depend on the intended use of the test results and on the characteristics of the test takers. In general, then, fairness needs to be assessed with reference to a purpose and a test-taking population. This chapter, however, does not include separate sections that discuss fairness findings for particular populations, such as women, people of color, English learners, and students with disabilities. Instead, examples involving various groups are interwoven throughout the chapter.

Validity, Fairness, and Test Consequences

In the late 1970s, two key legal cases about the consequences of educational testing were argued: *Larry P. v. Riles*, which involved the use of IQ tests to assign children to special education classes, a practice that resulted in the disproportionate representation of Black students; and *Debra P. v. Turlington* (see the section “Legal Perspectives on Test Fairness”), which concerned the use of graduation tests that were based on materials that some students had not had the opportunity to learn. These court cases brought to the fore the stark consequences that can result from testing policies.

The question of whether the social consequences of testing need be evaluated as part of a validity assessment became a prominent topic of debate that flourished in the 1970s and 1980s and has continued to the present day. These arguments are discussed in some

detail by Messick (1989), Kane (2006), Kane and Bridgeman (2021), and Lane and Marion (this volume). Messick (1989) explicitly included the social consequences of test use as a facet of validity:

The interpretation of test scores and . . . the use of test scores in the implementation of social policy falls well within the realm of validity inquiry, because the import of scores for action depends on the validity of their meaning and their value implications. (p. 63)

Cronbach, like Messick, argued for the importance of considering testing consequences (e.g., Cronbach, 1988), although their stances differed somewhat. Messick argued that negative consequences of testing “counted against” validity when they resulted from flaws in the test. Cronbach, however, argued that negative consequences were important to consider regardless of their cause, while remarking that this determination might not be part of the validation process (see Kane & Bridgeman, 2021). In subsequent contributions to the literature, Linn (1997), Moss (1998), and Shepard (1997) supported including the evaluation of consequences in test validation, while other measurement specialists, such as Mehrens (1997) and Popham (1997), argued for a narrower definition of validity assessment.

Once we acknowledge that fairness assessment is part of validation, however, there can be no debate as to the relevance of values and social consequences: These are central to the concept of fairness. In noting that some validation inquiries are “too narrow” because of their failure to consider social consequences, Cronbach (1988) highlighted an issue that particularly resonates today:

The obvious example of too narrow an inquiry is the validation of employment tests, which used to concentrate on predicting a criterion the employer cared about and neglected to collect facts on what kinds of applicants were most likely to be rejected by the test. (p. 7)

As this example makes clear, neither validity nor fairness can be unambiguously defined via technical means: Values are inevitably involved. In the situation mentioned by Cronbach (1988), a decision would be needed as to what demographic groups of employment candidates should be studied in evaluating test consequences (see the section, “Statistical Perspectives on Test Fairness”) and what outcomes would be acceptable.

To summarize, validity and fairness are inextricably bound together. A test-based inference cannot be valid without also being fair. Social values and consequences must be considered in evaluating fairness and thus are essential to determining validity as well.³

Representation of Fairness in the *Standards for Educational and Psychological Testing*

The *Standards*, issued jointly by the American Psychological Association, the American Educational Research Association, and the National Council on Measurement in Education, provides “criteria for the development and evaluation of tests and testing

practices and . . . guidelines for assessing the validity of interpretations of test scores for the intended test uses” (AERA et al., 2014, p. 1). As noted in the document itself, “it has been repeatedly recognized by regulatory authorities and courts as setting forth the generally accepted professional standards that developers and users of tests and other selection procedures follow” (p. 2).

Fairness was not explicitly discussed in the first two editions of the test standards, which appeared in 1954 and 1966, respectively (Sireci & Randall, 2021). During the civil rights era, issues of test bias and group performance differences became a more prominent feature of test validity discussions, and the 1974 *Standards* (American Psychological Association et al., 1974) included considerations of these issues (Messick, 1989), as did the 1985 and 1999 *Standards*.

The most recent edition, published in 2014, is the sixth version of this publication. In that edition, fairness is included in the “Foundations” section, which also contains the chapters on validity and reliability. The prominence of the fairness material reflects an attempt by the committee in charge of the revision to broaden the perspective on fairness and elevate its importance, relative to earlier editions. The committee made the decision not to include individual chapters on particular subpopulations in order to extend “the scope of fairness to include all examinees in the intended population of test takers” (Plake & Wise, 2014, p. 7; see Sireci & Randall, 2021, for further discussion of the treatment of fairness in the *Standards*).

The volume includes 20 fairness standards, beginning with an overarching standard stating that “all steps in the testing process . . . should be designed in such a manner as to minimize construct-irrelevant variance and to promote valid score interpretations” (AERA et al., 2014, p. 63).⁴ Construct-irrelevant variance is variability in the scores of a group of test takers that is attributable to characteristics, knowledge, or skills that are distinct from the construct the test is intended to measure.

The remaining 19 fairness standards are organized into four thematic clusters (AERA et al., 2014, p. 63):

1. Test design, development, administration, and scoring procedures that minimize barriers to valid score interpretations for the widest possible range of individuals and relevant subgroups
2. Validity of test score interpretations for intended uses for the intended examinee population
3. Accommodations to remove construct-irrelevant barriers and support valid interpretations of scores for their intended uses
4. Safeguards against inappropriate score interpretations for intended uses

The key principles presented in each of these clusters are briefly described here, followed by a discussion of the fairness perspective adopted in the *Standards*.

Cluster 1 notes that test developers must clearly define the construct that is to be measured, along with the characteristics of the intended population (Standard 3.1). In addition, the language used in tests should be appropriate to the purpose of

the test and should be familiar to “as wide a range of test takers as possible” (3.2). (The familiarity requirement does not apply to language that is a legitimate aspect of the construct that is being tested, as in a vocabulary test.) Also, “relevant subgroups” should be included in technical studies of tests and reviews of test material (3.3). An important concept described in this cluster is *universal design* (3.1), a test development process that “emphasizes the need to develop tests that are as usable as possible for all test takers in the intended test population, regardless of characteristics such as gender, age, language background, culture, socioeconomic status, or disability” (AERA et al., 2014, p. 57). (Further discussion of universal design appears in the section “Fairness of Test Content.”)

Cluster 2 asserts the importance of investigating reasons for subgroup mean differences, with an eye toward determining whether construct-irrelevant factors could be responsible (3.6), notes that studies of differential prediction should be conducted where relevant and possible (3.7; see the section “Prediction Invariance” for further discussion), and states that the possibility of biases in human and automated scoring of constructed responses should be investigated (3.8).

Cluster 3 describes the importance of “providing test accommodations, when appropriate and feasible, to remove construct-irrelevant barriers” that otherwise would compromise test takers’ performance (3.9) and the need to monitor and document implementation of any accommodations (3.10) or translations (3.12). When tests are altered to improve accessibility or translated from one language to another, studies should be undertaken to examine the efficacy of the accommodation or translation and to determine whether scores are comparable to those obtained from the original test (3.12, 3.13).

The standards of Cluster 4 state that tests should be used only for subgroups for which sufficient validity evidence exists to support the desired score interpretations while acknowledging that this principle may be superseded by legal requirements in some cases (3.16). When test scores are reported in aggregate form for multiple groups of test takers, evidence should be provided that scores have comparable interpretations across groups. If evidence of this kind is not available, appropriate cautionary statements should be attached to the reports (3.17). In diagnostic settings, test users should not use test scores as the sole measure of an individual’s capabilities; additional factors such as age, culture, and language should be considered (3.18). A key standard appearing in this cluster concerns opportunity to learn (see also the section “Opportunity to Learn”). According to Standard 3.19, when

the same authority [such as a state] is responsible for both provision of curriculum and high-stakes decisions based on testing . . . curriculum mastery, examinees should not suffer permanent negative consequences if . . . they have not had the opportunity to learn the test content. (p. 72)

Despite the expanded treatment of fairness in the 2014 *Standards*, the general perspective—that “the central idea of fairness in testing is to identify and remove

construct-irrelevant barriers to maximal performance” (AERA et al., 2014, p. 63)—has been criticized as being too narrow (Lorrie Shepard, personal communication, February 25, 2019). Shepard, a pioneer in the area of test fairness, takes a broad view of fairness issues, asserting that “equity in assessment requires a validity framework that evaluates whether an assessment system produces its intended positive effects without incurring familiar negative effects on students’ opportunities to learn” (Shepard, 2012, p. 812). She adds that “despite advances in statistical checks and test-making strategies, . . . the more fundamental question persists about when it is appropriate to use fallible tests that affect students’ life chances” (p. 809). (This issue is further considered in the “Summary and Conclusion” section.)

In this chapter, I consider fairness in testing and selection from a somewhat broader perspective than that taken in the *Standards*, devoting more attention to opportunity to learn, selection processes, and alternatives to testing. The *Standards* remains a key resource on test fairness that will continue to be recognized as a representation of the accepted standards among members of the measurement community.

Fairness as Equality of Performance

Outside the measurement community, a common belief is that a fair test will produce equal average test scores for all recognized test-taker groups (Zwick, 2002, 2017a). If average scores are unequal, this is often seen as a sufficient demonstration that the test is unfair. As noted by Zwick (2017a, p. 35), “endorsement of the equal performance principle often takes the form of automatically interpreting any group differences in test scores as a manifestation of unfairness or bias.” Although this view is explicitly rejected by the *Standards* (AERA et al., 2014, p. 54), it has been embodied in court settlements and proposed legislation and featured in countless news articles and testing critiques. An example is a bill introduced in the California Senate in 1998 and 1999 that stated that “a test discriminates . . . if there is a statistically significant difference in the outcome on test performance when test subjects are compared on the basis of gender, ethnicity, race, or economic status” (Hughes, 1998). If the bill had passed, test sponsors could have been fined \$750 per test taker for administering a test that showed performance differences among student groups.

Support for this perspective on fairness stems from well-founded concerns about the pervasive finding of large differences among demographic groups in average scores on standardized tests. On educational assessments, students from high-income families typically score higher, on average, than students from lower-income families, and on many tests, Asian and White students tend to score higher than Black, Latino, and Native American students. Gender differences are found on some tests as well. Clearly, these patterns warrant investigation, including examination of the test’s content and administration procedures for possible sources of bias.

In investigating these score differences, however, it is important to consider that other educational achievement measures often show patterns of performance similar

to those observed for tests. For example, high school grade point averages (GPAs) and college admissions test scores show similar patterns of results across ethnic and socioeconomic groups (e.g., Camara & Schmidt, 1999; Owings et al., 1995). Results from the Education Longitudinal Study, based on a nationally representative sample of the high school seniors of 2004, show that on admissions tests, the difference in average scores between the highest- and lowest-scoring ethnic groups was 1.3 standard deviation units (similar to recent ACT and SAT results) and the difference between the highest and lowest socioeconomic quartile was 1.1 units. The corresponding differences for high school GPA were 1.0 and 0.7. Within each ethnic group, both test score and GPA averages increased with socioeconomic level (Zwick, 2019b). (Technical reasons for the smaller differences on GPA than on test scores include reliability differences; see Zwick & Green, 2007.)

To conclude that these differences in average test scores and grades are in themselves evidence of unfairness would be sensible only if educational opportunities were the same for all groups in question, allowing all students to develop the same level of academic skill. In fact, opportunities and resources vary widely across communities. For example, teacher experience, teacher credential status, and student:teacher ratios vary with family and school-level socioeconomic status (SES; Betts et al., 2000; Organisation for Economic Co-operation and Development, 2010). In addition, childhood poverty rates for Black, Hispanic, and American Indian children in the United States are much higher than those for Asian and White children (National Center for Education Statistics, 2022). Even in kindergarten, ethnic and socioeconomic groups differ in school performance (Lee & Burkam, 2002).

Given these inequities, it would be surprising if educational achievements were equivalent for all student groups. At the same time, the existence of many plausible explanations for group differences should never serve as a reason to assume that tests are blameless.

Fairness of Test Content

Validity theorists such as Messick (1989) and Kane (2006) have noted that content-related evidence has only a limited role to play in test validation. Kane states that evidence that the tasks included in the test are representative of the domain and that the scores are generalizable “can make a basic positive case for the validity of an interpretation in terms of expected performance over some universe of possible performances, but to go beyond that basic interpretation, other kinds of evidence are needed” (2006, p. 19). Just as content evidence alone cannot be sufficient to demonstrate validity, neither can it demonstrate fairness. An evaluation of test content, however, is a crucial first step in assessing test fairness. In fact, test content must be scrutinized throughout the test development process, not merely as part of a post hoc review process.

Basic fairness principles dictate that demographic groups must be referred to using currently accepted terms and must be portrayed in a balanced and respectful way in test questions and reading passages. Many of the principles of universal design

of assessments have implications for test content as well. According to the National Center on Educational Outcomes (2016), “the goal of universal design principles is to improve access to assessments for all students” (para. 1). Noting that “more accessible tests may provide a more accurate understanding of what students know and can do,” the organization developed a list of seven elements of universal design, the first of which is an “inclusive assessment population.” The remaining principles are relevant to test content: The test should be based on precisely defined constructs and should be amenable to accommodations. It should contain accessible, nonbiased items; should feature simple, clear, and intuitive instructions and procedures; and should be designed for maximum readability, comprehensibility, and legibility.

Additional aspects of content fairness are considered in the following sections. The issues of construct representation, sensitive or unnecessarily challenging material, and coachability and vulnerability to compromise are addressed in the sections on “Construct Representation,” “Sensitive or Unnecessarily Challenging Material,” and “Coachability and Vulnerability to Compromise,” respectively. Opportunity to learn—a central issue in certain achievement-based tests—is discussed in a separate section within this chapter.

Construct Representation

As noted in the section “Concepts of Fairness,” the *Standards* (AERA et al., 2014) focuses heavily on the importance of minimizing construct-irrelevant variance in test scores. Ideally, individuals’ scores should not differ as a result of factors that are distinct from the characteristic that the test is intended to measure. In a test meant to assess only computational skills, for example, it is undesirable for test takers’ scores to vary because some have difficulty understanding the vocabulary used in the questions. A key concern is that the inclusion of construct-irrelevant factors may disadvantage certain populations. In this case, for example, English learners could be particularly harmed by the inclusion of difficult vocabulary. Further examples of construct-irrelevant test features are described in the sections on “Sensitive or Unnecessarily Challenging Material” and “Fairness of Test Administration and Scoring Procedures.”

Construct underrepresentation, a phenomenon in which a test fails to include key components of the intended construct, receives far less attention in the *Standards* than construct-irrelevant variance, but can have substantial implications for fairness. Consider the case of an employment test for an administrative assistant position. Suppose that answering phone calls and preparing correspondence are equally important features of the work, but that only keyboarding and English-language writing skills are included in the test. Because a key aspect of job performance—communicating by phone—is omitted, the needed job skills are incompletely represented by the test material. The underrepresentation would be particularly disadvantageous to test takers who excelled at telephone communications but were less skilled at keyboarding because of a disability or were less proficient in writing because they were English learners.

In the case of academic assessments, a key content-related concept is *alignment*. Tests that are designed to assess whether students have learned content that has been specified in curriculum materials are expected to be aligned with that content. These types of exams, such as end-of-year assessments in K–12 education, are expected to sample the prescribed content and to exclude material that was not part of the curriculum. Of course, inclusion in curricular materials is no assurance that material has been taught in a satisfactory way. This issue is discussed further in the section “Opportunity to Learn.”

Sensitive or Unnecessarily Challenging Material

Fairness requires that the content and format of a test not be more challenging for the test taker than required for the test’s purpose. According to the *Standards* (AERA et al., 2014),

Test developers should use language . . . that is consistent with the purpose of the tests and that is familiar to as wide a range of test takers as possible. Avoiding the use of language that has different meanings or different connotations for relevant subgroups . . . will help ensure that test takers . . . are able to understand what is being asked of them and respond appropriately. (p. 64)

In particular, a standard principle of test design is that esoteric or specialized vocabulary, such as military jargon, regionalisms, or terminology specific to U.S. culture, be avoided unless it is important for valid measurement.

More debatable is the idea that, unless they are needed for valid measurement, disturbing or polarizing topics should be excluded as well. The *ETS Guidelines for Developing Fair Tests and Communications*, for example, notes that

construct-irrelevant emotional barriers to success arise when language, scenarios, or images cause strong emotions that may interfere with the ability of some groups of test takers to respond to an item. . . . Test takers may respond emotionally rather than logically to excessively controversial material. (ETS, 2022, p. 24)

Examples of the topics of concern are accidents, illnesses, or natural disasters; advocacy of contested causes or ideologies; death and dying; sexual behavior; and depictions of “situations that are associated with excessive spending on what some members of the test-taking population would consider luxuries” (p. 29). The evolution of human beings, too, is listed as a topic to avoid except on tests in content areas that require knowledge of evolution.

In her 2003 book *The Language Police*, education historian Diane Ravitch expressed concern about the reviews of educational tests and textbooks that are now routine:

The bias and sensitivity reviewers work with assumptions that have the inevitable effect of stripping away everything that is potentially thought-provoking and colorful from the texts that children encounter. These assumptions narrow what children are exposed to, at least on tests and in textbooks. (p. 8)

As suggested by these comments, it is worth considering that rigid adherence to sensitivity guidelines carries its own risks: Test materials could become so bland and uncontroversial that they fail to represent the domain of interest or fail to engage respondents. These situations, like the inclusion of inappropriate material, have the potential to compromise the validity of the results.

Arguing from a perspective entirely different from Ravitch's, Randall (2021) deplored the fact that context "is routinely scrubbed from assessment items in service to a purified construct representation" (p. 82). Contending that "when the context is not clear (or seemingly not present), the implied context, historically, has been whiteness" (p. 83), Randall recommends "reenvisioning construct definition/representation in a way that decenters whiteness and acknowledges the ways of knowing and understanding associated with minoritized individuals as construct relevant, and arguably, construct critical" (p. 89).

This perspective is consistent with earlier literature on culturally relevant teaching and learning (see Ladson-Billings, 1995). Gutiérrez and Rogoff (2003), for example, discussed the importance of individuals' linguistic and cultural-historical repertoires—their "ways of engaging in activities stemming from observing and otherwise participating in cultural practices" (p. 22). They note that "individuals' background experiences, together with their interests, may prepare them for knowing how to engage in particular forms of language and literacy activities [and] play their part in testing formats" (p. 22). In particular, the authors noted that "students who have participated in varying cultural traditions would differ in repertoires for . . . answering known-answer questions [or] analyzing word problems on the basis of counterfactual premises" (p. 22).

In response to recent critiques, the educational measurement field is now undergoing a reconsideration of the historical principles that recommend the minimization of contextual material that is not directly related to the purpose of the assessment.⁵

Coachability and Vulnerability to Compromise

The possibility that some but not all test takers have the opportunity to improve their scores through test preparation programs is frequently raised as a criticism of standardized tests, particularly admissions tests. Although coaching on college admissions tests produces only modest gains on average (see Zwick, 2017a), unequal access to coaching, especially the more expensive forms, constitutes a threat to fairness, compounding the advantages that accrue to students from high-income families, such as better schooling, a wider range of cultural activities outside school, more educated parents, and more favorable environments for completing homework. More broadly, coaching threatens test validity because it can inflate scores without promoting any generalizable gains in knowledge or skills. Although it may be impossible to create a test that is not coachable, the problem of differential access to coaching can be ameliorated. Many testing programs in the early 21st century offer free online test preparation materials. Further improvement could be achieved through the establishment of widely available and inexpensive test preparation programs.

In the case of admissions testing, events that took place in 2019 made it obvious that wealthy families have easier access not only to costly test preparation, but also to opportunities for altering their children's test results that are not available to lower-income families. In a scandal nicknamed Varsity Blues, federal prosecutors charged 50 individuals in a scheme to purchase admission to elite universities. Most of those charged were parents of the applicants (Medina et al., 2019). In some of these cases, hired test takers took admissions tests in place of the actual college applicants; in others, test administrators altered the candidates' test scores. *The Code of Fair Testing Practices in Education* includes in its list of responsibilities of test users the responsibility for "eliminating opportunities for test takers to obtain scores by fraudulent means" (Joint Committee on Testing Practices, 2004, p. 7). Robust test security measures can reduce the likelihood of cheating in standardized test administrations. Reducing the incentive to cheat on tests is a more difficult goal, especially when educational and occupational opportunities are at stake.

Opportunity to Learn

Opportunity to learn is a well-established fairness principle that first received substantial formal consideration in the landmark *Debra P. v. Turlington* (1979, 1984) lawsuit, filed in 1978. In 1976, the state of Florida instituted a high school graduation test called the State Student Assessment Test, Part II (SSAT-II), a multiple-choice assessment of basic math and communication skills. Students were allowed to take the test more than once. After three administrations, the failure rate was 20% for Black students compared to 2% for White students.

The *Debra P.* plaintiffs charged that the SSAT-II was racially biased, that it was administered without sufficient notice, and that it was designed to place Black students in remedial classes. The case led to an examination of the fairness and validity of the test and an investigation of the students' opportunity to learn the material. In particular, how did Florida's history of discrimination and segregation affect Black students' opportunities to learn? More generally, were Florida schools teaching the material included on the SSAT-II?

Through 1967, Florida maintained completely separate school systems for Black and White students, with segregation continuing even longer in some counties. Court transcripts noted that the facilities, curricula, and textbooks for the Black schools were clearly inferior. The court ruled that this "past purposeful discrimination" was perpetuated by the use of the SSAT-II to deny high school diplomas and enjoined the state from using the test for this purpose until 1983. The intention was both to provide for adequate notice to test takers and to make sure that they would have had the chance to complete 12 years of schooling in integrated schools.

In subsequent court proceedings, the state provided results of a study intended to show that Florida students were being taught the material on the test, offered evidence of the remedial support available to those who initially failed the SSAT-II, and presented data on the much-improved pass rates for the class of 1983. A federal appeals court ruled in 1984 that the test could be used to award diplomas.

The *Debra P.* case underscores the fact that an educational test could be well aligned with the intended content domain and could have adequate psychometric properties yet could be unfair for certain purposes because some test-taker groups did not have sufficient opportunity to learn the material. In addition to appearing in Cluster 4 of the *Standards'* fairness principles (see the section "Representation of Fairness in the *Standards for Educational and Psychological Testing*"), opportunity to learn is also central to Standard 12.8 in the section on educational testing and assessment: "When test results contribute substantially to decisions about student promotion or graduation, evidence should be provided that students have had an opportunity to learn the content and skills measured by the test" (AERA et al., 2014, p. 197).

As the *Standards* makes clear, the requirement that test takers have had the opportunity to learn the tested material applies only to particular testing situations—those in which institutionally administered curriculum-based achievement tests are used to make high-stakes decisions about individual students, such as those involving promotion or graduation. The requirement does not apply to other types of assessments, such as licensing tests, employment tests, or diagnostic tests.

Although the opportunity-to-learn (OTL) principle is intended to protect test takers from unfair consequences of test results, Randall (2021) cautioned that, by providing an excuse for group differences in performance, the existence of OTL disparities can be invoked in ways that undermine test fairness rather than support it. She maintained that the OTL concept "has long been used to disregard arguments against the use of particular assessments that have had a historical legacy of privileging whiteness and further marginalizing all others" (p. 86). She argued that OTL should be investigated only after "the assessment itself has been thoroughly interrogated for white-supremacist content and antiracist content moved into its place" (p. 87). Randall's commentary is a reminder of the importance of continuously re-evaluating test fairness principles and incorporating a wide range of perspectives.

Fairness of Test Administration and Scoring Procedures

Even if the test content itself is appropriate to the purpose of the test, administration and scoring procedures may produce construct-irrelevant variance in test scores. These issues are considered in detail by Rodriguez and Thurlow (this volume); only a brief discussion is included here.

In nearly all testing situations, it is undesirable for scores to differ because some test takers are unfamiliar with the computers used to administer the assessment (e.g., see Zwick & Bridgeman, 2014), find the print too small in a test booklet, or are made physically uncomfortable because of the testing conditions. Time restrictions that are not needed for valid measurement may also be an impediment to fairness, particularly for students with certain disabilities, such as attention deficit/hyperactivity disorder. These are examples of test administration factors that can introduce construct-irrelevant variance in test scores.

It is important to recognize that fair testing does not imply uniformity of test content or administration procedures across test takers. An obvious example is the use of testing accommodations. In this context, the departure from uniformity is intended to enhance fairness. Mislevy (2018) elaborated on this principle by introducing the concept of *conditional fairness*, which addresses “principled departures” from uniformity:

Sometimes task situations . . . or evaluation procedures . . . can be adapted to students in principled ways . . . such that even though the procedures are less similar across examinees, the resulting *evidence* is more comparable. (p. 219)

Accommodations intended to reduce or remove construct-irrelevant sources of variance are commonly used for students with disabilities such as blindness, deafness, or attention deficit/hyperactivity disorder. For example, screen reader software that transmits text in the form of synthesized speech may be available to a blind test taker or an assistant may be engaged to read the test material aloud. For test takers with learning disabilities, additional testing time is often requested.

A challenge involved in developing appropriate accommodations is that the construct assessed by the accommodated version of a test may depart from the intended construct. For example, if an assistant provides an oral description of a graph on a math test to a blind test taker, the construct may be subtly altered. It may not be possible to improve accessibility of the test material without modifying the construct. This is an extraordinarily difficult issue to investigate because both the test and the population are different from those in a standard administration. Often, attempts to validate particular test accommodations involve an effort to show that scores on the accommodated test bear the same relationship to other factors (say, course grades) as scores on the unaccommodated version. Research in this area is not always possible, however, because of the sparsity of data for particular combinations of disabilities and accommodations.

The test scoring process can also be a source of construct-irrelevant variance. This can happen, for example, if individuals scoring a test intended to assess students’ abilities to create a coherent and engaging essay are influenced by the students’ handwriting quality. Of course, test scores should not be influenced by any knowledge scorers may have about a test taker’s personality, appearance, classroom behavior, or performance on other tests or activities. Automated scoring procedures that have been developed by maximizing the similarity between automated and human scores (as in the case of automated essay scoring; see Shermis et al., this volume) must be examined to ensure that they have not “inherited” any biases that were present in the human scoring process.

Respectful Treatment of Test Takers

Although considerations of test fairness often focus on equal treatment of population groups, fairness also encompasses some general principles that do not depend on group membership. To take an obvious example, it would be unfair for a test proctor to offer high scores for a price, and this would be true regardless of the test’s purpose or the demographic groups to which test takers belonged.

More generally, fairness in measurement and selection requires that test takers be treated respectfully and impartially and that they be provided with information about the assessment, its scoring criteria, and its intended use, as noted in the *Standards* (AERA et al., 2014, pp. 133–134). As indicated in the *Code of Fair Testing Practices in Education* (Joint Committee on Testing Practices, 2004), “fairness also extends to the accurate reporting of individual and group test results” (p. 2). This same document, developed as a cooperative effort among several professional organizations, points out test users’ obligation to provide timely test results in a comprehensible form, protect scores from unauthorized release, and “avoid using a single test score as the sole determinant of decisions about test takers” (p. 9; see also AERA et al., 2014, p. 198).

The availability of sophisticated technical methods for assessing particular aspects of test fairness should not distract measurement professionals and test users from the importance of respectful treatment of test takers, including adherence to clearly stated procedures, and straightforward communication about the purposes of tests and the meaning of test scores.

Fairness of Remotely Proctored Testing

The COVID-19 pandemic that began in 2020 led to a significant reduction in the frequency of educational testing and major changes in the administration of many tests. Because most school systems in the United States were closed for at least part of the year (Map: Coronavirus and School Closures, 2020), the number of tests administered at the K–12 level was greatly reduced. In addition, the majority of undergraduate institutions (Jaschik, 2020a) and some graduate programs (Hu, 2020) made the submission of admissions test scores optional for applications filed in 2020, decreasing the demand for this type of test. A number of large testing programs, including those offering the Advanced Placement tests, Graduate Management Admission Test (GMAT), Graduate Record Examinations (GRE), Law School Admission Test (LSAT), Test of English as a Foreign Language (TOEFL), HiSET high school equivalency test, and the Praxis tests for those entering the teaching profession, offered candidates the option of taking tests at home (or in another location they selected, such as a workplace or a relative’s home), with remote proctoring.

In remotely proctored testing programs, candidates take the test via the Internet, while being monitored by a test proctoring organization. Typically, the proctoring service installs software on test takers’ computers, preventing the use of software that would facilitate cheating. In addition, test-taker behavior, including unusual movement, is tracked using artificial intelligence approaches. A human proctor may also remotely monitor test takers and their surroundings, using the computer’s audio and video functions, to ensure that test takers are not relying on any collaborators or materials in answering test questions. Video recordings of testing sessions may be made as well.

Although remote testing is a welcome opportunity for many test takers, it brings with it many significant questions about the validity and fairness of this mode of test

administration. To what degree is test accessibility affected by inadequate computer equipment or Internet access, especially for low-income test takers or those from underserved ethnic groups? Are test takers with disabilities able to obtain the accommodations they need for optimal test performance? Are monitoring procedures applied equitably across groups? To what degree are test takers able to evade the proctors and obtain answers from outside sources? And ultimately, how do these factors affect test performance?

Candidates' ability to gain access to the test is a fundamental concern. To be eligible for home testing, the candidate must have a computer that meets certain specifications and must have Internet access. In explaining its decision not to offer an at-home version of the SAT, the College Board cited "concerns that many students would not have access at home to the three hours of reliable Internet service that would be required" (Anderson, 2020). According to 2019 data from the Digest of Education Statistics, 16.8% of individuals of ages 3 and above do not have Internet access at home, and the percentage varies widely over ethnic and income groups. For example, about 15% of Asian and White people are without access, compared to 20% to 23% for those who are Black, Hispanic, or American Indian/Alaska Native. For those with annual incomes of \$150,000 or more, the percentage without access is 8.6, compared to 34% to 35% for those with incomes less than \$20,000 (National Center for Education Statistics, 2020; see also Herold, 2020; Langenfeld, 2020).

Even if candidates have computing facilities that are deemed adequate, those with older computers and weaker Internet access may still be at a disadvantage because of the greater likelihood of disruptions. Test takers who do not have access to a quiet, uncluttered place to take the test may also be unable to perform as well as they would in a test center.

Another significant fairness issue is the availability of testing accommodations for students with disabilities. Certain accommodations that are possible in test centers may not be available in remote testing situations. In a class-action suit against the College Board in connection with its remote version of the Advanced Placement tests, plaintiffs claimed that "questions remained about the availability and applicability of legally required accommodations for students with disabilities" (*Class Action Lawsuit*, 2020). Similar issues were at the core of a complaint filed in connection with *Smith v. Regents of the University of California* (2019), a University of California case involving admissions test use (see the section, *Smith v. Regents of the University of California*). In a press release, attorneys for the plaintiffs stated that

even under normal circumstances, students with disabilities are required to navigate a byzantine set of requirements just to access the tests with the accommodations they need. These students must undergo costly evaluations and, since [University of California] does not require test sites to accept students' accommodations, must search (often in vain) for their own testing locations—all to take tests that have limited, if any, validity for them. This process has become virtually impossible to complete during the pandemic. (*Students Sue to Enjoin*, 2020)

A related issue involves test takers with disabilities who may have conditions that lead to involuntary movements or may engage in repetitive movements to remain alert. Concerns have been raised that these activities could be interpreted as cheating and could lead the proctoring software or a human proctor to trigger an alarm or lock the exam (Patil & Bromwich, 2020).

Another potential problem is that human proctors may apply monitoring procedures in ways that depend on the ethnicity or gender of the test takers. Biases of this kind have been observed in the classroom (The Graide Network, 2018; Rauschenberg, 2014; van Ewijk, 2011) and, of course, in noneducational settings, such as traffic stops. In addition, test-taker reports suggest that proctoring software may sometimes be unable to verify the identity of people of color, making it difficult for them to access their exams (Patil & Bromwich, 2020).

In addition, remote proctoring can be distracting and anxiety producing. Some test takers may be particularly disturbed by the loss of privacy (Langenfeld, 2020; Patil & Bromwich, 2020). A complaint filed in 2020 against five proctoring companies stated that “forcibly collecting personal information from test takers, including sensitive biometric data, is inherently invasive” (Chin, 2020), and in 2022, a federal court sided with a university student who argued that the scanning of his bedroom that was required as part of the remote proctoring of an exam was an unconstitutional search (Swaak, 2022).

Yet another issue is test security. Cheating on remotely administered tests may involve the purchase of devices that allow test takers to obtain assistance without alerting the proctoring system or the purchase of test items themselves. Like all test cheating methods, these workarounds are likely to be more easily available to wealthier test takers. Their use compromises the validity and fairness of the tests.

Despite these many challenges, eliminating the opportunity to take tests remotely would certainly be undesirable. Individuals who were required to take tests for admission to educational institutions, employment, professional licensing or certification, or course credit would be severely disadvantaged if these tests were unavailable in any form. A substantial research effort is needed to investigate and address the intertwined issues of technical adequacy, fairness, and privacy that affect remote testing.

LEGAL PERSPECTIVES ON TEST FAIRNESS

Controversies about the fairness of educational tests have frequently landed in the courtroom, sometimes resulting in significant changes in the content and use of tests. Rebell (1989) noted that “courts have had a significant impact on the formulation of public policy issues associated with testing, so much so that it may not be an exaggeration to say that they have become a major public policy forum in this area” (p. 135). Here, I describe four cases, each of which illustrates a key fairness issue: *Golden Rule Insurance Company v. Washburn*, *Association of American Medical Colleges v. Carey*, *Breimhorst v. Educational Testing Service*, and *Smith v. Regents of University of California*. (In addition, *Debra P. v. Turlington*, the landmark case involving opportunity to learn, is described in

the section on “Opportunity to Learn.”) Rebell (1989) and Phillips (2016) provided accounts of many other significant cases.

Golden Rule Insurance Company v. Washburn (1984)

In 1976, the Golden Rule Insurance Company sued the Illinois Department of Insurance in Illinois Circuit Court, charging that a set of employment tests for insurance agents, developed by Educational Testing Service for the department, was biased against African American test takers. The evidence presented was that African American test takers received lower scores on average, making it difficult for them to become licensed insurance agents. The case was notable in that its eventual out-of-court settlement, which occurred in 1984, included a specific set of compulsory procedures for test construction. In selecting items for use in a test form, preference was to be given to those for which the rates of correct response for Black test takers, White test takers, and all test takers combined were at least 40% and for which the rates of correct response for Black and White test takers differed by no more than 15 percentage points. (Formal hypothesis tests were to be used to determine whether these criteria were met.) This approach to test development came to be known as the Golden Rule procedure, a name that unfortunately seemed to suggest that the method was an equitable one. Subsequent court decisions and legislative proposals involving other assessments, such as teacher certification tests, embodied versions of the procedure (Faggen, 1987; Linn & Drasgow, 1987).

In fact, the method was deeply flawed: It de-emphasized the quality and content of the test items and focused instead on the rates of correct response obtained for previous test takers. A flurry of technical analyses showed that using the Golden Rule approach tends to produce tests with low reliability and to eliminate those test questions that best distinguish more proficient test takers from less proficient ones, reducing the validity of the assessment. In addition, the procedure is unlikely to eliminate items that are, in fact, biased and may distort the content of the test (Hackett et al., 1987; Linn & Drasgow, 1987; Marco et al., 1988). Yet another drawback is the fact that, in many cases, eliminating the more difficult test questions excludes those with the smallest group differences, a result contrary to the goals of the settlement (Linn & Drasgow, 1987). In the measurement community, an overriding concern was that the Golden Rule approach implicitly endorsed the idea that performance differences are in themselves evidence of bias (see the section “Fairness as Equality of Performance”).

ETS president Greg Anrig, who had agreed to the settlement, ultimately acknowledged that doing so was a mistake, given the technical concerns and the unanticipated attempts to generalize the approach beyond the tests involved in the litigation (Anrig, 1987a, 1987b). He also presented data seeming to show that the approach did not have the desired effect of increasing the passing rate for Black candidates on the insurance tests (Anrig, 1987b).

A positive effect of the Golden Rule case and its aftermath was the development and implementation of procedures for the detection of item bias (later to be renamed differential item functioning, or DIF) that were easy to use and understand (see Camilli & Shepard, 1994; Holland & Wainer, 1993). These methods, unlike the Golden Rule procedure, involve comparisons of the item performance of groups of test takers who have been matched in terms of the overall proficiency that the test is intended to measure (see the section “Differential Item Functioning”). Although bias-detection procedures had been developed earlier (e.g., Angoff & Sharon, 1974; Lord, 1977), the Golden Rule settlement and its subsequent repudiation spurred the widespread adoption of DIF detection procedures as a routine quality check.

Association of American Medical Colleges (AAMC) v. Carey (1990)

In 1979, New York State passed a law called the Standardized Testing Act, sometimes called the truth-in-testing law or the LaValle law, after the state senator who introduced it. The law required that testing agencies “file copies of test questions and answers with the Commissioner of Education’s office and that students be provided the opportunity to request copies of test questions, correct answer keys, scoring instructions, and their answer sheets” (McAllister, 1991, p. 20). The New York law followed similar legislation passed in California in 1978.

In *AAMC v. Carey*, the AAMC, sponsor of the Medical College Admission Test, sued New York State (whose governor was Hugh Carey) in U.S. District Court in 1980, setting off a chain of legal actions that were not resolved until 1999. The AAMC claimed that the Standardized Testing Act would compel it to quickly deplete the supply of usable Medical College Admission Test questions and that it was in conflict with federal copyright law. The AAMC was granted a preliminary injunction in 1980, exempting it from the law’s provisions. Other testing agencies, including ACT, College Board, ETS, the Graduate Management Admission Council, the Graduate Record Examinations Board, and the Law School Admission Council, initiated voluntary disclosure policies (McAllister, 1991) following negotiations about the number of test forms that needed to be released. In 1990, a federal district judge ruled that the New York law was indeed in direct conflict with federal copyright law and that the state could not compel the AAMC to disclose its test forms. At that point, test sponsors who had been voluntarily complying with the state filed suit, seeking to expand the court ruling and thus exempt themselves from the disclosure requirements (McAllister, 1991). However, the 1990 decision was subsequently overturned and all exemptions from it were withdrawn. After a lengthy period of litigation and negotiation between the state and the testing agencies, the court modified its original order to require that some but not all test forms be disclosed (Phillips, 2016). It was not until 1999 that all test disclosure lawsuits were dismissed (Zwick, 2002).

The suits challenging the truth-in-testing laws present an interesting example of a fairness issue that is not a question of equal treatment of test-taker groups. Instead, the case centers on a very general question of transparency: Do test takers have a right to examine at least some admissions test questions, along with their intended answers? Given the high-stakes nature of admissions tests and their role in distributing a valued asset—access to an educational program—it seems entirely reasonable to grant that right. It is now accepted practice for testing agencies to release a portion of admissions test questions, along with the answers.

Breimhorst v. Educational Testing Service (2000)

In 2000, Mark Breimhorst filed suit against ETS in federal court in California concerning an annotation that accompanied his GMAT score. (ETS was then the sponsor of the GMAT, which is now owned by a separate company.) Because Breimhorst had a disability—he had no hands—he took the test on a computer with a trackball instead of a mouse and was also granted 25% extra time. The notation that appeared with his scores said, “Scores obtained under special conditions” (Phillips, 2016).

The Breimhorst lawsuit sparked an industry-wide reconsideration of the policy of flagging test scores that had been obtained under nonstandard conditions. Flagging policies had long been a source of controversy. Proponents claimed that information about testing conditions was necessary for a correct interpretation of test scores and was also helpful in discouraging those who might request undeserved testing accommodations. Critics argued that flagging was a form of discrimination and that it stigmatized those with disabilities and violated their privacy (Zwick, 2002). The *Standards* acknowledges the difficulty of resolving this issue. According to the 2014 *Standards* (which largely echo the 1999 version in place at the time of the Breimhorst suit),

when there is clear evidence that scores from regular and altered tests or test administrations are not comparable, consideration should be given to informing score users, potentially by flagging the test results. . . . Where there is credible evidence that scores from regular and altered tests are comparable, then flagging generally is not appropriate. There is little agreement in the field on how to proceed when credible evidence on comparability does not exist. (AERA et al., 2014, pp. 61–62)

Despite these ambiguities, ETS agreed, as part of the 2001 settlement of the lawsuit, to discontinue flagging the scores of test takers who received extra time on the GMAT, GRE, TOEFL, and Praxis teacher certification tests. In 2002, after convening an expert panel on the subject, the College Board decided to stop flagging SAT scores obtained under nonstandard conditions and ACT stopped annotating scores obtained with extended-time administrations (Phillips, 2016).

Surprisingly, these flagging issues, which had apparently been resolved by 2002, re-emerged in 2018, when ACT, Inc., was sued by California test takers with disabilities, who claimed that ACT was providing information about their disability status and

test accommodations to colleges (Agrawal, 2020). According to an ACT spokesman, ACT had stopped annotating the test scores themselves with information about testing accommodations following the Breimhorst case, but had continued to relay information to colleges about test takers' disabilities if they had included that information in the survey that accompanies the test registration materials (Gewertz, 2018). The suit also claimed that ACT included test takers' disability status in a database sold to colleges to help them identify recruits. ACT agreed to stop providing all such information to schools and, in 2020, agreed to pay \$16 million to settle the case (Agrawal, 2020).

At the core of the Breimhorst case is the question of whether scores obtained under nonstandard conditions are comparable to those obtained in the usual way. Conducting rigorous research on this question is extremely difficult because there are typically very small numbers of test takers who share a particular disability and a particular type of nonstandard administration. In the Breimhorst case, the court placed the burden of proof on the testing agency to produce evidence that the test taker's scores were not comparable. By contrast, in a somewhat similar and roughly concurrent case, *Doe v. National Board of Medical Examiners* (1999), the court placed the burden on the test taker to show that his score, obtained under nonstandard conditions, was valid (Phillips, 2016). As Phillips noted, the 2014 *Standards* provides some clarity on this issue, stating that it is the responsibility of "test developers and/or users" to obtain and document evidence of the validity of score interpretations when a test is "changed to remove barriers to the accessibility of the construct being measured" (AERA et al., 2014, Standard 3.11, p. 68; see also Standard 9.9, p. 144).

Smith v. Regents of University of California (2019)

In December 2019, Kawika Smith, an African American high school student, along with three other students and six nonprofit organizations, sued the University of California [UC] and its then-president, Janet Napolitano, in California Superior Court, charging that the SAT and ACT, required for UC admission, "are demonstrably discriminatory against the State's least privileged students, the very students who would most benefit from higher education." (A separate case, for which the plaintiff was the Compton, California, school district, was consolidated with the Smith case.) The complaint goes on to say that the

mere presence of the discriminatory metric of SAT and ACT scores in the UC admissions process precludes admissions officers from according proper weight to meaningful criteria, such as academic achievement and personal qualities, and requires them instead to consider criteria that act as a proxy for wealth and race and thus concentrate privilege on UC campuses. (*Smith v. Regents of University of California*, 2019, p. 4)

The Smith lawsuit further claimed that admissions test scores contribute little to the prediction of college performance and that "affluent students can effectively purchase higher scores through expensive private tutoring services" (pp. 5–6).

In May 2020, the UC Regents voted to phase out existing admissions tests by 2025, contrary to the advice of the university's own Standardized Testing Task Force (University of California Academic Senate, 2020). The Regents' action was an endorsement of a recommendation by Janet Napolitano, who cited "the correlation of the SAT and the ACT to the socio-economic level of the student, and in some case[s], the ethnicity of the student" (Wilner, 2020). Test-optional policies, in which applicants decide whether to submit test scores, were to be put in place immediately, to be followed in 2023 by test-blind policies, in which test scores were not to be considered in admissions decisions even when submitted. However, a test-blind policy was initiated sooner than expected after the plaintiffs in the Smith case filed an additional complaint focusing on the inaccessibility of tests to applicants with disabilities because of pandemic-related disruptions. Under these circumstances, even test-optional policies were claimed to be unfair. The court ruled in favor of the plaintiffs and granted a preliminary injunction prohibiting the consideration of admissions test scores at any of UC's 10 campuses (Hoover, 2019; 2020), a decision that was subsequently upheld by an appeals court (Jaschik, 2020b).

A settlement of the Smith lawsuit was reached in May 2021, with UC agreeing to extend its test-blind policy through at least 2025 (*Settlement Agreement*, 2021). Later in the year, UC went a step further, announcing that the university would "continue to practice test-free admissions now and into the future" (Watanabe, 2021), requiring neither the SAT nor any other standardized test of its applicants. This statement appeared to foreclose the possibility, previously raised, that UC would develop a new admissions test.

The crux of the argument in *Smith v. Regents* was that

SAT and ACT scores are largely a proxy for a student's socioeconomic background and race. Instead of measuring students' academic ability or mastery of curriculum, SAT and ACT scores reflect demographic and socioeconomic characteristics like family income, parental education, and race. (p. 4)

The idea that admissions test scores are predictive of college grades only because both test scores and grades are influenced by SES has gained some traction (e.g., Geiser & Studley, 2002; Rothstein, 2004), but has been refuted by recent research. For example, Sackett and his colleagues conducted a series of meta-analyses in which they obtained partial correlations between test scores and subsequent grades, controlling for SES. They found that "across all studies, the admissions test retains over 90% of its predictive power when SES is controlled" (Sackett & Kuncel, 2018, p. 27).

Implicit in the argument advanced in the Smith lawsuit is the belief that a fair test will lead to equivalent performance by all relevant test-taker groups—in this case, groups defined by SES and race. (See the section "Fairness as Equality of Performance" for a discussion of this definition of fairness.) Admissions tests, which do not meet this criterion, are seen as an obstacle to the equitable consideration of college applicants. This perspective has been more widely embraced in the United States as a result of an

increased focus on racism and societal inequities, spurred by recent events. In addition, the coronavirus pandemic has magnified issues of test accessibility because of the closure of many test centers. The confluence of these factors has led to a powerful movement against the use of standardized admissions tests.

Conclusion: Legal Perspectives on Test Fairness

As Rebell (1989) noted more than 30 years ago, it is difficult to neatly summarize the impact of the courts on testing practices. In some cases, judicial intervention “has had the effect of upgrading the general level of psychometric practice throughout the industry,” while in others, judges have “venture[d] onto areas beyond their technical competence, with attendant detrimental results” (Rebell, 1989, p. 161). Rebell stressed the need to promote effective dialogue between the legal and psychometric professions as a way to maximize the chances of positive outcomes. As Phillips (2016) noted, better communication may also increase the chances of resolving issues outside the courtroom.

STATISTICAL PERSPECTIVES ON TEST FAIRNESS: MEASUREMENT, PREDICTION, AND LINKING INVARIANCE

During the civil rights era of the 1960s, the interest in using statistical analyses to aid in investigations of test fairness increased (Cole, 1993). In the early 21st century, statistical checks intended to examine test fairness are routine. In addition to general performance comparisons across demographic groups, these statistical analyses often include investigations of differential validity (e.g., Young, 2004) and DIF (Camilli & Shepard, 1994; Holland & Wainer, 1993). In selection contexts, fairness analyses typically focus on differential prediction of a criterion variable, such as performance in college (Young, 2004; Zwick, 2017a) or in an employment setting. In some testing situations, the factorial structure of tests and, more recently, the functions used to link one test form to another have been compared across groups as well.

Determining which groups should be explicitly considered in analyses of invariance or selection is complex. Historically, analyses of test fairness have focused on women and on racial and ethnic groups that are considered “protected” in the employment setting,⁶ but there is some disagreement about the rationale for focusing on these groups. In the educational research context, membership in particular racial or ethnic groups is sometimes viewed as a proxy for socioeconomic disadvantage (see Dorans & Cook, 2016). Novick and Ellis (1977) argued that, rather than accepting group membership as a surrogate for disadvantage, education and employment selection policies should consider “the explicit identification of those [candidate] attributes that constitute disadvantage” (p. 318). Policies that compensate for these disadvantages can then be crafted, they proposed. However, this viewpoint fails to account for the fact that members of some racial and ethnic groups, as well as women, people with disabilities, and members of various other groups, including those defined by age, national origin, language, or religion, may be subject to discrimination in selection

because of their group membership per se. Special consideration of members of these groups may therefore be appropriate even if they have not experienced disadvantage of the sort considered by Novick and Ellis, such as “deprivation of exposure to ‘educated’ persons, economic deprivation, or unstable home environment” (p. 319). The difficulty in determining which groups require special scrutiny in educational testing and selection is evidence of the degree to which values play a role in evaluations of validity and fairness.

In general, the goal of analyses of measurement invariance is to verify that the test “works the same way” for all groups. Statistical analysis results can never be sufficient to demonstrate fairness; other aspects of the testing situation, including test content and administration conditions, and in some cases, opportunity to learn, must be considered as well. Analysis results, however, can serve to bolster the case for a test’s fairness or to provide evidence that the test may not, in fact, be fair.

Some fairness analyses—in particular, DIF and factorial invariance analyses—are best understood from the perspective of measurement invariance. According to Millsap (2011, p. 1), “measurement invariance is built on the notion that a measuring device should function in the same way across varied conditions, so long as those varied conditions are irrelevant to the attribute being measured.” Millsap offers an example from the realm of physical measurement: A weight scale should not yield different results for two objects that have the same weight, but vary in shape—an irrelevant characteristic. A departure from measurement invariance is of particular concern when the irrelevant factor is subpopulation membership. This is reflected in the definition offered by Liu and Dorans (2016), who noted that measurement invariance “refers to the degree to which an instrument measures an entity in the same way across different subpopulations” (p. 84).

Although it may seem to be an aspect of measurement invariance, prediction invariance (i.e., the absence of differential prediction) is best considered a separate phenomenon. As detailed in the “Prediction Invariance” section, a “deep inconsistency” between measurement and predictive invariance can be shown to exist in many plausible situations (Millsap, 2011, p. 299). In the following sections, measurement invariance (including DIF and factorial invariance) is considered first, followed by prediction invariance and linking invariance. Invariance of validity coefficients is discussed in the context of prediction invariance. Examples from the research literature are included to illustrate the kinds of information that these analyses can yield.

Measurement Invariance

The most stringent definition of measurement invariance requires that, for two population groups, G_1 and G_2 ,

$$P(\mathbf{X}|\boldsymbol{\theta}, G_1) = P(\mathbf{X}|\boldsymbol{\theta}, G_2), \quad (1)$$

where $\mathbf{X}$ is a p -dimensional vector random variable consisting of the scores on p observable measures such as test or item scores; $\boldsymbol{\theta}$ is an r -dimensional vector random variable, $1 \leq r \leq p$, representing the unobservable characteristics that the measures are

intended to assess; and $P(A|B, C)$ represents the conditional distribution of A , given B and C . Equation 1 states that the conditional distribution of the observed measurements, given the (possibly multidimensional) target construct, does not vary across groups. As an example, X could represent item scores on the math section of the SAT, θ could be a set of unobservable true math proficiencies (e.g., algebra, problem-solving, and geometry), and G_1 and G_2 could represent native English speakers and nonnative English speakers. If Equation 1 held, that would mean that the distribution of math item scores, given the test takers' true math proficiencies, was the same for these two groups. For simplicity, only the two-group case is described in the sections that follow.

An important assumption in evaluating the plausibility of the hypothesis of Equation 1 is that the conditions of measurement, such as the timing, instructions, and administration mode, are the same for both groups (Dorans & Middleton, 2012). Unless these conditions are the same, any departures from invariance cannot be attributed to group membership per se.

Differential Item Functioning

In a typical DIF analysis, both X and θ in Equation 1 are univariate. X represents an item score and θ is the construct the test is intended to measure, such as math proficiency or knowledge of U.S. history. A separate DIF analysis is conducted for each item.⁷ Only the case of dichotomously scored items is discussed here. DIF analysis methods for polytomous items are discussed by Penfield and Camilli (2007) and Zwirk et al. (1997). For dichotomous items, the purpose of a DIF analysis is to determine whether the probability of a correct response is the same for individuals from two groups who are matched with respect to θ . Typically, only the items on the test itself are available as measures of θ . In essence, then, the item being assessed for DIF—the *studied item*—is scrutinized to determine whether it measures something different from the construct that is assessed by the entire set of test items, considered as a whole. This aspect of DIF analysis—the fact that each item is evaluated with respect to the test as a whole—has been pointed out as a weakness of DIF analysis (e.g., Camilli & Penfield, 2007), and it is indeed true that DIF procedures would not identify any items as problematic if they were all similarly biased. Instead, DIF analyses are useful in identifying items that assess a skill or characteristic that is not the intended target of measurement.

Suppose that some individuals taking an algebra test are English learners, while others are native speakers of English. Most of the test questions contain only equations, but one includes a substantial amount of English text. Assuming that an adequately powerful statistical procedure were used, this item would be found to show DIF that was unfavorable to the English learners under the following conditions: (a) responding correctly to the item required a skill, comprehension of English (say, θ'), that was outside the intended construct, algebra proficiency (θ); (b) this auxiliary skill was not measured by the remaining items on the test; and (c) the conditional distribution of this secondary skill, given the intended construct, differed across the two language groups. That is,

$$P(\theta' | \theta, G_1) \neq P(\theta' | \theta, G_2). \quad (2)$$

(see Millsap 2011, p. 55). Dozens of DIF analysis methods have been developed since the 1970s. (Earlier methods were referred to as *item bias* detection methods. Researchers gradually switched to the more neutral term, *differential item functioning*, to reflect the fact that test-taker groups could differ in their conditional item performance for many benign reasons, such as differences in interests or in course background.) A key dimension on which these DIF methods vary is the manner in which the construct of interest is measured for purposes of matching test takers. Some methods are based on particular item response theory (IRT) models and involve attempts to compare the item performance of two groups, conditional on θ , the unobserved construct assessed by the test. Others match test takers on observed test scores and do not require any assumptions about the form of the item response function.⁸ The main categories of DIF methods currently in use are briefly outlined here and some key issues in DIF analysis are considered. The required computations are described by Camilli (2006), Millsap (2011), and Penfield and Camilli (2007).

In the case of dichotomous item i with score X_i , the hypothesis of interest in DIF analysis takes the form of Equation 1. More specifically, the hypothesis is

$$\Pr(X_i = 1 | \theta, G_1) = \Pr(X_i = 1 | \theta, G_2) \text{ for all } \theta, \quad (3)$$

where $X_i = 1$ indicates a correct score and $X_i = 0$ indicates an incorrect score. Equation 3 states that the probability of correct response is the same for the two groups at all θ levels; that is, the item response functions for Groups 1 and 2 are identical. This is Lord's (1980) definition of the absence of item bias. In terms of the earlier example, the hypothesis in Equation 3 would be satisfied if, at every level of algebra proficiency (θ), the native and nonnative English speakers had the same probability of correct response on the item.

One way to test the hypothesis in Equation 3 is to use likelihood ratio tests to compare the fit of competing IRT models (Thissen et al., 1993). A specific IRT model (ordinarily a logistic or normal ogive model) is assumed to hold. All items except the studied item are assumed to be free of DIF and therefore to have item parameters that are common across the two groups. Then the fit of a model that constrains the item parameters for the studied item to be the same for the two groups is compared to the fit of a model that does not include those constraints. If the less-constrained model fits better to some pre-determined degree, the item is assumed to have DIF. Other IRT-based methods include graphical comparison of the item response functions of the two groups and evaluations of the area between the item response functions.

The most widely used observed-score approaches for DIF detection are the Mantel-Haenszel (MH; Holland & Thayer, 1988; Mantel & Haenszel, 1959), standardization (Dorans & Kulick, 1986), and logistic regression (Swaminathan & Rogers, 1990) methods.⁹ The MH and standardization statistics are computed based on a $2 \text{ (groups)} \times 2 \text{ (item scores)} \times K$ contingency table, where K is the number of levels of the total

test score, $S = \sum X_i$. The importance of including the studied item when computing S is discussed by Holland and Thayer (1988) and Zwick (1990). It is important that the matching variable be free of any DIF items (other than possibly the studied item). Therefore, in MH and standardization DIF analyses, it is common practice to use a refinement procedure (see Zwick, 2012). This involves conducting a preliminary analysis to identify any DIF items on a test. These items are then removed from the matching variable, with the exception that the score on the studied item must always be included. When refinement is used, S is redefined as the sum of the scores on all DIF-free items on the test, plus the score on the studied item.

In both the standardization and the MH procedures, the difference between the studied item scores of the two groups, conditional on S , can be tested for statistical significance. The standardization-based DIF statistics, however, are often used purely for descriptive purposes (Zwick, 2012). The most frequently used effect size measure associated with the standardization approach is the difference between the observed proportion of correct responses on the studied item for the group of primary interest (say, Group 1) and the predicted proportion of correct responses that would have been attained by Group 2 if its distribution on S had been the same as that of Group 1 (Dorans & Kulick, 1986). The MH method yields an effect size measure that is based on the ratio of the odds of getting the item right for Group 1 to the odds for Group 2, conditional on S ; it is an assumption of the MH approach that this odds ratio is constant over all levels of S . A system for classifying DIF severity into three levels, labeled A (negligible), B (slight to moderate), and C (moderate to large), was developed at ETS and is now widely used. The criteria for classifying items are based on statistical significance tests in combination with effect size measures (see Zwick, 2012, pp. 3–5).

The logistic regression approach to DIF detection involves fitting a model to predict the item score, X_i , in which the predictors are S , G (group membership), and the $G \times S$ interaction. If the interaction exceeds a criterion value, indicating that the predictive value of S varies across groups, the item is judged to have DIF. The logistic regression approach can yield effect size measures as well (Penfield & Camilli, 2007).

Observed-score DIF methods like the MH, standardization, and logistic regression test a hypothesis that can be viewed as an approximation to the hypothesis in Equation 3. Specifically, they test the hypothesis that two groups are equally likely to answer an item correctly, conditional on test score S :

$$\Pr(X_i=1|S, G_1) = \Pr(X_i=1|S, G_2) \text{ for all } S. \quad (4)$$

Except in special circumstances, the hypotheses in Equations 3 and 4 are not equivalent. That is, test takers who are matched in terms of total score S will not, in general, be matched on θ . Suppose that Group 2 has a lower mean on θ than Group 1, that is, $E(\theta|G_2) < E(\theta|G_1)$, and that test reliability is the same for the two groups. Then, under the assumptions of classical test theory, $E(\theta|S, G_2) < E(\theta|S, G_1)$. Only when S is a sufficient statistic for θ does this matching problem disappear.¹⁰ Sufficiency occurs for the Rasch model (and the partial credit model, in the case of polytomous items),

but not for other common IRT models (Holland & Thayer, 1988; Zwick, 1990; Zwick et al., 1997). The higher the reliability of S , the smaller the practical effect of the difference between the hypotheses of Equations 3 and 4.

Another well-established DIF detection method, the SIBTEST procedure (Shealy & Stout, 1993), is neither an IRT-based method nor, strictly speaking, an observed-score method. It can be applied to a single item or to a set or “bundle” of items. When applied to one item, it is similar to the standardization approach except that it includes an adjustment to the matching variable that is intended to avoid errors in matching caused by measurement error in the observed score.

A DIF ANALYSIS EXAMPLE In an early application of the MH DIF method, Zwick and Ercikan (1989) analyzed U.S. history items that were administered to a nationally representative sample of 11th graders as part of the National Assessment of Educational Progress (NAEP) in 1986. More than 7,000 students took one of four history blocks, each consisting of 34 to 36 items. In the initial analyses, test takers were matched on their number-right scores on the history blocks to which they responded; subsequent analyses also took into account students’ course background in history. Here, we consider only the items that showed moderate to large DIF—C items in the ETS classification—in the initial analyses that compared Hispanic and Black test takers, respectively, to White test takers. In the Hispanic–White comparison, the only C item, which was differentially easier for Hispanic test takers, was about Latin American and Asian immigration to the United States. The Black–White comparison yielded three C items favoring Black test takers; the topics were Martin Luther King, Harriet Tubman, and the Underground Railroad. In neither of these analyses was there any C item that was differentially easier for White test takers. These DIF findings lend themselves to at least two possible explanations. One is that White students were less likely to have attended history classes that included the topics in question or to have learned the material outside school; the other is that these topics were of less interest to White students than to Hispanic and Black students with the same number-right score, leading to inferior performance.

These results illustrate why a policy of simply deleting all items that show DIF would be unwise. The DIF items in the U.S. history assessment addressed topics that were clearly part of the intended construct; the DIF was probably caused by differences in exposure to the material or in prior knowledge or interests. In typical assessment programs, items found to have DIF are reviewed by subject area experts from diverse backgrounds to determine whether item responses are likely to have been affected by some construct-irrelevant factor. If the review takes place during a pilot test phase, items can be revised or simply eliminated.

In most instances, the reasons for DIF findings are far less apparent than in the NAEP example. However, in studies conducted in the late 1980s and early 1990s, certain patterns emerged. For example, DIF favoring men was found on items about scientific topics, sports, and military activities, while DIF favoring women was found on questions about human relationships and the arts (see Zwick, 2002). The associations between

test content and DIF that were observed in these early studies had an impact on test development practices (Zieky, 1993) and on the sensitivity review procedures that are now routine practice at testing companies (see Ramsey, 1993). Whether these patterns would hold today is an open question. Little research of this kind has been conducted in recent years.

Although the vast majority of DIF research has been observational in nature, Schmitt et al. (1993) pointed out that more useful information can be obtained from randomized DIF studies that involve items specially constructed to test particular DIF hypotheses. In one such study, for example, Schmitt et al. (1988) found convincing evidence that *true cognates*—in this case, English words that were similar to Spanish words with the same meaning—facilitated the performance of Hispanic test takers. In particular, “the true cognates that consistently made the items differentially easier for Hispanics were words with a higher frequency of usage in the Spanish language” (Schmitt et al., 1993, p. 301).

Factorial Invariance

In educational testing, analyses of factorial invariance are far less common than DIF analyses, which are now considered standard quality-control procedures. Analyses of factorial invariance are more likely to be performed in the fields of intelligence and personality testing or in other areas in which a particular factor structure has emerged from psychological theory.

In analyses of factorial invariance, both $\mathbf{X}$ and $\boldsymbol{\theta}$ in Equation 1 are multivariate and continuous. $\mathbf{X}$ is a $p \times 1$ vector of item or subtest scores, and $\boldsymbol{\theta}$ is an $r \times 1$ vector of scores on the latent common factors assumed to underlie these scores. Here, we assume $r < p$ (i.e., a strict inequality holds). In the simplest case, $\mathbf{X}$ is assumed to be related to $\boldsymbol{\theta}$ through a linear factor model within each group:

$$\begin{aligned}\mathbf{X} &= \boldsymbol{\tau}_G + \boldsymbol{\Lambda}_G \boldsymbol{\theta} + \mathbf{U}, \\ E(\mathbf{X}|\boldsymbol{\theta}, G) &= \boldsymbol{\tau}_G + \boldsymbol{\Lambda}_G \boldsymbol{\theta}, \\ \text{Cov}(\mathbf{X}|\boldsymbol{\theta}, G) &= \text{Cov}(\mathbf{U}|G),\end{aligned}\tag{5}$$

where $\boldsymbol{\tau}_G$ is a $p \times 1$ vector of latent factor intercepts for group G , $\boldsymbol{\Lambda}_G$ is the $p \times r$ factor pattern matrix for group G , and $\mathbf{U}$ is a $p \times 1$ vector of scores on the p unique factors. The unique factors are assumed to be uncorrelated with the common factors $\boldsymbol{\theta}$ and with each other. $\text{Cov}(\mathbf{U}|G)$ is a diagonal matrix whose elements are the p variances of the unique factors in group G . The factor model in Equation 5 says, in essence, that the observed test scores can be expressed as a weighted sum of the underlying factors, plus an intercept term and a residual term. For example, $\mathbf{X}$ might contain scores on a set of math tests and the factors $\boldsymbol{\theta}$ might correspond to broad areas of mathematical proficiency such as algebra, geometry, trigonometry, and calculus.

Under the assumption that $\mathbf{X}|\boldsymbol{\theta}$ is multivariate normal, the following two conditions are sufficient to establish measurement invariance in the two-group case (Millsap, 2011):

$$\begin{aligned} E(\mathbf{X}|\boldsymbol{\theta}, G_1) &= E(\mathbf{X}|\boldsymbol{\theta}, G_2) \\ \text{Cov}(\mathbf{X}|\boldsymbol{\theta}, G_1) &= \text{Cov}(\mathbf{X}|\boldsymbol{\theta}, G_2) \end{aligned} \quad (6)$$

It is not necessary to assume that the common factor means and covariance matrices are invariant across populations; the invariance property applies to the conditional distribution of the observed variables $\mathbf{X}$, given $\boldsymbol{\theta}$.

If multivariate normality does not hold, additional conditions may be needed to establish the most stringent type of factorial invariance because higher order moments of the conditional distributions of $\mathbf{X}$ given $\boldsymbol{\theta}$ may differ across groups even when the conditions of Equation 6 hold. Weaker forms of factorial invariance, which do not require identity of the conditional distributions, are described by Millsap (2011) and Liu and Dorans (2016). Statistical techniques used to investigate factorial invariance include exploratory and confirmatory factor analysis and structural equation modeling.

A FACTORIAL INVARIANCE STUDY EXAMPLE An example of a factorial invariance analysis is a study by Chiorri et al. (2016), who sought to investigate the factor structure of the Big Five personality factors (Extraversion, Agreeableness, Conscientiousness, Neuroticism, and Openness to Experience), as well as its invariance across gender. According to the authors, these factors are so well established that they constitute “a universal language in personality psychology” (Chiorri et al., 2016, p. 88). The authors administered a 44-item measure called the Big Five Inventory to a large Italian community sample and then analyzed the results using exploratory structural equation modeling, described as an integration of confirmatory and exploratory factor analysis. They found the expected five-factor structure (although with some minor departures from simple structure, in which each item loads on only a single factor) and determined that the gender comparisons met the invariance criteria of Equation 6. Although measurement invariance does not require that the factor means and covariance matrices be the same across groups, the authors tested these conditions as well. They concluded that the factor covariance matrices, but not the factor means, were the same for men and women. Women scored higher on all factors except Openness to Experience. The authors argued that their methodological approach was an improvement over more traditional confirmatory factor analysis methods and that their study therefore provided more appropriate tests of factorial invariance as well as more reliable evidence of gender differences in the personality factors measured by the Big Five Inventory.

Prediction Invariance

In many contexts, including admissions testing and employment testing, scores are used to predict a criterion measure using linear regression models that take the following form for Group G :

$$\begin{aligned} Y &= \alpha_G + \boldsymbol{\beta}_G' \mathbf{X} + U, \\ E(U) &= 0, \text{ and } \text{Var}(U) = \sigma_G^2, \end{aligned} \quad (7)$$

where Y is a criterion measure (assumed here to be unbiased), α_G is the intercept term, β'_G is a $1 \times p$ vector of coefficients, $\mathbf{X}$ is a $p \times 1$ vector of predictors, U is an error term, and p is the number of predictors. For example, in a typical study of college admissions testing, the predictors $\mathbf{X}$ are admissions test score and high school GPA, the β_G are the weights for combining the predictors, and the criterion Y is first-year college GPA.

Under the linear regression model (which is the only prediction model we consider here), the predicted value of Y , given $\mathbf{X}$, is

$$\hat{Y} = E(Y|\mathbf{X}) = \alpha_G + \beta'_G \mathbf{X} \quad (8)$$

Under prediction invariance,

$$P(Y|\mathbf{X}, G_1) = P(Y|\mathbf{X}, G_2). \quad (9)$$

Equation 9 says that the distribution of Y , given $\mathbf{X}$, is the same across groups. If the regressions were not the same across groups in the college admissions testing example, then the predicted college GPA would, in general, differ for members of Groups 1 and 2 who had the same test score and high school GPA.

Under normality of $Y|\mathbf{X}$, satisfying the invariance condition in Equation 9 requires only that

$$(\alpha_1, \beta'_1, \sigma_1^2) = (\alpha_2, \beta'_2, \sigma_2^2), \quad (10)$$

which means that the intercepts, regression coefficients, and residual variances are the same for Groups 1 and 2. Although some researchers have discussed the importance of equality of the residual variances σ_G^2 (see Einhorn & Bass, 1971; Jensen, 1980), particularly under certain selection rules, most studies of differential prediction focus on the less stringent requirement that

$$(\alpha_1, \beta'_1) = (\alpha_2, \beta'_2), \quad (11)$$

which Millsap (2011) called regression invariance.

Regression invariance is at the root of one of the most commonly invoked definitions of bias in the field of educational measurement and statistics. Drawing on a principle suggested by Humphreys (1952), Cleary (1968) stated in a now-classic article that

[a] test is biased for members of a subgroup . . . if, in the prediction of a criterion for which the test was designed, consistent nonzero errors of prediction are made for members of the subgroup. . . . The test is biased if the criterion score predicted from the common regression line is consistently too high or too low for members of the subgroup. With this definition of bias, there may be a connotation of "unfair," particularly if the use of the test produces a prediction that is too low. If the test is used for selection, members of a subgroup may be rejected when they were capable of adequate performance. (p. 115)

The *Standards* includes a similar statement but departs from Cleary's viewpoint in that it does not identify differential prediction as evidence of test bias:

The term *predictive bias* may be used when evidence is found that differences exist in the patterns of associations between test scores and other variables for different groups, bringing with it concerns about bias in the inferences drawn from the use of test scores. (AERA et al., 2014, p. 51)

This distinction reflects the fact that factors other than test bias may produce departures from regression invariance. It is well known, for example, that measurement error in the predictors can lead to violations of prediction invariance (e.g., see Linn & Werts, 1971). Suppose a test score X , which is a measure of θ , is used to predict Y for two groups of test takers. If X is not perfectly reliable and if the groups have different means on θ , then members of the two groups who are matched on X are not, in fact, matched on θ . These errors in matching, analogous to those described in the section on DIF, will generally cause the observed-score regressions to differ even when the regression of Y on θ is the same for all groups. In fact, measurement error in the predictors can fully explain the overprediction of the criterion variable for lower scoring groups, a phenomenon that has been replicated consistently in the testing literature since the 1970s. In particular, it is frequently found that when admissions test scores and high school GPA are used to predict college GPA, the use of a single regression model will result in predicted college GPAs that, on average, exceed the actual college GPAs for Black and Latino students, a result that many outside the measurement community find surprising. (Factors other than measurement error, such as quality of previous schooling, may contribute to this recurrent pattern as well; see Zwick, 2002, 2017a; Zwick & Himelfarb, 2011).

Model underspecification can also lead to differential prediction. The admissions literature again serves as a useful example. The prediction models applied in most admissions research typically include only admissions test scores and previous grades as predictors because these are the factors most often used by postsecondary institutions. The existence of other important predictors of college GPA that have distributions that vary across groups (conditional on the included predictors) will produce violations of regression invariance (Linn, 1973; Linn & Werts, 1971) in these sparse models. In addition, regression models that are identical in the population can be rendered unequal via selection, and different regressions can be rendered equal (Linn, 1984). Finally, the criterion variable Y could itself be biased (Linn, 1973), causing the regressions to differ, although we have assumed that is not the case in this section.

How does prediction invariance differ from measurement invariance? To illustrate the inconsistency between these two phenomena, Millsap (2011, pp. 285–300) reformulated the regression parameters (Equation 10) in terms of the parameters of factor models in which X and Y are considered jointly (i.e., in the model of Equation 5, Y is treated as though it is an additional X variable). He began with the case in which a single factor underlies (X, Y) . Among his conclusions are the following: When factorial invariance (Equation 6) holds and there are no group differences in common factor variances, slope invariance will hold but intercept invariance will not: $\beta'_1 = \beta'_2$, but $\alpha_1 \neq \alpha_2$. The predictive bias in this situation will penalize the higher scoring group if a common regression equation is used for prediction. Conversely, it is possible

for regression invariance to hold when measurement invariance is violated. Millsap showed that these types of inconsistencies are not anomalies, but can occur under very general conditions. That is, “the presence or absence of group differences in regression intercepts is not diagnostic for the presence or absence of measurement bias” (Millsap, 2011, p. 291). He recommended that latent variable models be used to explore the causes of both measurement and prediction invariance (see, e.g., Culpepper et al., 2019).

EXAMPLE OF A PREDICTION INVARIANCE STUDY In a study of about 8,000 high school sophomores who participated in the High School and Beyond survey, Zwick and Sklar (2005) investigated the degree to which prediction of first-year college GPA varied across four student groups that were based on ethnicity and first language (Black/English, Hispanic/English, Hispanic/Spanish, and White/English). The strategy followed, which was based solely on observed scores, is sometimes called moderated multiple regression (e.g., Millsap, 2011). It involves fitting a series of nested regression models. The first model, Model 1, included only the two academic predictors, high school GPA and total SAT score. Model 2 added indicators for group membership, and Model 3 added all two-way interactions between group membership and the academic predictors.

Model 1 provides a test of whether the academic predictors contribute to the prediction of college GPA (Zwick & Sklar, 2005). Assuming Model 3 does not subsequently produce a statistically significant increase in the value of R^2 (which measures the degree of association between GPA and the predictors), Model 2 provides a test of the hypothesis of equal intercepts across groups, the hypothesis of greatest interest in analyses of this kind. Model 3 provides a test of whether the strength of the relationship between college GPA and the two academic predictors varies across groups—a test of equal slopes. (If there is evidence of different slopes, the test of equal intercepts is not meaningful.)

The Model 1 results showed that both academic predictors were statistically significant, jointly producing an R^2 value of .22, which indicates that 22% of the variability in college GPA was accounted for by these predictors (Zwick & Sklar, 2005). The R^2 obtained for Model 2 showed a statistically significant increase from the value obtained for Model 1, but the Model 3 R^2 was not statistically different from the value obtained for Model 2. Therefore, the Model 2 results could legitimately be interpreted as a rejection of the hypothesis of equal intercepts. In particular, the study found that the Black/English group had a lower intercept than the White/English group, which served as a reference group. This means that a member of the Black/English group would have a lower predicted college GPA than a member of the White/English group with the same high school GPA and SAT score. A regression equation based on both groups combined would overpredict the college GPAs of the Black/English group. There was no statistically significant evidence of intercept differences for the two Hispanic groups.

DIFFERENTIAL VALIDITY Differential validity analyses involve the comparison of validity coefficients (test-criterion correlations) across groups (e.g., Young, 2004). These analyses will not necessarily yield the same conclusions about invariance as differential prediction analyses because identity of regressions does not in general imply identity of correlations, nor does identity of correlations imply identity of regressions.¹¹ Because of its implications for selection in some admissions and employment testing situations, prediction invariance is arguably more relevant to fairness than is invariance of validity coefficients. Nevertheless, it is generally of interest to assess the magnitude of the test-criterion correlations across key demographic groups, and this information is typically included in technical documentation for tests. The *Standards* indicates that test developers “should include relevant subgroups in validity, reliability, precision” and other studies and that “if sample sizes permit, it is often valuable to carry out separate analyses for relevant subgroups of the population” (AERA et al., 2014, p. 64).

Linking Invariance

On tests for which multiple forms exist, linking procedures must be used to ensure that scores on the alternate versions can be used interchangeably. Linkages also come into play when scores on one test may be substituted for scores on another. For example, in the case of the ACT and SAT, both used in college admissions, university officials are interested in knowing how scores on the two tests are related. When linkages must be established among different tests or test forms, the question of whether linking functions are invariant across groups becomes relevant.

Linking invariance differs from both measurement invariance and prediction invariance. Borrowing the notation used by Liu and Dorans (2016), linking invariance holds if

$$L(Y \leftarrow X|X, G_1) = L(Y \leftarrow X|X, G_2), \quad (12)$$

where X and Y represent the scores on two tests or two versions of a single test. Equation 12 says that the function used to link X to Y is the same for Groups 1 and 2.

Kolen (2004) reviewed the literature on population invariance in equating and linking, which dates back to the 1950s. (Equating is a particular kind of linking in which the various versions of a test have been developed using the same content and statistical specifications; see Dorans & Holland, 2000, for further detail.) His conclusion was that equating theory, “in combination with empirical research suggests . . . that when alternate test forms are constructed so that they are very similar in content, difficulty, and reliability, population invariance holds approximately” (Kolen, 2004, p. 11). However, invariance cannot be assumed to hold; it must be investigated for each linkage and test-taker group.

Dorans (2004) recommended that linking invariance be assessed as a routine component of fairness analysis for tests that exist in alternate forms. Dorans and Holland (2000) proposed two indexes that could be used to assess the degree to which a set of linking results departed from invariance. One is a root-mean-square

difference (*RMSD*) measure that is computed for each value of Y . The *RMSD* is computed by first obtaining the squared difference between the results of applying each subpopulation linking function and the overall population linking function at $Y = y$. The square root of the weighted sum (over subpopulations) of these squared differences is obtained and then divided by the population standard deviation of X . The second index, called the root expected-mean-square difference (*REMSD*), is obtained by averaging the *RMSD* values over the distribution of Y before taking the square root. This yields an overall summary measure of the departure from linking invariance. Additional indexes are discussed by Liu and Dorans (2013). In general, the linking functions for particular groups are compared to an overall (population) linking function. Departures from invariance are then evaluated to determine whether they are practically meaningful.

EXAMPLE OF A LINKING INVARIANCE STUDY As an illustration of linking invariance analysis, Dorans and Holland (2000) studied the invariance of several ACT–SAT linkages over gender groups. (In this analysis, the linking functions for men and women were compared; a population linking function was not obtained.) Under the parallel-linear linkage models used in this analysis, the *RMSD* does not vary over values of Y and, therefore, the *REMSD* and *RMSD* statistics are equivalent. Of particular interest is the linkage between the ACT Composite score and the sum of the SAT Verbal and Math scores ($SAT\ V + M$), which had a correlation of .916. For assessing invariance over gender groups, the *RMSD* was found to be 5.4% of a standard deviation unit. This translated to 0.3 points on the ACT Composite scale and 10.5 points on the $SAT\ V + M$ scale, which Dorans and Holland judged to be small deviations. For the linkage between the math sections of the ACT and SAT, which had a correlation of .892, the *RMSD* was found to be even smaller, at 1.5% of a standard deviation unit. By contrast, the *RMSD* for the linkage between the ACT English and SAT Verbal sections, which had a correlation of .83, was much larger, at 7.4%. Dorans and Holland stressed that these *RMSD* values pertained only to invariance over gender groups and that there could be “other subgroups that will exhibit even larger linear linking function differences than those for males and females” (p. 296). It is important to note that linkages between different tests (e.g., the ACT and the SAT) are likely to result in larger departures from linking invariance than linkages among forms of a single test.

SELECTION FAIRNESS

Fairness in selection, which is relevant mainly in admissions and employment contexts, is a complex topic because selection decisions typically involve not only test scores, but also additional characteristics or accomplishments of the candidates. Decisions may also depend on policies imposed by governments or institutions. In addition, selection processes may involve predictions of future performance.

Regression models such as those discussed in the section on “Prediction Invariance” often play a role in the process of selecting candidates for employment and for admission to higher education. As noted in that section, determining whether regressions are invariant across groups is not a straightforward process because of the impact of measurement error, omitted predictors, and selection effects. In the decade following the publication of Cleary’s (1968) landmark article, a host of “culture-fair” selection procedures were proposed as alternatives to the regression approach. It is notable that this area of study was motivated by an openly stated belief that the use of standardized tests was in some sense unfair. In the lead article of a special issue of *Journal of Educational Measurement* devoted to this topic, Petersen and Novick (1976, p. 3) noted that the goal of this area of study was to “eliminate cultural or racial unfairness arising from the use of tests” in selection.

Detailed reviews of the selection fairness research published during this time appear in Camilli (2006) and Petersen and Novick (1976); here, I briefly review some of the key contributions. It is assumed that two groups of test takers, one of which is at risk for being treated unfairly, are given a test that is intended to predict success on a criterion measure, such as job performance or grades earned in higher education. In the literature of the time, the groups were often labeled “minority” and “majority” and the minority group was assumed to have lower averages on the test and the criterion measure. Success on the criterion was typically conceptualized as performance exceeding a particular value. Each fairness method provided a way of determining what cut scores should be used on the test for selection purposes.

Einhorn and Bass (1971) recommended that each group’s cut score be chosen so that the risk of failure on the criterion at the cut score is the same across groups. Even if the two groups have identical regression slopes and intercepts, resulting in fair selection according to Cleary’s definition, selection is unfair according to Einhorn and Bass if the two groups have different residual variances. That is, the invariance condition in Equation 10, not merely the condition in Equation 11, is claimed to be necessary for fair selection.

Robert Thorndike (1971) demonstrated that a selection rule that is fair according to the Cleary model will generally be unfair to the lower scoring group “in the sense that the proportion qualified on the test will be smaller, relative to the higher-scoring group, than the proportion that will reach any specified level of criterion performance” (p. 63). He proposed a *constant ratio model*, which requires that cut scores for each group be chosen so that the ratio of the proportion selected to the proportion successful on the criterion is the same across groups. It is possible for a selection rule that is biased under the Cleary model to be fair according to the Thorndike model. If the distribution of the criterion measure differs across groups, the two models will agree that a selection rule is fair only if the two groups have the same regression slopes and intercepts and the test has perfect validity (Petersen & Novick, 1976).

Cole (1973) suggested that, in evaluating fairness, the focus should be on the conditional probability of selection, given success on the criterion. According to Cole,

[the] basic principle of the conditional probability selection model is that for both minority and majority groups whose members can achieve a satisfactory criterion score . . . there should be the same probability of selection regardless of group membership. (p. 240)

Some models proposed during the culture-fair selection era required the user to assign numerical values to particular outcomes based on their perceived desirability from a social justice perspective. For example, Darlington (1971) developed a framework involving three variables—a predictor, a criterion, and a group membership variable. He proposed a selection model that would require the user to specify, in quantitative terms, the value of choosing individuals from particular cultural groups. Darlington's model would, in effect, "add a specified number of points to the [predictor] scores of one subpopulation and then use the same predictor cut score" for all groups (Petersen & Novick, 1976, p. 23).

Another type of selection model that requires the user to assign values to outcomes based on social justice principles is the decision theory approach proposed by Gross and Su (1975) and Petersen (1976). Petersen assumed that minority and majority group members are to be considered for selection based on a test score, and "qualified" candidates are those who have the potential to be successful. Utility values are assigned to each possible selection decision (e.g., "accept a qualified candidate who is a minority group member"), with higher values representing more desirable outcomes. Principles of decision theory are then used to calculate the cut scores for each group that maximize the expected utility.

None of the fairness models put forward during the 1970s was widely applied outside the research community. The proposed selection procedures were controversial—as they would be today—because they embodied particular social justice goals and required that, in order to promote these goals, qualifying scores on selection measures be allowed to vary across demographic groups. Today, any such methods would be prohibited in the employment context because of a provision in the Civil Rights Act of 1991 that states that it is

an unlawful employment practice for a respondent, in connection with the selection or referral of applicants or candidates for employment or promotion, to adjust the scores of, use different cutoff scores for, or otherwise alter the results of employment related tests on the basis of race, color, religion, sex or national origin. (Civil Rights Act, 1991, Title VII)

The selection methods proposed in the 1970s had a further drawback that compounded any possible political or philosophical objections: The techniques were complex and, in some cases, internally contradictory in the sense that reformulating them in terms of the proportions of individuals rejected, rather than the proportions selected, led to different selection rules (Petersen & Novick, 1976). As Cole stated in 1981, "the large amount of technical work on bias in the last 15 years cannot be said

to have significantly clarified the public controversies or to have resolved many issues associated with bias in the public mind” (p. 1067).

Despite the failure to produce a consensus about the meaning of fairness or to improve communications with the public on this topic, the focus on statistical approaches to fairness during this period did have a positive effect: It led to creative thinking about the ways in which statistical analyses can be used to support investigations of equity. Partly as a result of the research conducted during this period, examinations of differential prediction, differential validity, and DIF are now widely regarded as necessary steps in evaluating fairness in measurement and selection.

More recently, researchers have proposed additional ways of using test scores in higher education admissions that are intended to mitigate any possible negative effects on disadvantaged applicants, though most of these methods have been applied only in a research setting. An approach that attracted media attention in the late 1990s was the Strivers method, developed by an ETS vice president. It was described as a way to identify “students who score better than expected on SATs, given their economic and social backgrounds,” with the goal of awarding them “extra credit” (Carnevale & Haghighat, 1998, p. 123). A candidate’s SAT score was predicted using a regression analysis in which the predictors were socioeconomic factors, such as parents’ income and education and school quality. Candidates whose actual SAT scores exceeded their predicted scores by more than 100 points were considered strivers. After the idea was publicized, controversies quickly erupted, and the method was never implemented. Regression-based approaches in the same spirit had been proposed much earlier (Manning, 1977); others appeared later (Gaertner & Hart, 2013; Studley, 2004; Young & Johnson, 2004).

Indexes of disadvantage have also been proposed as ways of providing context for test scores (Bastedo et al., 2021; Blatter & Glynn, 2016; Gaertner & Hart, 2013; Goggin, 1999; Stricker et al., 2002; Zwick et al., 2021), and constrained optimization procedures have been used (mainly in research settings) to maximize the average admissions test scores and grades of the incoming class, while simultaneously imposing requirements on class composition (e.g., Durán & Wolf-Yadlin, 2011; Kreiter et al., 2003; Pashley & Thornton, 1999; Zwick, 2020; Zwick et al., 2019; Zwick, 2023).

Finally, test-optional and test-blind admissions programs have been growing in popularity (see Zwick, 2019b). The rationale typically provided for moving to a test-optional policy is that it is expected to increase the diversity of the admitted class. Actual results have been mixed.

SUMMARY AND CONCLUSION

Despite the breadth and complexity of the concept of fairness in testing, it may be possible, at least within the measurement community, to agree on a set of general fairness principles:

- Test takers should be treated respectfully and should be fully informed about the purpose of the test and the ways the scores will be used.
- The test, including its content as well as its administration and scoring procedures, should assess the intended construct; no more, no less.
- Tests should “work the same way” for all groups. More formally, measurement invariance, prediction invariance, and linking invariance should hold. For example, equally skilled students should have equal probabilities of answering a test item correctly, regardless of group membership.
- In determining student promotion or graduation, achievement test results should be excluded from consideration unless all students have had the opportunity to learn the tested material.

Of course, these ideals cannot be met perfectly. Consider an example involving one type of measurement invariance—the absence of DIF. We cannot realistically expect that the hypothesis in Equation 3, representing the identity of item response functions across groups, will be perfectly satisfied for every test item and every pair of groups. The unavoidable challenge in implementing these fairness principles is determining how much of a departure from perfect equality is acceptable.

Because the idea of fairness is far too complex to boil down to a single simple definition, fairness claims about a particular test require much more than a set of statistical analysis results or a brief procedural description. As suggested by Zieky (2016), a fairness argument can be crafted as a component of a larger validity argument. In explaining the concept of argument-based validation, Kane (2006) noted that “the proposed interpretations and uses [of test scores are to be] explicitly stated as an argument, or network of inferences and supporting assumptions, leading from observations to the conclusions and decisions” (p. 17). This argument, once publicized, can be evaluated in terms of its coherence and plausibility.

The purpose of a fairness argument is to “build a chain of reasoning using documented evidence to support the fairness of the intended uses and interpretations of the test scores” (Zieky, 2016, p. 96). The argument should first present the specific claims that are being made about the test’s fairness (e.g., “Appropriate accommodations were provided to test takers when needed, in compliance with fairness guidelines”) and should then lay out the pertinent evidence. Support for fairness claims could include information about the quality of the fairness guidelines used in developing and evaluating the test, the training and experience of the test developers and fairness reviewers, the nature of the test-taker groups used in pilot testing, and the results of any relevant statistical analyses, such as assessments of DIF and differential prediction. A fairness argument could address claims about opportunity to learn as well, by including course descriptions, curricula, and classroom observations that document that the targeted material was in fact, taught.

Ideally, a fairness argument should also weigh the effects of test use against the effects of other methods of assessment or selection. In his treatise on validity, Messick (1989) suggested that the evaluation of testing consequences should include a comparison of

the proposed test use to alternative assessment techniques and policies. In the college admissions setting, for example, this comparison would need to include a consideration of both the advantages and the drawbacks of using high school grades and personal characteristics in admissions decisions (see Zwick, 2017b; 2019b). High school grades reflect 4 years of academic accomplishments and provide indirect measures of characteristics like industriousness and perseverance (Willingham et al., 2002), but grading stringency varies over high schools, courses, and teachers, and the assignment of grades can be inappropriately influenced by factors such as a student's SES, gender, or ethnicity. Personal characteristics like conscientiousness and grit seem relevant to college success, and assessments of these characteristics often display smaller group differences than test scores. However, measuring noncognitive factors accurately and without bias is challenging (Duckworth & Yeager, 2015) and studies have raised doubts about their predictive value (Niessen & Meijer, 2020). In general, alternative admissions criteria have lower reliability than standardized tests and have not been studied as thoroughly. In keeping with Messick's recommendation, the research findings about alternative admissions criteria would be considered in weighing the fairness of admissions testing.

Messick noted that "a particularly powerful and general form of counterproposal is to weigh the potential social consequences of the proposed test use against the potential social consequences of *not* testing at all" (1989, p. 86). This type of consideration, in fact, has contributed to the increase in test-optional college admissions policies, which are typically adopted in the hope that they will facilitate campus diversity. Shepard sees the admissions testing situation this way:

If the correlation [of admissions test scores] with success at Berkeley were .7, then doing without the test information might be unfair to high scorers. But given [the much lower actual correlation] and adverse impact, why NOT do without the test? (Lorrie Shepard, personal communication, August 15, 2020)

Arguing from the opposite perspective, Ebel (1966), who is cited by Messick in this context, speculated that the abandonment of educational tests would lead to dire consequences:

the distinctions between competence and incompetence would become more difficult to discern . . . the encouragement and reward of individual efforts to learn would be made more difficult. . . . Educational opportunities would be extended less on the basis of aptitude and merit and more on the basis of ancestry and influence. (p. 28)

Ebel's views echoed the assertions that were made about standardized admissions tests in the early 20th century. The tests, it was claimed, would lead to the admission of the most talented candidates rather than those from the wealthiest or most influential families.

In the early 21st century, institutions that elect to require admissions test scores do so for a number of practical reasons, which I have summarized in Zwick (2019b):

In predicting college performance, using test scores along with high school grades leads to more accurate results than using grades alone. . . . In addition to their utility in predicting college outcomes, standardized admissions tests allow efficient comparisons of students whose high school grades are influenced by the schools they attended and countless extraneous factors. Test scores can provide a way to evaluate international students, home-schooled candidates, and those with a high school equivalency diploma . . . and can sometimes serve to identify talented students with weak academic records (p. 144).

The never-ending debate about college admissions is an illustration of the fact that there will never be consensus on the definition of test fairness. Any mechanism that plays a role in the distribution of desirable goods will always be the subject of contention. In alluding to the multiple meanings of fairness, the *Standards* notes that “it is possible that individuals endorse fairness in testing as a desirable social goal, yet reach quite different conclusions about the fairness of a given testing program” (AERA et al., 2014, p. 49).

While controversies about test fairness will inevitably persist, they should not be permitted to serve as justification for giving short shrift to fairness issues. Given the sharp inequities in our society, it is essential that test makers and test users work toward promoting tests and testing policies that contribute to the fairness of measurement and selection.

ACKNOWLEDGMENTS

I appreciate the thoughtful reviews provided by Linda Cook, Neil Dorans, Mary Pitoniak, Lorrie Shepard, Frank Worrell, and Michael Zieky.

NOTES

1. There is some disagreement on this point. Some historians include tests given much earlier, during the Han dynasty (206 B.C.E.–220 CE; Webber, 1989).
2. The statistical meaning of bias is not related in any way to fairness. “Any statistic whose mathematical expectation is equal to a parameter $[\mu]$ is called an *unbiased* estimator of the parameter $[\mu]$ ” (Hogg & Craig, 1978, p. 204). Suppose that in a particular population—say eighth graders in the United States—the average score on a test is μ . We can estimate μ by taking a random sample of eighth graders and calculating the sample mean of their test scores, $\bar{X}$. We know from statistical

theory that $E(\bar{X}) = \mu$; that is, the expectation of $\bar{X}$, which is its theoretical average over random samples, is equal to μ . Therefore, we can say that $\bar{X}$ is an unbiased estimate of μ . This tells us nothing whatever about whether the test in question is a fair test.

3. From a practical standpoint, it is necessary to limit the examination of consequences to some degree. For example, it would be neither possible nor desirable to attempt to determine all possible effects of a given selection test throughout the lifetimes of the test takers. The term *proximal consequences* may be useful, although it does not resolve the ambiguity of meaning.
4. The use of the term *construct* in the *Standards* differs from some historical uses. Rather than reserving the term for characteristics that are not directly observable, the *Standards* uses *construct* to refer to “the concept or characteristic that a test is designed to measure” (AERA et al., 2014, p. 11). I adhere to this usage throughout this chapter.
5. For example, in 2022, the National Council on Measurement in Education held a webinar titled *Cultural Relevance Versus Construct Relevance*. The description includes the following: “Traditional assessment practices have suggested that to make assessments accessible to all students, regardless of racial or cultural background, we must remove any construct-irrelevant variable, including culture-specific contextual items, that may unintentionally privilege or hinder performance. However, a growing body of literature calls for the use of culture-specific contextual items, citing that culturally relevant material will increase engagement, interest, and inclusion of marginalized students.” See <https://www.youtube.com/watch?v=bB1FtEJLqAE>. For further discussion, see Walker et al. (2023).
6. A lexicon of Equal Employment Opportunity Program Terminology appearing on a U.S. government website lists the following groups as having “minority” status because of their exclusion from the economy: American Indian or Alaskan Native, Asian or Pacific Islander, Black, and Hispanic. It is also noted that “women are not classified as a minority. However, they have experienced the same kind of systematic exclusion from the economy as the various minorities. Thus, they are considered as having ‘minority status’ as far as the law is concerned” (Equal Employment Opportunity Program, 2021). It should be noted that this lexicon is rendered obsolete by the January 2025 rescission of the Equal Employment Opportunity Act of 1965.
7. Because the DIF analysis for a single test typically involves a large number of hypothesis tests, it is sometimes suggested that multiple comparison procedures, such as the Bonferroni method, be used to control the overall Type I error rate. The opposing point of view, which has largely prevailed, is that Type II errors are of greater concern in the DIF context, implying that the usual concerns about the compounding of Type I error are inappropriate in this case. Surprisingly little discussion has been devoted to this issue.

8. My conceptualization of DIF departs from that of Liu and Dorans (2016, pp. 84–85) in that they view DIF methods based on observed scores as ways of assessing prediction invariance, whereas DIF methods that invoke latent variable models are assumed to assess measurement invariance. I consider all DIF methods to be ways of assessing measurement invariance, regardless of whether the analyses explicitly involve latent variables. The distinction between DIF methods based on IRT models and those based on observed scores is somewhat artificial because the IRT methods must rely on *estimates* of θ (or the distribution of θ) that are themselves based on the observed item scores.
9. Variations of these methods that use scores derived through IRT (e.g., see Zwick et al., 1994) or other alternative scoring techniques have been developed.
10. Informally speaking, sufficiency of S in this case means that the distribution of the item scores, conditional on S , does not depend on θ . That is, θ provides no additional information about the item scores beyond what is contained in S .
11. If $p = 1$ and X and Y have been standardized to have mean zero and variance 1, then a test of differential prediction via regression (see Equation 11) is equivalent to a test of differential validity. This equivalence does not hold for $p > 1$.

Cambium Assessment

The intended audiences for this chapter are students and professionals—both early career and seasoned—engaged in the design and development of educational assessments. The focus of this chapter is the design and development of large-scale interim and summative assessments of educational achievement for which the primary intended purposes are reliable classification of student performance into one of three or more categories, or performance levels, with the intended inferences of what students know and can do with regard to specified learning standards supported by a compelling validity argument. For the purposes of this chapter, we define interim assessments as those that occur multiple times throughout a school year and are used primarily to inform instruction and track student progress. The term summative is used to refer to assessments that occur less frequently, such as once per year, and are used primarily for educational accountability. We believe that the design of educational interim and summative assessments as defined here and with these respective purposes is the same.¹

Since the rise and proliferation of federally mandated end-of-year testing began in 1994 (Improving America's Schools Act, 1994), the educational measurement field has learned a great deal about what is needed to design and develop assessments that are intended to support interpretations about what students know and can do (Ferrara & DeMauro, 2006; Lane et al., 2016; Mislevy, 2006; National Research Council [NRC], 2001; Pellegrino et al., 1999, 2016; Rupp & Leighton, 2017). However, many of the recommendations by these scholars and practitioners are still, frustratingly, emergent rather than commonplace (Ferrara & DeMauro, 2006; Huff et al., 2017). Supporting valid inferences about what students have learned requires more sophisticated approaches to test design and development than in the past, when most educational tests were designed primarily, if not solely, for various norm-referenced decision-making or rank ordering (e.g., college admissions, to select the top 2% for gifted and talented programs, or the bottom 20% for special services). We posit that contemporary educational testing is faced with additional complex challenges that routine design practices simply cannot meet; we group these challenges into four categories: (a) the complexity of target constructs, (b) using assessment results for multiple purposes, (c) assessment quality, and (d) accessibility for increasingly diverse student populations.

First, the constructs of interest are being articulated in more sophisticated ways than in the past, as our scholarship continues to evolve in the learning sciences and as learning standards begin to reflect the sociocognitive nature of learning: how students develop the kinds of deep understanding required not only for disciplinary practice but also that set the stage for additional learning (Mislevy, 2006; NRC, 2000, 2001, 2002, 2005; Penuel & Shepard, 2017). The following are examples of standards and frameworks that reflect increasing complexity than their respective prior versions: The Common Core State Standards (CCSS; National Governors Association Center for Best Practices & Council of Chief State School Officers [CCSSO], 2010), the Next Generation Science Standards (NGSS; NGSS Lead States, 2013), the National Assessment of Educational Progress (NAEP) Technology and Engineering Literacy Framework (National Assessment Governing Board [NAGB], 2018); the 2026 NAEP

Mathematics and Reading Frameworks (NAGB, 2021a, 2021b) and the Advanced Placement curriculum frameworks for science and history (College Board, 2019).

For example, as of this writing, most states have based their K–12 reading learning standards on the CCSS, which set expectations for comprehension from multiple sources, such as reading Martin Luther King’s “Letter from a Birmingham Jail” and listening to one of his speeches and then responding to a writing prompt by citing evidence from both sources. In mathematics, there is now an expectation that students go beyond procedural fluency to conceptually understand multiple ways to problem-solve as an aspect of demonstrating proficiency in mathematical practices. Another example is the multidimensional nature of the NGSS, which integrate concepts that span the science domains, discipline-specific knowledge, and scientific practices. Therefore, the tasks we devise to measure these complex learning standards with unprecedented cognitive load, the coding schemes we use to score student responses, the measurement models we use to estimate student proficiency, and the concepts and indices used to evaluate technical quality of the assessment all need to reflect the intended complexity of the construct of interest. As an example of the new demands on evaluating technical quality, the conventional notions of comparability and reliability will likely need to evolve to keep up with contemporary needs.

Second, in addition to the challenges of measuring student proficiency with regard to sophisticated constructs, test users are demanding that educational assessments, both interim and summative, serve a variety of purposes as all manner of stakeholders—policy makers, parents, teachers, and students themselves—call for less testing, which results in the need for a greater variety of uses of the assessments that remain in place (Hart et al., 2015; Huff & Goodman, 2007). In practice, the results of interim and summative assessments are used to inform determinations at various levels of the educational system, including but not limited to instructional next steps at the individual or group level, whether the student needs additional testing for English language proficiency or dyslexia, grade promotion, algebraic readiness, educator effectiveness, school ratings, and district- and state-level policy decisions about curriculum and professional development resources. According to the *2014 Standards for Educational and Psychological Testing* (see Chapter 1; American Educational Research Association [AERA] et al., 2014), it is incumbent on the user to collect and evaluate evidence to support the assertion that the inferences from the assessment are valid for any use that is additional to or a departure from the purposes and use for which the assessment was originally designed and, presumably, validated (see also Lane & Marion, this volume). To meet the demands of less testing but increased usage of the results of any single test, test providers are looking for ways to design assessments from the beginning to serve more than one purpose.

With increased public discourse about the role of educational testing in schools, a third challenge has emerged that is not likely to subside anytime soon: Test quality is under scrutiny. As a condition for some federal education funding, the United States Department of Education requires state summative assessments to be reviewed for

technical quality by a panel of peers. Similarly, some states are requiring reviews for interim assessments before they are approved for use in classrooms (e.g., Louisiana Department of Education, 2020; South Carolina Department of Education, n.d.). As the level of scrutiny increases, there is greater burden on the test makers to have documented, transparent, and understandable validation arguments that support the variety of intended inferences about what students know and can do.

The fourth and last category of contemporary assessment design challenges is the increased need to ensure that our assessments provide results that support valid inferences about all students regardless of their sociocultural background, including home language, or disability.² We refer to this aim as ensuring that our assessments are accessible to all students. Teaching and learning are fundamentally sociocultural endeavors (Penuel & Shepard, 2017) that need to acknowledge and build on students' background knowledge and cultural experience. Assessment needs to reflect this principle to remain authentic and relevant to students' classroom experience. Additionally, there is a growing research base exploring the hypothesis that without this contextual relevance, we will not engage students during the assessment, which will demotivate them and thus undermine the accuracy of the resulting scores as a measurement of best performance, in part because of lack of consideration of construct-irrelevant factors that are present when sociocultural factors are not considered (Brown et al., 1989; Wise, 2020).

Students with disabilities must also have equal opportunity to demonstrate what they know and can do through accessible assessments. Implementation of the universal design for learning principles that guide assessment design (CAST, 2018; Johnstone et al., 2006) have been available to inform practice for some time for both paper-and-pencil and computer-based assessments. In addition, as more assessment systems are delivered via the Internet, many providers hold themselves accountable to the Web Content Accessibility Guidelines (WCAG; World Wide Web Consortium (W3C), 2018), which address features such as use of color and images, speech-to-text availability, captioning, and more. Simultaneously ensuring that students from various sociocultural backgrounds are engaged during the assessment, that the assessment is free of barriers for students with disabilities and multilanguage learners, and that the target of measurement has not been compromised requires a more contemporary approach to assessment design than is currently commonplace. When the targets of measurement are defined such that all ambiguity is eliminated, then discussions about what constitutes construct-relevant versus construct-irrelevant variance can occur with a level of precision that is typically absent, allowing for designing assessments that eliminate barriers to access that might otherwise be present. Creating assessments that are free of bias, are accessible to all students, and are culturally and linguistically responsive requires undisputed clarity on the target of measurement by the full interdisciplinary team.

It is in the context of these contemporary challenges that we write this chapter. To meet contemporary demands, educational achievement tests must be designed with more deliberate, interdisciplinary decision-making about each design feature and must make all assumptions and rationales transparent for interrogation. The intended inferences

about what students know and can do must have a compelling—and understandable—validation argument that resonates with policy makers, educators, and parents. Transparent design and a compelling, understandable validation argument are critical to support the varied intended purposes and uses of educational interim and summative assessments, especially in a climate when educational testing is under unprecedented scrutiny and criticism. In this chapter, we illustrate how principled assessment design (PAD) is not a rigid set of processes that require a new jargon-filled lexicon, but rather a discipline requiring a particular mindset and the use of tools that can help us build assessments that meet contemporary educational needs.

Two assertions are made throughout the chapter. First, assessments designed with conventional approaches do not adequately serve the purposes for which assessments are used in 21st-century educational systems; PAD offers a solution. Given the primary use case for large-scale assessments of educational achievement—to support valid inferences of what students know and can do in relation to a given set of learning outcomes for a given purpose and use—we, as a field, can no longer support approaches to educational assessment design and development that implicitly assume the measurement of a largely fixed latent trait for the purpose of rank ordering and selecting students and that define adequate validation evidence as a disconnected series of post hoc analyses to be collected and published in the technical manual. This is especially true as the constructs to be assessed become more complex, assessment results are used for a variety of purposes, assessment quality is under more public scrutiny, and our understanding of accessibility becomes simultaneously broader and more nuanced.

Conventional approaches to educational assessment design are fragmented and must be integrated and supplemented to best serve the intended role of large-scale educational assessments, whether designed to inform instruction, to make student-level decisions, or for broader accountability purposes. Fragmentation in design and development undermines the coherence required to support the inferences the assessment results are intended to support within the larger context of the educational endeavor (Herman, 2010; Huff et al., 2017). Thus, our second assertion is that PAD integrates what is fragmented in conventional approaches into a coherent design approach and validation argument. For example, historically there has been a stark divide in teams and processes between the item writing and the analysis of the resulting data, as if the creation of the test were an assembly line or a relay with handoffs. One clear consequence of this disjunction is the existence of test content specifications that are separate from the test psychometric specifications. In conventional approaches to assessment design, these two design elements are developed separately by respective teams with the exception of a few touchpoints. This divide in mindset and practice can be bridged through the discipline and practice of PAD.

PAD is an umbrella of test design approaches including construct-centered measurement (Messick, 1994; Wilson, 2005), cognitive design systems (Embretson, 1998), evidence-centered design (ECD; Huff et al., 2010; Mislevy & Haertel, 2006; Mislevy et al., 2003; Pearlman, 2008a, 2008b), principled design for efficacy (Nichols et al., 2016),

and assessment engineering (Luecht, 2013). PAD is distinguished from conventional approaches to assessment design and development by three overarching characteristics (see Figure 7.1).

First, the construct is defined by how students learn and build knowledge in the domain of interest, with a careful consideration that students from different cultural backgrounds bring different funds of knowledge that need to be valued and serve as the foundation for learning (Gay, 2000; Randall, 2021). A compelling example of construct definition is how the Advanced Placement (AP) program redesigned its science and history exams over the course of several years beginning in 2005 in response to criticism from the NRC (2002), where both the AP and International Baccalaureate examinations were criticized for overemphasizing declarative and procedural knowledge and for a lack of pedagogical and learning science research in science and historical thinking to inform assessment design. Given that assessments have consequences for what is taught and valued in the classroom, the NRC challenged the test providers to do better at ensuring that what is measured on the exam is also valued in the discipline. Other examples of this move away from overvaluing declarative and procedural knowledge as targets of measurement are the focus on scientific practices in the NGSS and the focus on mathematical practices in the CCSS. Both sets of learning standards were informed by research from the learning sciences and practitioners in the respective disciplines (CCSSO, 2010; NGSS Lead States, 2013).

A second distinguishing characteristic of PAD is the explicit articulation of all assumptions, design decisions, and rationales for those decisions, with particular attention to our need to serve a diverse student body—students from various sociocultural backgrounds, multilanguage learners, and student with disabilities. The various articulations result in a set of design tools that are used throughout the design and development process and are also subject to continuous improvement throughout the life of the assessment program as data are collected from students and used as feedback to inform refinements to our assumptions, design decisions, and tools. Use of these

FIGURE 7.1
Distinguishing Characteristics of Principled Assessment Design

tools consistently by all players in the design and development endeavor not only helps to ensure coherence from construct definition through task development and score inference (and all the steps in between), but also serves as infrastructure for the inferential, evidential, and validation arguments. Briefly, the inferential argument is the chain of reasoning that is woven throughout the assessment design (e.g., How do these items measure the intended construct and support the claims about what students know and can do?), the evidential argument is the evidence for the inferential argument, and the validation argument is how well the evidence supports the intended inferences.

Finally, the last distinguishing characteristic of PAD is an adherence to the mindset that assessment is the process of reasoning from imperfect evidence, and that process begins with design. Reasoning from first principles—in short, leaving no assumption left implicit—is an explicit requirement throughout the design, development, and evaluation process.

The benefits of this shared discipline of PAD are many. Employing PAD will force us to make intentional and explicit the necessary relationships among performance-level descriptors (PLDs), task design, and scale properties that result in a strong body of evidence to support inferences about what students know and can do. In other words, we need the psychometric properties of the scale (e.g., sufficient measurement information across the scale, especially at various cut scores) to support reliable classification of students into performance categories and for those classifications to support valid inferences about what students know and can do. Rather than leaving this to happenstance, we need to purposefully design tasks that require students to demonstrate the knowledge and skills associated with various performance categories. PLDs are our guidance for task design at the beginning of assessment design and our guidance for score interpretation once we have scores for each student. That is, the PLDs articulate the inferences we eventually want to make about what students know and can do, and using them as a primary element of task design is a strong foundation for the inferential and validation arguments for the assessment.

In PAD, there is an almost obsessive focus on clarity, articulation, and documentation of all aspects of assessment design, especially the targets of measurement, the evidence required to support inferences about those targets of measurement, and the tasks that are best suited to collect that evidence given the constraints of the assessment. Later in the chapter, we will address how the evidentiary arguments supporting how specific tasks yield valid evidence for inferences regarding specific targets of measurement are a subcomponent of a larger evidentiary argument for the assessment as a whole. Suffice to say for now that these intentionally designed layers of evidence, made explicit and transparent, result in increased clarity in the field about the intended targets of measurement of the assessment and the constructs to which the inferences about students can be generalized, which results in greater coherence between what inferences the assessment results support with regard to what students know and can do and the role the assessment plays in a larger educational context. This clarity and coherence help the assessment results better serve the diverse needs of policy makers, educators, students, and parents—and it is our hope that this, in turn, will make the results more meaningful

for them. As a field, we must make our assessments more meaningful and useful for educators, parents, and students—not only because it is the right thing to do to support teaching and learning, but also in light of the many demands facing educational testing in the early 21st century. PAD gives us a way to do that.

SIMILARITIES TO CONVENTIONAL ASSESSMENT DESIGN AND DEVELOPMENT

In 1989, Jason Millman and Jennifer Greene wrote the test development chapter for *Educational Measurement*, third edition, which opened,

This chapter is about making tests. It is directed to the professional test constructor, not to the classroom teacher. Our goal is to emphasize options for specifying and developing tests, not to produce a procedural manual. (p. 335)

We have the same goal. There are many sources that outline in much detail the precise steps for developing an assessment. Specifically, the *Handbook of Test Development*, second edition (Lane et al., 2016), includes 32 chapters devoted to every aspect of test development, administration, scoring, and evaluating validity evidence for the intended purpose and use of the assessment. The editors did an excellent job of balancing conventional approaches and PAD in their selection of authors and chapter topics. Another excellent resource is the 2013 publication by CCSSO and the Association of Test Publishers entitled *Operational Best Practices for Statewide Large-Scale Assessment Programs*.

Operationalizing PAD does not exempt the test developer from the nuts and bolts of test development; appropriate subject matter experts (e.g., classroom teachers, learning scientists) are engaged in the process, items are developed and reviewed against various criteria, items are field tested, and psychometric analyses are conducted (including but not limited to analysis of item difficulty, discrimination, differential item functioning, scaling, equating, standard setting, and more). Rather than devote this chapter to an explication of these well-documented processes and procedures, we have attempted—like many before us since the early 1980s—to question the status quo and make a compelling argument for shifting our practice to better support inferences about what students know and can do. As Huff et al. (2010) said of ECD—which applies equally to PAD—“ECD can be a first step toward challenging the assumptions and ‘breaking out of the current paradigm’ of large-scale assessment” (p. 316).

THE EVOLUTION OF PAD

There is a saying, “Nothing comes from nowhere.” This is true of PAD. The current PAD approach grew from a number of influences, some obviously traced but others more obscure. In this section, we will review the following influences on the development of PAD: the integration of psychology and psychometrics, the focus on evidential reasoning, and the influence of design science.

Integration of Psychology and Psychometrics

The writers and researchers advocating close integration of psychology and psychometrics have been an important influence on the development of PAD. Leveraging contemporary research on how students learn and build knowledge to define constructs distinguishes PAD from conventional approaches to test design. Early advocates often approached the integration of psychology and psychometrics from the perspective of validity (Anastasi, 1967, 1986; Lindquist, 1951; Loevinger, 1957; see Snow and Lohman, 1989, and Lawrence and Shea, 2008, for more extensive reviews). For example, Loevinger (1957) made the pithy observation about test development driven by criterion-related validity (here, *criterion* is used to mean what the test predicts well):

The argument against classical criterion-related psychometrics is thus twofold: it contributes no more to the science of psychology than rules for boiling an egg contribute to the science of chemistry. And the number of genuine egg-boiling decisions which clinicians and psychotechnologists face is small compared with the number of situations where a deeper knowledge of psychological theory would be helpful. (p. 82)

The 1980s saw a proliferation of authors both urging and demonstrating a closer coordination of psychology and psychometrics. An impetus for this movement may have been that psychology was escaping from the restrictions of behaviorism (Lachman et al., 1979). As Glaser (1981) noted, learning scientists had begun studying learning and individual differences in domains of interest to educators such as mathematics and reading, whereas past psychological research concentrated on the discovery of domain-agnostic mechanisms of thinking and learning. By the end of the decade, progress in the integration of learning science and psychometrics led Snow and Lohman (1989) to question the usefulness of conventional, trait-based, psychometric score interpretations:

The implication is that sign-trait interpretations of test scores and their intercorrelations are superficial summaries at best. At worst, they have misled scientists, and the public, into thinking of fundamental, fixed entities, measured in amounts. Whatever their practical value as summaries, for selection, classification, certification, or program evaluation, the cognitive psychological view is that such interpretations no longer suffice as scientific explanations of aptitude and achievement constructs. (p. 317)

The 1990s saw the promise of integrating psychology and psychometrics turned into practical applications. Researchers proposing practical applications of an integrated approach included Lohman and Ippel (1993), who described a cognitive diagnostic framework for creating assessments that took advantage of research identifying item features that could be manipulated to vary cognitive complexity and item difficulty. Another researcher proposing an integrated approach was Nichols (1994), who claimed that theories of learning and cognition were well suited to informing assessment design

and development. Nichols proposed a framework for test development that consisted of an observation design and a measurement design. The observation design describes the characteristics of assessment activities, such as tasks or items, that make demands on the test taker, how these characteristics are to be organized in the construction and ordering of tasks or items, and the nature of the responses required. The measurement design defines the object of measurement and describes the procedures to assign a value or category to an object of measurement. In addition, Embretson (1998) described a cognitive design system consisting of a conceptual framework that integrated models of learning and cognition into test design and a procedural framework that described the steps necessary to implement the conceptual framework.

Focus on Evidential Reasoning

Another important influence on the development of PAD has been writers, particularly Schum (1994, 2009) and Toulmin (1958, 2006), who examined the evidence we gather and use as a basis for making claims in the fields of law and philosophy and that have been applied to assessment design beginning with ECD.

From Schum (1994) came an emphasis on first principles that encouraged PAD practitioners to step outside the implicit assumptions and customary practices of conventional psychometrics and reconsider the evidentiary reasoning underlying probabilistic inferences about emerging complex constructs. When reconsidering conventional psychometrics, PAD practitioners have borrowed from Schum the principles of relevance, credibility, and force of evidence. First, questioning the relevance of evidence has motivated practitioners to critically examine the bearing of evidence on intended score interpretation and use leading to, primarily, a greater inclusion of cognitive process evidence and less reliance on correlational and predictive evidence. Second, questioning the credibility of evidence has resulted in practitioners articulating and carefully examining the trait-based assumptions implicit in conventional psychometric practices. Finally, a skeptical stance toward the relevance and credibility of conventional psychometric evidence has led practitioners to reconsider the weight given to particular evidence in a score interpretation and use argument made within a principled assessment framework.

From Toulmin (1958, 2006) came an emphasis on practical arguments, such as those used in nonmathematical fields like law, rather than formal logic. When arguments are evaluated in formal logic, the goal is to determine whether an argument is true or false. Practical arguments cannot be usefully evaluated by the rules of formal logic because the assumptions used in practical arguments cannot be taken for granted; the available evidence is often incomplete or questionable. As such, the practical argument is, at best, convincing or plausible rather than true or false.

The combined influence of Schum (1994) and Toulmin (1958, 2006) contributed to the role of evidentiary reasoning as an integral part of PAD. The emphasis on making evidential reasoning visible through the explicit articulation of all assumptions, design decisions, and rationales for those decisions is a distinguishing characteristic of PAD.

Similar influences are apparent in the development of an argument-based approach to validity (Kane, 2006, 2013; Messick, 1989) and design propositions in design science (van Aken & Romme, 2009), creating compatibility with PAD.

Design Science

The emergence of design science as a field has been an important, if difficult to trace, influence on the development of PAD. In the seminal book *The Sciences of the Artificial*, Herbert Simon (1969, p. 113) argued for a science of design that is “tough, analytic, partly formalizable, partly empirical, teachable doctrine.” The response to this call was design science. The purpose of design science is to produce and communicate evidence-based design propositions (Johannesson & Perjons, 2014) of the form, “If you want to achieve Y in situation Z, then apply intervention X.” There are four defining characteristics of design science (Johannesson & Perjons, 2014) that influenced PAD. First, the goal of design science is to generate and test hypotheses about artifacts, such as assessment design patterns, as solutions to design challenges. Next, these hypotheses are tested and theory is built using rigorous research methods typically borrowed from the social sciences, including protocol analysis and field trials. Third, explicit prescriptions are offered on how to design and develop an intervention, such as game-based or three-dimensional science assessment. Finally, new findings on effective design are communicated to both practitioners (e.g., psychometricians) and researchers (e.g., learning scientists in areas such as learning progressions in science education).

This way of thinking in terms of design propositions supporting both the construction of assessments eliciting targeted knowledge and skills and the creation of evidentiary arguments supporting score interpretation is evident in PAD through the mindset of reasoning from imperfect evidence. In PAD, for example, design propositions undergird design patterns, and the latter are a link in the evidentiary argument supporting reasoning from imperfect evidence. These four defining characteristics of design science come into play not only in the design process, but also in the ongoing validation process, particularly with regard to the theory of action (addressed in a later section of this chapter).

PAD: ESSENTIAL ELEMENTS

To decide to engage in PAD does not mean that one has committed to a rigid set of processes in a particular order; PAD is not like putting together a piece of furniture from a kit with step-by-step directions. Rather, at its essence, it is “a mindset that results in a useful set of documentation” (M. Pearlman, personal communication, 2003). As described in the previous paragraph, that mindset is reasoning from imperfect evidence. And reasoning requires ruthless interrogation of ones’ assumptions, always coming back to the essential question, What is my rationale for this decision or action? This question can be asked of any action within PAD, for example, What research has informed this definition of the construct? Are these the knowledge and skills valued in

the discipline? Why did I choose to use this item type for this target of measurement? What evidence will this item yield to help me place the student along the underlying proficiency trajectory? Why do I believe that is so? And so on. At its heart, the PAD endeavor involves a team of interdisciplinary players who are committed to this type of thinking and discourse throughout the design and development process. When the answers to these questions are transformed into reference documents and design tools, and then the resulting documentation is used as the infrastructure for the inferential and validation arguments that are articulated and refined continuously throughout the design and development process, then one has engaged in PAD.

In what follows, we have distilled PAD to six essential elements organized into three general steps. It is critical to keep in mind that we have organized in this way for ease and clarity of description, but in practice the lines between the steps are blurred as the elements (or, to be more specific, the artifacts representing the elements) are refined through the iterative design and development process. These elements and steps represent the design and development process up to the first field-testing event. After data are collected, those data are used to inform revisions to the artifacts. This feedback loop of using data to inform refinement of the artifacts continues through the life of the assessment program.

The use of PAD will vary depending on the training, expertise, and philosophical orientation of the individuals comprising the assessment design team and the particular needs of the assessment program. For example, PAD will be implemented differently by a team who has extensive experience applying ECD or assessment engineering in a variety of large-scale assessment contexts versus by a team whose focus of applying PAD, ECD, or assessment engineering has been in a single domain (e.g., scientific inquiry in chemistry) and whose work has been designing rich, performance-based tasks for the classroom. The former may use terminology like “student model,” “evidence model,” “observable evidence,” “task model,” “difficulty drivers,” and “grammar,” whereas the latter may use terminology like “focal knowledge, skills, and abilities,” “unpacking,” and “design patterns.” These differences in terminology are simply different access points to the same desired outcomes of PAD, which we have distilled here into the six essential elements. Similarly, engaging in PAD will look very different when one is at the very beginning of designing an assessment versus whether one is using PAD to make improvements to an assessment program that has been operational for years. We posit that as long as some form of one or more of these essential elements is used—and the mindset is present—PAD will have some of the positive impact intended.

The three general steps are: (a) analyze the domain, (b) model the domain, and (c) create design patterns. As one moves through the steps, greater specificity and more attention to the constraints of the assessment are required. For example, in the domain analysis, one may articulate at a very high level the prioritized assessment targets (e.g., in mathematics, modeling, reasoning, and problem-solving are prioritized over procedural knowledge; algebraic reasoning is prioritized over geometric proofs). Then, as one moves into domain modeling, one must be much more specific to articulate the PLDs that will undergird the test and item specifications and support the intended score

FIGURE 7.2
Principled Assessment Design Essential Elements

Note. PAD = Principled Assessment Design; PLD = Performance Level Descriptor.

inferences. Greater specificity still is required when creating design patterns because the constraints of the assessment must be considered when determining what kinds of tasks are best suited for the intended targets of measurement and how many tasks will be required to appropriately sample the domain and collect enough evidence to reliably support the intended claims about what students know and can do. Assessment design experts could reasonably disagree on when the assessment constraints should be considered in the design process. We argue that when an assessment is designed with the intention of cohering with instruction, the constraints of the assessment should be introduced at the domain model rather than during the domain analysis, and then the constraints are used more directly to shape the design pattern elements. In this way, the full breadth of the construct can be articulated and prioritized free of considerations of available item types and scoring mechanisms since those same constraints are not present in the classroom or in the discipline. Examples of richly articulated domain analyses can be found in the 2026 NAEP Mathematics and Reading Frameworks (NAGB, 2021a, 2021b), where the reader can readily envision reading and mathematics as sociocognitive and sociocultural endeavors in the classroom and in the real world without having to consider the respective constructs through a restrictive lens of constraints and features that are specific to the NAEP examination context.

See Figure 7.2 for the steps and elements of each step. Each will be discussed in detail in the following paragraphs.

ANALYZE THE DOMAIN

Define the Construct

It is unusual in the education context for the assessment developer to be charged with defining the construct, but when this is the case, the construct should be defined based on what we know about how students learn and build knowledge in the domain of interest and how that knowledge is used in the relevant discipline(s). In other words, for assessments of, say, biology, the construct should be defined based on what we know

about how students learn and build deep conceptual understanding in biology, as well as how this knowledge is used and employed in the biological sciences through the scientific practices. The role of learning science in the domain analysis cannot be understated for assessments that are intended to support inferences about what students know and can do, and even more so for assessments that are design to support instructional decisions (NRC, 2001; Perie & Huff, 2016). The theory of learning is the first segment of the assessment triangle from Pellegrino et al. (2011), cognition: What are our research-based hypotheses about how students learn and grow in the domain? It is this theory of learning that undergirds how cognitive complexity plays out in the domain model and, ultimately, the design patterns. For example, the NGSS are considered unprecedented in their complexity because they attempt to lay the groundwork for how science knowledge is not only acquired but also used in practice, which is why the standards are presented as performance expectations that reflect the integration of disciplinary core ideas (i.e., the learning that is required as the foundation for more learning), science and engineering practices (i.e., how knowledge is used and applied in the discipline), and crosscutting concepts (i.e., making connections across science domains is a way that students can make meaning of new information).

Another example of the essential role that learning science plays—or should play—in what we teach, learn, and assess has played out quite publicly between the mid-2010s and the mid-2020s in the United States (Goldstein, 2020; Hanford, 2018, 2019). As fourth-grade reading proficiency rates on NAEP continued to hover in the 30%–40% range for decades, Hanford (2018, para. 3) asked,

How do we know that a big part of the problem is how children are being taught? Because reading researchers have done studies in classrooms and clinics, and they've shown over and over that virtually all kids can learn to read—if they're taught with approaches that use what scientists have discovered about how the brain does the work of reading. But many teachers don't know this science.

Although a number of empirical studies have shown that children need explicit phonics instruction to learn to read, “there is a history of ignorance, complacency and resistance in colleges of education with regard to disseminating this critical information to pre-service teachers” (Hurford et al., 2016, abstract). This same kind of ignorance, complacency, and resistance is evident in conventional approaches to assessment when it comes to building on learning science research in our design endeavors. As this example demonstrates, it is critical that scientific research about how students learn in the domain of interest be the foundation of our work in the domain analysis, which paves the way for modeling the domain, where we articulate with more specificity the approach to cognition in the performance levels as well as how students move from novice to mastery with regard to each grade-level expectation.

Similarly, when defining the construct, we must consider that the assessment should yield valid interpretations for all students: students from various sociocultural backgrounds, multilanguage learners, and students with disabilities. Understanding from the

outset what the research indicates about how students from these various populations relate to learning the domain of interest is critical to defining the construct in ways that do not automatically include construct-irrelevant features for these students (Hong & Lissitz, 2017; Randall, 2021; Solano-Flores, 2019; see also Ercikan & Solano-Flores, this volume).

Assessment Targets

Once the construct is defined in this way, then the prioritized assessment targets can be defined at a high level. As mentioned in the section “PAD: Essential Elements,” we recommend that assessment constraints are not considered at this point, so that the assessment targets can serve not only as a basis for interim and summative assessment, but also for a variety of classroom and formative assessments. For example, in the redesign of the AP science courses, an approach was used to organize the domain into big ideas, enduring understandings for each big idea, and supporting understandings for each enduring understanding (Ewing et al., 2010). It was decided early in the design process that the target of learning, and therefore assessment targets, should be enduring understandings because these are the foundations that best prepare the learner for additional learning. Similarly, when the CCSS Mathematics were released, the guidance was for the major work of the grade, supporting standards, and additional standards to be proportioned 70%, 20%, and 10%, in curricular design, instruction design, and assessment design. These types of high-level guidance that are determined free of consideration of the interim or summative assessment constraints are critical to support coherence across instruction and assessment.

Most often in assessment of educational achievement, however, the analysis of the domain is provided to the test makers in the form of learning standards and test specifications that take the constraints and design features of the assessment into account. The constraints of the assessment program delimit the design features. Constraints and design features are determined by the answers to questions such as, but not limited to, the following.

The following are examples of constraints:

- How much time is there for design and development? What resources are available (e.g., personnel, funds)?
- What are the time limits for administration of the assessment? What is the expected turnaround time for score reporting?
- Must the assessment maintain a scale and/or comparability with an existing assessment, or is there freedom to depart?
- What item types are possible given the item authoring platform that will be used?
- What scoring mechanisms are available? For example, how much time and money exist for human raters, or must everything be machine scorable? What format(s) do the scoring mechanisms support (e.g., text, spoken word)?

The following are examples of design features:

- Is the assessment paper based or computer based?
- If computer based, is the assessment linear or adaptive?
- Does the client require a specified balance of item types?

We will return to the notion of constraints and design features in the section on “Design Patterns.”

When the assessment designer is provided the learning standards (either with or without test specifications) as a starting place, the PAD process can start with modeling the domain. If the learning standards were not developed from a research base of how students learn, then the relevant learning science research must be integrated in the domain model and design pattern elements. Sometimes this process is called *unpacking* (Harris et al., 2016, 2019).

When test specifications are also provided as a starting place, excavating the implicit judgments that undergirded the myriad decisions that were made to get from learning standards to test specifications is of utmost importance in PAD. Otherwise, the assumptions about the relationships among the learning standards and the evidence yielded by an assessment with the said specifications are left unarticulated, which undermines the coherence required for a strong inferential argument and a strong validity argument to support the resulting interpretations about what students know and can do.

Model the Domain

As stated previously, various instantiations of PAD throughout the years have taken different perspectives on what activities are associated with each step of the process and what artifacts are created in that step. For example, Mislevy and Riconscente (2005) used PAD as a tool for developing rich, computer-based performance tasks of scientific inquiry. In their approach, the domain model includes, among other elements, the assessment argument in Toulmin form (1958, 2006) and the design patterns. However, for the purposes of this chapter and in the context of designing interim and summative assessments of educational achievement for which one of the primary purposes is to classify students categorically along a latent performance trajectory, the two critical elements that must be articulated after the domain analysis is complete and before task design can begin are: (a) an articulation of the approach to cognition and (b) development of the PLDs.

Approach to Cognition

It is not yet common practice for educational assessment programs to identify explicitly the model of cognition that is implicit in the PLDs, the tasks, the evaluation of student work, the scoring model, and, ultimately, the interpretation of what students know and can do (Ferrara & DeMauro, 2006; Huff et al., 2017). This is true despite the great advances that cognitive research in how students process information has made since the publication of the fourth edition of *Educational Measurement* in 2006 and that of

the current volume in 2025. When we pay more attention to the role of cognition in learning, we unleash enormous potential to improve assessment design and sharpen our interpretations about what students know and can do when we pay more attention to the role of cognition (Huff et al., 2010; Leighton & Gierl, 2011; Mislevy, 2006; Nichols & Huff, 2017; NRC, 2001; Snow & Lohman, 1989). If the role of cognition is not explicitly engineered into the assessment design process, then we risk the emergence of an implicit, fragmented, and flawed proxy “model,” which most often leads to defaulting to the measurement of declarative or procedural knowledge or happenstance complexity (Huff et al., 2017).

We posit that given the constraints within which most educational assessments are designed and developed, it is likely to be a bridge too far to expect that a model of cognition be researched and defined *a priori*. However, it is essential that what we are calling the *approach to cognition* be articulated prior to (or in conjunction with) development of the PLDs. If not, then the assumptions about cognition will remain implicit in the individual minds of each player in the design endeavor, and it is unlikely that these implicit assumptions cohere. When models of cognition remain implicit in the minds of the various designers of PAD elements and consumers (primarily, educators), coherence is not achieved and the meaningfulness of the assessment results is compromised.

Before we describe what is meant by *approach to cognition*, a few comments on terminology are warranted. Table 7.1 gives a few illustrative examples of how related terms—*cognitive model*, *cognitive demand*, *cognitive complexity*, etc.—are defined by various authors. We recommend that for the purposes of most interim and summative

Table 7.1 Various Characterizations of Cognition Related to Assessment

Term	Citation	Definition
Cognitive model	Leighton & Gierl, 2007	A simplified description of human problem-solving of standardized educational tasks, which helps to characterize the knowledge and skills students at different stages of learning have acquired and to facilitate the explanation and prediction of students' performance
Theory of cognition	Huff et al., 2017	Prioritized value of knowledge and skills within a domain, organized to reflect structures and progressions along a learning trajectory, that articulates the precise knowledge and skills required to respond correctly to an assessment item
Cognitive demand	Perie & Huff, 2016	The degree to which tasks require more complex knowledge and skills for students to respond correctly and comprehensively
Cognitive complexity	Ferrara et al., 2014; Koedinger et al., 2012	The condition encoding requirements and the response requirements of the task; how many response operations are needed; interactions among different sources of complexity
Intrinsic cognitive load	Gillmor et al., 2015	Construct-relevant item features that contribute to item difficulty

educational assessments, becoming facile with these terms and definitions would be helpful but is not a requirement to achieve the baseline clarity and precision required for coherence. What is critical is that there is consensus on the assumptions undergirding student cognition for the domain of interest, that these assumptions are based in scientific research, and that the assumptions be explicitly reflected in the PLDs and design patterns. This degree of thought, discussion, and consensus among the design team regarding articulation of the approach to cognition reaps dividends as the team starts to author and review items from the perspective of whether the item yields sufficient evidence for the intended target of measurement, item clarity and quality, accessibility, sensitivity, bias, and cultural and linguistic responsiveness. When the PLDs and design patterns are authored with clarity on how student cognition is represented in the targets of measurement, conversations about construct-relevant versus construct-irrelevant variance start from a place of shared understanding rather than implicit assumptions.

There are at least three essential issues for the PAD team to debate and on which to reach consensus when building a shared understanding of the approach to cognition. The first is related to the fact that students can use many different cognitive processes and strategies to solve problems. For the intended purpose and use of this assessment, and given the prioritized knowledge and skills of the domain and the assessment targets that were defined in the domain analysis, what process and/or strategies will be assessed, if any? Or is it out of scope for the intended purpose and use of the assessment to prioritize process and/or strategies as targets of measurement? The intended purpose and use of the assessment will determine whether the process or strategy used to respond correctly to an item is also a measurement target. For example, in multiplication of multidigit integers, students may employ one of many strategies to correctly solve 125×10 . One common strategy is to regroup, for example, $(100 \times 10) + (25 \times 10)$. Another common strategy is to factor, for example, $125 \times 2 \times 5$. Whether strategies are a target of measurement must be articulated a priori because this decision will have an impact on the cognitive approach, PLDs, and design patterns. It is worth noting that if it is determined that processes and strategies are not prioritized as targets of measurement, assessment designers will still need to articulate and discuss the processes and strategies used by students because they are directly related to preconceptions and misconceptions, which need to be articulated as part of the design patterns.

The second issue for the team to discuss is the verbs that will be used to represent skills and how those verbs are defined in terms of observable evidence. The importance of using clear explicit action verbs cannot be understated (Egan et al., 2012; Perie, 2006; Perie & Huff, 2016). For example, verbs such as “know” or “understand” are ambiguous and are not nearly as readily interpretable as “identify,” “describe,” and “explain.” Another layer of clarifying verbs is to ensure that any synonyms are identified, for example, do we mean the same thing when we say *identify* versus *determine*? *Interpret* versus *analyze*? Perhaps one of the most critical elements of defining the approach to cognition is to define each verb in terms of observable evidence. In other words, if I asked a student to *interpret* a graph, what would I be looking for in the resulting interpretation

as evidence that the student interpreted rather than just, say, *described* the graph? What would I circle, underline, or highlight as evidence of an *interpretation*?

It is crucial that this thought process and discussion among the design team members occur without consideration of the assessment constraints, for two reasons. First, the approach to cognition is the first essential element of the domain model as it will directly inform PLDs. And, as cautioned earlier about introducing assessment constraints too soon, if the PLDs are to serve both curricular design and assessment design, and have reasonable generalizability to the domain of interest, they need to be written with applicability in the classroom as well as for the assessment (which does need to be addressed during PLD development, but not during approach to cognition; see the next section).

Second, suppose the assessment must be limited to two item types: multiple choice and short fill in the blank. If the team discussion about observable evidence of *interpretation* assumes the constraints of a particular item type, then the discussion is actually about what can be done within those item-type constraints. Establishing the key observable elements of the skill *interpret* should lead to the design of the item type or the selection of the best item type available to elicit the observable evidence of the skill. An example of this will be provided in the section on “Design Patterns.”

The third issue for the design team to discuss is: What assumptions do we have about how knowledge and skills relate to each other and cognitive demand? For example, in the assessment of historical thinking (as opposed to the assessment of recalling historical facts), it is generally agreed that the historical thinking skill “*identify and explain* historical developments” has less cognitive demand than “*analyze* patterns and connections between and among historical developments” regardless of the historical content, for example, pre-Columbian migration patterns or Victorian morality (Ercikan & Seixas, 2015), whereas in the sciences, the pairing of skill and content matters (Ewing et al., 2010). For example, the cognitive demand of accurately *describing* Heisenberg’s uncertainty principle is likely higher than the cognitive demand of, say, *analyzing* the equation $\text{force} = \text{mass} \times \text{acceleration}$, even though one would normally assume that *analyzing* requires more cognitive demand than *describing*.

Using skill taxonomies such as Webb’s Depth of Knowledge (DOK), Bloom’s taxonomy, SOLO taxonomy (Anderson & Krathwohl, 2001; Biggs & Collis, 1982; Webb, 2005), or others can be useful in considering the cognitive approach but are not sufficient, because the cognitive approach must be defined in light of the domain analysis—that is, in light of the prioritized knowledge and skills and in response to how students learn in the domain of interest. Given that most assessments of educational achievement are based on a set of learning standards that are not developed using PAD, it is likely that the design team will need to create an approach to cognition that is complementary to the learning standards. For example, suppose that the learning standards use a preponderance of ambiguous or less challenging verbs to represent skills (e.g., know, understand, identify, determine). The design team will have an opportunity to probe for clarity and desired level of rigor with stakeholders during the PLD development

process. Clarity will also be required when the learning standards include skills that are not generally fully assessed via typical exam constraints (e.g., evaluate, design, explore, create). The designers and stakeholders will need to reach agreement on the acceptable and reasonable evidence of these learning standards given the exam constraints.

Building consensus for—and documenting—the cognitive approach before developing the PLDs is critical because any latent ambiguity will cascade to the PLDs, the design patterns, and, ultimately, inferences about students. For assessment designers working on an assessment program that is already operational, where PAD was not present in the original design, all is not lost. There are at least two ways to infuse research-based approaches to cognition into an operational assessment program. First, most assessment programs need some new items each year. These consensus-building discussions that reveal latent assumptions about skills, verbs, and the relationships among skills and content can be used to improve item development specifications and item review criteria. Second, most educational assessment programs designed to classify students conduct standard setting on a specified cadence of every 3–5 years, or when needed, and most assessment programs take this as an opportunity to update PLDs (see Ferrara et al., this volume, for a discussion of standard setting). Updating PLDs is the perfect opportunity to infuse a transparent approach to cognition into the assessment design.

PLDs

PLDs are the claims about what students know and can do as they grow in mastery in the domain. In PAD, PLDs must be developed in advance of design patterns because they are essential elements in item design, scale development, and standard setting (Bejar, 2010; Bejar et al., 2007; Egan et al., 2012; Huff et al., 2017; Schneider et al., 2013). Generally speaking, PLDs reflect how knowledge and skills become more sophisticated as the achievement levels progress from representing *Novice* or *Emergent Mastery* through *Advanced Mastery*. The PLDs should emerge directly from the domain analysis and the approach to cognition that have been previously determined in the PAD process, both of which must emerge from the science of learning in the domain. Without this coherence, we risk that the inferences about where students are along the learning trajectory will not be useful to educators (Bejar, 2010; Frederiksen & Collins, 1998; Nichols et al., 2009; Schneider, 2017).

Egan et al. (2012) distinguished between the following PLD types and their uses in test development and score reporting: policy PLDs, range PLDs (RPLDs), target PLDs, and reporting PLDs. We discuss each in turn. More emphasis is given to the RPLDs given their role in item design, standard setting, and scale development.

Policy PLDs

Policy PLDs are high-level descriptions of what students should know and be able to do at each performance level. This description is developed for each domain and is typically common across grades. The policy-level definitions from NAEP Grade 4 Mathematics are shown in Figure 7.3. Policy-level PLDs are critical for setting the baseline expectations of the more detailed range, target, and reporting PLDs.

Grade 4

NAEP Basic (214)	Fourth-grade students performing at the NAEP Basic level should show some evidence of understanding the mathematical concepts and procedures in the five NAEP content areas. Fourth-graders performing at the <i>NAEP Basic</i> level should be able to estimate and use basic facts to perform simple computations with whole numbers, show some understanding of fractions and decimals, and solve some simple real-world problems in all NAEP content areas. Students at this level should be able to use—though not always accurately—four-function calculators, rulers, and geometric shapes. Their written responses will often be minimal and presented without supporting information.
NAEP Proficient (249)	Fourth-grade students performing at the NAEP Proficient level should consistently apply integrated procedural knowledge and conceptual understanding to problem solving in the five NAEP content areas. Fourth-graders performing at the <i>NAEP Proficient</i> level should be able to use whole numbers to estimate, compute, and determine whether results are reasonable. They should have a conceptual understanding of fractions and decimals; be able to solve real-world problems in all NAEP content areas; and use four-function calculators, rulers, and geometric shapes appropriately. Students performing at the <i>NAEP Proficient</i> level should employ problem-solving strategies such as identifying and using appropriate information. Their written solutions should be organized and presented both with supporting information and explanations of how they were achieved.
NAEP Advanced (282)	Fourth-grade students performing at the NAEP Advanced level should apply integrated procedural knowledge and conceptual understanding to complex and nonroutine real-world problem solving in the five NAEP content areas. Fourth-graders performing at the <i>NAEP Advanced</i> level should be able to solve complex and nonroutine real-world problems in all NAEP content areas. They should display mastery in the use of four-function calculators, rulers, and geometric shapes. The students are expected to draw logical conclusions and justify answers and solution processes by explaining why, as well as how, they were achieved. They should go beyond the obvious in their interpretations and be able to communicate their thoughts clearly and concisely.

FIGURE 7.3

National Assessment of Educational Progress Grade 4 Mathematics Policy-Level Definitions

Note. NAEP = National Assessment of Educational Progress.

RPLDs

RPLDs are detailed descriptions of what students should know and be able to do in each performance level. RPLDs acknowledge that students within a given performance level represent a range of performance; for example, students at the low end of *Proficiency* have a different level of knowledge and skill than students at the high-end range of that level. Several factors should be considered in the organization and format of the RPLDs. First, the definition of the construct and prioritized assessment targets (the two essential elements of the domain analysis) and the approach to cognition (the first essential element of the domain model) should inform the structure and grain size of the RPLDs. Both the Partnership for the Assessment of Readiness for College and Career (PARCC) and the New York State Testing Program (NYSTP) used different elements of PAD in their development (Huff et al., 2017). In each case, the testing programs were provided with the domain analysis in the form of the CCSS that were designed to inform both curriculum and assessment and contained some high-level guidance on which standards should take priority. The CCSS also provided a starting

PARCC PLD Example

Grade 3 Math: Content (Sub-Claim A) The student solves problems involving the Major Content for the grade/course with connections to the Standards for Mathematical Practice.			
Exceeds Expectations	Meets Expectations	Approaches Expectations	Partially or Does Not yet Meet Expectations
Products and Quotients: 3.OA.1, 3.OA.2, 3.OA.4, 3.OA.6, 3.OA.7-1, 3.OA.7-2			
Understands and interprets products and quotients of whole numbers.	Interprets products and quotients of whole numbers.	Interprets products and quotients of whole numbers.	Determines products and quotients of whole numbers within 100.
Determines the unknown whole number in a multiplication or division problem by relating multiplication and division. Both factors are greater than 5 and less than or equal to 10.	Determines the unknown whole number in a multiplication or division problem by relating multiplication and division. One factor is greater than or equal to 5.	Determines the unknown whole number in a multiplication or division problem by relating multiplication and division, with both factors less than or equal to 5, or with one factor of 10.	Determines the unknown whole number in a multiplication or division problem by relating multiplication and division, with both factors less than or equal to 5, or with one factor of 10.
Represents a multiplication or division situation as an equation.			
Accurately multiplies and divides within 100, using strategies relating multiplication and division or properties of operations.	Accurately multiplies and divides within 100, using strategies relating multiplication and division or properties of operations.	Multiplies and divides within 100, using strategies relating multiplication and division or properties of operations.	
Multiplication and Division: 3.OA.3-1, 3.OA.3-2, 3.OA.3-3, 3.OA.3-4			
Uses multiplication and division within 100 to solve word problems involving equal groups, arrays, area, and measurement quantities other than area. Both factors are greater than 5 and less than or equal to 10.	Uses multiplication and division within 100 to solve word problems involving equal groups and arrays. One factor is greater than or equal to 5.	Given a visual aid, uses multiplication and division within 100 to solve word problems involving equal groups and arrays, with both factors less than or equal to 5, or with one factor of 10.	Given a visual aid, uses multiplication and division within 100 to solve word problems involving equal groups. Both factors are less than or equal to 5, with both factors less than or equal to 5, or with one factor of 10.

NYSTEP PLD Example

Grade 3 Mathematics Performance Level Descriptions				
Cluster	Performance Level 4	Performance Level 3	Performance Level 2	Performance Level 1
Students represent and solve problems involving multiplication and division. (3.OA.1-4)	Interpret and represent products and quotients of whole numbers. Determine the unknown whole number in a multiplication and division problem by relating multiplication and division. Represent a multiplication or division situation as an equation. Use multiplication and division within 100 to solve word problems involving equal groups, arrays, area, and measurement quantities other than area. Identify proper context given a numerical expression involving multiplication and division. Both factors are less than or equal to 10.	Interpret products and quotients of whole numbers. Determine the unknown whole number in a multiplication or division equation relating three whole numbers by relating multiplication and division. Factors are greater than 5 and less than 10. Use multiplication and division within 100 to solve word problems involving equal groups, arrays, area, and measurement quantities other than area. Both factors are less than or equal to 10.	Interpret products of whole numbers. Determine the unknown whole number in a multiplication equation by relating multiplication and division. Limit to factors less than or equal to 5. Given visual models and/or manipulatives, use multiplication and division within 100 to solve word problems involving equal groups and arrays. Both factors are less than or equal to 10.	Given visual models and/or manipulatives, interpret products of whole numbers with factors less than or equal to 5. Determine the product in a multiplication equation with whole number factors less than or equal to 5. Given visual models and/or manipulatives, compute products within 25 in the context of word problems.
Students understand properties of multiplication and the relationship between multiplication and division. (3.OA.5, 6)	Justify the use of properties of operations (commutative, associative, and distributive) as strategies to multiply. Restate a division problem as an unknown factor problem, and explain the relationship between division and finding an unknown factor.	Apply properties of operations (commutative, associative, and distributive) as strategies to multiply. Restate a division problem as an unknown factor problem.	Apply the commutative property as a strategy to multiply. Restate a division problem as an unknown factor problem.	Given visual models and/or manipulatives, identify equivalent expressions that illustrate the commutative property within 10.

FIGURE 7.4**Range Performance-Level Descriptor Examples**

place for the approach to cognition in the form of the mathematical practices and an articulation of the relationship among the reading standards and text complexity. Figure 7.4 shows the different ways that the RPLDs were organized by PARCC and NYSTP; different approaches were used, but each was reasonable. For PARCC, the performance levels were organized by standard, whereas for NYSTP, cluster was the organizing unit. NYSTP also provided a bit more granularity in the PLDs than PARCC.

It is important to consider whether the RPLDs will be used to support curriculum, instruction, and broader assessment uses in the classroom or just the interim or summative assessment that will need to meet large-scale assessment psychometric and validation requirements. In a coherent educational system, the promise is that the RPLDs will be used to support both the classroom and the large-scale assessment, and if that promise is to be realized, then issues related to the verbs used to represent skills and the difference between assessment constraints and classroom constraints need to be considered in advance of RPLD development.

For example, take the two skills “identify” and “name” into consideration with regard to different kinds of parallelograms. Let’s suppose identify is defined in the approach to cognition as a student’s ability to select the correct term from a set of options (e.g., square, rectangle, rhombus) when presented with a shape with particular features, whereas name is defined as the student’s ability to independently generate the correct term. Unless ground rules are laid in advance, the RPLD developers could introduce unnecessary limits on the RPLDs by taking the assessment constraints into account. That is, if it is known in advance that the assessment will not be able to accommodate constructed response or speech recognition for name, then some would argue that because the RPLDs will serve item design, standard setting, and scale development, then the skill “name” should not be used in the RPLDs. However, that would make the RPLDs less useful for the classroom, which does not have the same constraints as the assessment setting. As such, we recommend that when the intent is for the RPLDs to serve both the classroom and the large-scale assessment, the RPLDs be written without the assessment constraints taken into account. We argue that the resolutions required for the RPLDs to serve item development, standard setting, and scale development can happen at a later time. For standard setting, a skills glossary can be provided for panelists that indicates, for example, “for the purposes of this methodology, assume the verb *identify* each time the verb *name* is used,” or the verbs can be changed accordingly in the PLDs that will be used in standard setting. For item and scale development, the design pattern is where resolutions between targets of measurement (skills, knowledge) and assessment constraints (e.g., item types) are addressed.

Claims about students in the RPLDs should reflect the approach to cognition previously articulated, reflect the knowledge or content prioritized in the domain analysis, and identify any relevant context that has an impact on the cognitive demand, and therefore the performance level in which the student claim is situated (Egan et al., 2012; Ferrara & Steedle, 2015; Ferrara et al., 2015; Schneider et al., 2013; Valencia et al., 2014). Before giving an example, it is important to note that the development of

the RPLDs will likely require some iteration with the approach to cognition. It is still advisable to document the approach to cognition prior to RPLD development so that all are working from a shared understanding and a shared vocabulary, which will facilitate productive iteration as opposed to unproductive churn.

Table 7.2 provides an example of RPLDs where the approach to cognition, knowledge (or content), and context is embedded in ways that are intended to model a progression of cognitive demand, from early grade-level mastery (left column) to advanced grade-level mastery (right column).

Typically, students in the earlier stages of mastery need reduced cognitive load to demonstrate what they know and can do with grade-level content and skills, so it is critical to include this kind of context at the appropriate RPLD performance level to differentiate on grade-level performance with scaffolds from below-grade-level work.

Target PLDs

Rather than the range of performance within a particular level, the target PLDs (sometimes referred to as the threshold PLDs) focus on the distinguishing characteristics

Table 7.2 Example Range Performance-Level Descriptors

Approach to Cognition: Verb Used to Represent the Skill		
Knowledge/content: The similarities and difference among similes, metaphors, allusions, alliteration		
Context: Text (stimuli) can require different levels of inference		
Early grade-level mastery	Mid-grade-level mastery	Late grade-level mastery
Student identifies an author's use of easily inferred figurative language or other literary devices (e.g., similes and metaphors) in a literary text.	Student identifies an author's user of figurative language or other literary devices (e.g., allusions and alliteration) and interprets how this language contributes to the meaning of a literary text (e.g., how a metaphor expresses a theme).	Student identifies an author's user of figurative language or other literary devices and evaluates how this language contributes to the meaning of a literary text that is complex and requires a high degree of inference.

at the “threshold” of each performance level. This facilitates necessary discussions in various standard-setting procedures where panelists need to reference a shared understanding of what knowledge and skills represent a student who is “just barely” in one level as opposed to the one just preceding it.

Reporting PLDs

Once the cut scores are finalized, any adjustments that need to be made for reporting what students in each performance level know and can do should be made. For example, a decision could be: Should the reporting PLDs reflect the minimally sufficient knowledge and skills of the placement level or the typical knowledge and skills of the placement level?

DESIGN PATTERNS

The third step in PAD—creating design patterns—has two essential elements: (a) an articulation of the task³ features that are required to elicit the evidence necessary to support the intended claim about the student as articulated in the RPLDs and (b) an identification of the task features that impact cognitive demand (frequently referred to as difficulty drivers) and, by extension, item psychometric characteristics and scale properties. Both of these essential elements build on essential elements that have been articulated previously in the PAD process: the definition of the construct, the prioritized assessment targets, the approach to cognition, and the RPLDs. There are many other elements of the assessment design endeavor that will need to occur after RPLDs are authored before an assessment is ready for field testing; Figure 7.5 provides a summary.

We have chosen to highlight task features and difficulty drivers as essential elements because they are the unique features of PAD that typically remain implicit in conventional approaches to assessment design. As with other aspects of PAD, the

FIGURE 7.5
Remaining Steps in Assessment Design

Note. PAD = Principled Assessment Design; RPLD = range performance level descriptor.

terminology for the process of task design used in various publications and applications can be daunting and off-putting (e.g., design patterns; task models; task features; task specifications; variable features; fixed features; focal knowledge, skills, and abilities; assessment framework). In an attempt to clarify, we posit that some of the key benefits of PAD can be achieved if the task features and difficulty drivers are carefully articulated, used to develop items, and refined accordingly as data are analyzed as part of iterative, ongoing design. For operational testing programs not developed under PAD, infusing task features and difficulty drivers into the item design specifications can be done over time.

One of the most challenging aspects of creating design patterns is what grain size to start with: A single learning standard? An RPLD component? A single target of measurement for a single item? As Hendrickson et al. (2010) described, these decisions are arbitrary and the process is iterative. A good starting place will be influenced by the structure of the RPLDs and the assessment constraints and design features. For example, the NYSTP Grade 3 Mathematics RPLDs are organized by cluster (an organizing feature within CCSS) and then become more granular as the progression is articulated against four performance levels (see Figure 7.4). The first row of the first cluster has to do with *products and quotients of whole numbers* and is ordered from below grade-level performance to advanced grade-level performance as such:

- Level 4: Interpret and represent products and quotients of whole numbers.
- Level 3: Interpret products and quotients of whole numbers.

FIGURE 7.6

Design Pattern Organization and Grain Size

- Level 2: Interpret products of whole numbers.
- Level 1: Given visual models and/or manipulatives, interpret products of whole numbers with factors less than or equal to 5.

It seems that the first row of the first cluster would be a likely place to start and yield a useful grain size for a design pattern. However, if time and resource constraints are a factor, a design pattern that applies to the full cluster will be sufficient and better than no design pattern at all. Figure 7.6 provides an example of two different approaches to creating design patterns for a reading comprehension domain. In the first approach, the design patterns are organized by text genre, number of passages in the stimuli, and then specific skill. In the second approach, design patterns are organized by skill clusters and then by other features depending on the cluster. The take-home message from this example is twofold: There is variability and choice in the grain size of design patterns depending on the specific needs of the testing program and the resources available; and both the organization and the grain size of the design patterns are arbitrary. What is essential is that the task features that anchor items to the RPLDs and the difficulty drivers that impact cognitive demand are articulated prior to beginning item development. Although task features and difficulty drivers may change depending on whether one is working with a single informational passage where the target of measurement is identify versus explain, if there are not resources to create design patterns at that level of specificity, then having a design pattern one or two layers up is still beneficial. We must start where we can and claim small PAD victories along the way.

Task Features

Articulation of the task features provides the essential, explicit link between the RPLDs and the tasks to be written by explicating the features of stimuli (e.g., text, graph, video, map, diagram), prompt (the question or problem to be solved), key (the correct answer), distractors (incorrect answers based on preconceptions and misconceptions), and other ways in which unique aspects of the item type can be manipulated to help ensure that each item captures evidence relevant to placing the student along the latent performance continuum (Hendrickson et al., 2010; Luecht, 2013, 2019). Each feature of the task contributes to the cognitive demand of the task (Ferrara et al., 2015; Koedinger et al.; 2012; Schneider & Johnson, 2019), so each must be considered carefully in relation to the RPLDs. The constraints of the testing program will delimit each of the task features. For example, an assessment program that is restricted to machine-only real-time scoring and must be relatively short in duration (e.g., an adaptive interim assessment) will have task features that differ from an assessment program—of the same content and skills—that includes, say, essays or computer-based simulations. Each decision about task features should be warranted by the learning science research that undergirds the domain analysis and the domain model.

For example, a design pattern for the RPLDs shown in Table 7.2 would need to address, at minimum, the task features that differentiate performance between the levels with greater specificity. Currently, the RPLDs suggest that similes and metaphors

are associated with a different RPLD than allusions and alliterations. Given that similes, metaphors, allusions, and alliterations are provided as examples, what about other figurative language devices such as personification or hyperbole? Is each on grade level for this standard, and if so, are they associated with a particular RPLD? Other features that should be addressed in the design pattern include the features of text that must be present to support the kinds of questions that students will be asked to respond to in relation to the text, such as, What are features of text that make figurative language “easily inferred” as opposed to requiring a “high degree of inference”?

Also to be addressed in the design pattern are how different item types that are available for the assessment relate to the intended targets of measurement and performance levels. For example, the assessment design team may determine that the skill identify can be assessed with fidelity with either multiple choice or drag and drop, whereas the skill evaluate requires students to highlight relevant text in the passage. In each case, the rationale for the use of the item type(s) for the skill should be documented in the design pattern, as well as any specific features of the item type that must be present to elicit evidence for that particular skill. In addition, we need to refer to the approach to cognition when creating design patterns. In the approach to cognition, we define the observable features of the skills, in this case what constitutes an *identification* and an *evaluation*. One common characteristic of evaluation that distinguishes it from identification is a judgment of quality. In the design pattern, we articulate how the task features elicit from the student evidence of the RPLD claim (or part of the claim) that is the target of measurement, in this case, evidence that gives one confidence that the student is *evaluating* rather than *identifying*.

Difficulty Drivers

In the previous section, we asserted that an essential element of design patterns is to articulate the task features that elicit evidence that a student is in one placement level versus another. When the RPLDs are constructed carefully, the distance to get from RPLDs to design patterns is a few steps rather than a journey. A second essential element of design patterns is difficulty drivers, that is, What are the task features that we can manipulate to alter cognitive demand but stay within the intended RPLD? Recall that any performance level represents a range of proficiency, and items are needed that represent the range. Identifying the task features that can be manipulated to adjust cognitive demand is helpful to support development of items that will span a range of observed difficulty. When considering the relationships among task features and cognitive demand, it is imperative to consider the diversity of the student population such that we are avoiding construct-irrelevant difficulty for students from various sociocultural backgrounds, multilanguage learners, or students with disabilities.

Figure 7.7 shows an excerpt from a detailed design pattern from an AP Biology research study on automatic item generation (Huff et al., 2013). Here, the researchers identified six ways to manipulate the difficulty of items while still targeting the claim within the *Basic* performance level. Also noteworthy is that the researchers identified two task features that do not impact cognitive demand, which is also helpful information. Note that evidence

Construct Identifier:	Biology
Primary Context:	Cell division
Competency Claim	The student can construct explanations of how DNA is transmitted to the next generation via the processes of mitosis, meiosis, and fertilization.
Proficiency Level	Basic
<i>Evidence Documentation</i>	
1.	Description of the purpose of mitosis and meiosis
2.	Description of the products of mitosis and meiosis
3.	Description of the behavior of the chromosomes during the phases of mitosis and meiosis
4.	Explanation of the processes of mitosis and meiosis
5.	Comparison and contrast of the processes of mitosis and meiosis
6.	Use and recognition of vocabulary specific to cell division
<i>Manipulable features of complexity</i>	
1.	Type of cell division (mitosis is simpler than meiosis)
2.	Number of steps in process (mitosis has fewer steps than meiosis)
3.	Type of statement/alternative (definition is less challenging than explanation)
4.	Use of vocabulary particular to cell division will increase complexity: ploidy, tetrads, synapsis, crossing over, sister chromatids, homologous chromosomes, segregations, equatorial plate, cytokinesis
5.	Phase of cell division in question; the events in some phases are more conceptually difficult than the events of other phases
6.	Making a comparison (more challenging) vs. selecting a true statement (less challenging)
<i>Features irrelevant to complexity</i>	
1.	Number of chromosomes in a cell
2.	Type of organism in which the processes occur

FIGURE 7.7

Snapshot of Design Pattern With Manipulable Features of Complexity (Difficulty Drivers)

documentation in Figure 7.7 is the observable evidence of an explanation within this particular context of cell division; this is another example of how different approaches to PAD have the essential elements associated with different processes. No matter the differences, the intent is the same: to make transparent all that is typically implicit in task design so that we can debate our assumptions, document our consensus, and use those documents as design tools and as evidence of our inferential chain of reasoning.

Ferrara et al. (2014) worked with a team of researchers across many testing organizations and practitioners across many states to develop an approach to considering cognitive complexity for the CCSS. The goals for these new metrics were to provide a systematic and replicable way of determining cognitive complexity for each task and to provide measurement precision at all levels of the score scale. Figures 7.8 and 7.9 provide taxonomies of cognitive complexity for English language arts (ELA)/literacy and math, respectively. Note that for ELA/literacy, the complexity and length of the text is considered a source of cognitive complexity along with the processing demands of the task (e.g., the

Proposed Sources of Cognitive Complexity for Items and Tasks: ELA/Literacy (Summary)

The goals and uses of cognitive complexity are:

- Provide a systematic, replicable method of determining item cognitive complexity
- Provide measurement precision at all levels of the test score scales

FIGURE 7.8

Sources of Cognitive Complexity for Partnership for Assessment of Readiness for College and Careers English Language Arts/Literacy

stimulus and prompt presented to the student), as well as the response demands of the student (e.g., selected response versus constructed response). Similarly, for math, both stimuli demands and response demands are considered sources of complexity, as well as which mathematical practice is required in the task. For both ELA and math, there exist research-based rules for how to roll up these various features into a single metric of low, moderate, and high cognitive complexity that can be used in design patterns as a more sophisticated approach to difficulty drivers than conventional practice.

While this section has focused on design patterns, PAD does not negate the need to implement training to produce items of good technical quality and fairness. Readers desiring additional information in these areas should refer to Schmeiser and Welch (2006) or the *Handbook of Test Development* (Lane et al., 2016). The development of items must include focus on the accuracy, clarity, and accessibility of the items; the items being free of sensitivity and bias; and the items being culturally and linguistically responsive. We argue that when the PAD mindset of reasoning from imperfect evidence is shared by the design team and some of the PAD essential elements are developed and used as design tools, the resulting items have a strong pedigree—that is, a strong evidential argument regarding the validity of inferences we need to make about what students know and can do.

Proposed Sources of Cognitive Complexity for Items and Tasks: Mathematics (Summary)

The goals and uses of cognitive complexity are:

- Provide a systematic, replicable method of determining item cognitive complexity
- Provide measurement precision at all levels of the test score scales

FIGURE 7.9

Sources of Cognitive Complexity for Partnership for Assessment of Readiness for College and Careers Math

INTEGRATION OF DESIGN AND PSYCHOMETRICS

One of the primary advantages to using PAD is the integration of several aspects of test design that are distinct and even siloed in conventional approaches. Integration of skills and content into claims about students, integration of RPLDs into item design, and, finally, integration of item design and scale design are beneficial in multiple ways and represent a true evolution in the assessment industry.

Although standards-based assessments or, more specifically, assessments intended to support inferences regarding the degree to which students have met learning objectives have grown in demand and prominence from the 1980s to 2025, the publication date of this volume, the way we design and develop large-scale educational assessments is still largely situated within philosophies, structures, and processes that evolved to support assessments for which normative information was the primary inference of interest, such as percentile rank with regard to a specific population. Item development processes and psychometric research on these norm-referenced tests—SAT, ACT, Iowa Tests (formerly Iowa Tests of Basic Skills), TerraNova, SAT-10, and GRE, to name a few from the field of education—have informed much if not most of educational

measurement and educational test development. When testing companies—and the psychometricians and item writers⁴ in those companies—shifted from building “off the shelf”⁵ or selection tests to tests based on state-specific learning standards with the primary purpose of classifying students into proficiency categories, the required shifts in philosophy and practice were minimal at best.

The primary metrics of conventional norm-referenced K–12 tests to support inferences about students are percentile-rank based on a nationally representative population and grade-equivalent scores—another norm-based metric devoid of any connection to learning standards—not inferences about what students know and can do with regard to a set of learning standards that represent what is valued in the classroom and the discipline. For college or graduate school admission tests, the primary metric to support inferences is, again, percentile-rank based on a nationally representative population, and the primary validity evidence is prediction of future grades. From a business perspective, it only made sense to keep as many practices and processes in place as possible during this pivot into the new space of state-specific standards-based testing.

Many test designers and psychometricians, with the best intentions, likely assumed that the only necessary changes to traditional practices concerned producing what the states needed to meet federal requirements: a post hoc alignment of banked items from these off-the-shelf tests to the state’s learning standards and a standard setting after the first operational administration to establish cut scores for the performance levels. As discussed in the second paragraph of the chapter, the cry for a different philosophy and practice for educational assessment design gained strength and numbers during this era and culminated with the NRC’s *Knowing What Students Know* (NRC, 2001). At the time of this writing over 20 years later, practitioners are either still fighting for evolution in the direction of PAD for assessments designed to tell us about what students know and can do or maintaining status quo either out of a lack of knowledge of a different way or out of a belief that the cost of evolution in design practices is neither warranted nor worthwhile from a business perspective. The authors of this chapter are firmly in the first category.

As mentioned at the beginning of this chapter, the conventional approach to test development, if viewed from a high level, may not appear to differ from a PAD approach. For example, below is a synopsis of the main phases of the test development process as outlined by Schmeiser and Welch (2006):

Step 1: Identify intended purpose and use

Step 2: Determine test design features and constraints (e.g., time to test, time to score, paper delivery or computer based, item type balance)

Step 3: Test specifications

Step 4: Item development

Step 5: Field testing

Step 6: Evaluation of test results

The PAD approach is essentially the same as the conventional approach when viewed at this grain size, especially for Steps 1, 5, and 6. When one goes into the details of the processes and documentation of Steps 2–4, however, there are many differences, especially for educational achievement tests that require performance levels and standard setting. One key operational and pragmatic differentiator between conventional approaches and PAD that has a ripple effect throughout the design and development process—as well as implications for the inferential and validity arguments—is that the former has distinction, if not fragmentation, in areas whereas the latter has integration and coherence. Three related areas of integration that are hallmarks of the PAD approach are: (a) the integration of content and skills to be assessed in the test specifications; (b) the integration of PLDs into the item design process; and (c) using PAD to engineer desired scale properties. These types of integration require a deeper partnership among item writers and psychometricians—as well as representatives from other related disciplines who should also have a seat at the table—during the design phase of the assessment than is typically the case.

Data to Inform Design and Development

In Schmeiser and Welch (2006), field testing is noted as Step 5. Field testing (sometimes referred to as field trials, pretesting, or item tryouts) is generally defined as when items are administered to a sufficient number of students to support initial psychometric analyses. New or trial items do not count toward a student's score, primarily to avoid miscalculating the student's score should subsequent psychometric analyses reveal a flaw with the item or because the trial item is not yet properly scaled with all the other items on the test. The sample size for field testing will depend on the intended psychometric analyses; for example, classical item statistics do not require as many student responses as item response theory–estimated parameters. In PAD, just as in conventional test design, data from a well-designed field test are required to do the psychometric analyses described in this section. However, there are various opportunities for gathering data throughout the design process prior to field testing that should be taken.

For example, administering early prototypes of items to relatively small samples of students in settings where students can be observed and interviewed (e.g., cognitive labs) can confirm or help us revise our assumptions about the cognitive processes employed in responding, or the interaction between cognitive demand and item type. We can use this information to update our artifacts that represent the essential elements of PAD: approach to cognition, RPLDs, and/or our task models and difficulty drivers. For computerized assessments, it is strongly advised to frequently observe students navigating through multiple components of the assessment as they are developed, with a keen eye toward how the accessibility features are performing for students with various needs. When time and resources are available, using tools such as eye-tracking equipment can also provide fascinating insights into how students are engaging with the assessment and help improve how the tasks and navigation are designed. At the time of this writing, we are beginning to see testing programs gather input from students on item design as

part of an effort to better represent diversity and inclusion in our assessments. In each of these cases, the data from these opportunities serve as invaluable feedback to the design process and only serve to strengthen the evidentiary argument for the assessment.

Content and Skill Integration

In PAD, the content and skills to be assessed are integrated in the form of claims—for example, a student can classify two-dimensional figures in a hierarchy based on defining attributes, where “classify” is the skill and the content is “two-dimensional figures in a hierarchy based on defining attributes.” As discussed in the previous section, these claims are arranged along a progression, in the form of RPLDs, that demonstrate how a student moves within a school year from novice to grade-level proficiency. RPLDs in and of themselves cannot serve as test specifications because test specifications need to consider the number of items, the type of items, and other design features and constraints of the assessment to guide form assembly in a fixed-form assessment or the item selection algorithm in an adaptive testing environment. In a conventional approach, although content and skills may be weighted or balanced in the test specifications (e.g., the 12 items in the geometry domain should have a skills distribution of 30%–40% application and 60%–70% comprehension), the content and skills are not integrated as a claim about what students know and can do. As we argue in the section “Using RPLDs to Guide Assessment Design,” this lack of integration does not support the type of scale properties that are optimal for supporting performance standards (also referred to as cut scores) and inferences about what students know and can do that are based on the RPLDs.

Figure 7.10 provides two examples of typical mathematics test specifications for state accountability tests for elementary grades. In each case, the testing program goes on to give descriptions of each component in some detail but falls short of articulating how the content and skills (represented in each case by DOK) should be integrated to support the intended inferences regarding student proficiency. For instance, for the example on the right side of Figure 7.10, the technical manual includes descriptions of both DOK and the mathematical practices, and it indicates that two mathematical practices, *justification and explanation* and *modeling*, result in reportable scores but does not specify guidelines for how the mathematical practices and the DOK levels relate to one another or how they should be integrated into the assessment design. Without a priori hypotheses about how these various design components relate to eliciting the required evidence from students documented in design patterns or other item-writing specifications, these decisions are left to each individual item writer. Regardless of the depth of expertise of any given item writer, it is extremely unlikely that a coherent perspective on the following will occur by happenstance:

- Which item types and item features are best suited to elicit the types of skills implied by DOK 1 versus DOK 2 versus DOK 3?
- What is the best way to elicit evidence of mathematical practices given the item types and manipulatable item features available?
- What are the relationships between DOK and mathematical practices?

Example 1

DOMAIN	MIN.	MAX.
Operations and Algebraic Thinking	29%	38%
Number and Operations—Base 10	18%	22%
Number and Operations—Fractions	27%	31%
Measurement, Data, and Geometry	18%	22%
DOK 1	18%	31%
DOK 2	38%	58%
DOK 3	9%	20%

Example 2

OPERATIONAL ITEMS	NUMBER OF ITEMS
Item Types	
Multiple Choice	21–23
Technology Enhanced	0–6
Constructed Response	3
Reporting Categories	
Progress to Grade Level	19–20
Number and Ops—Base 10	3–5
Number and Ops—Fractions	4–5
Ops & Algebraic Thinking	3–6
Geometry	3–4
Measurement & Data	3–4
Mathematical Practices	
Integration	7–8
Justification/Explanation	3
Modeling	≥7

FIGURE 7.10**Conventional Test Specifications With Separate Considerations of Components**

- What is the optimal way to pair content and skills (or, in these examples, DOK level) given the intended inferences about student proficiency?

In their chapter on the role of cognitive models in large-scale educational test development, Huff et al. (2017) contended that with PAD,

all assumptions, especially those regarding student cognition, are brought to the foreground and examined. As a result, when the cognitive model is selected a priori and is made explicit, there is the opportunity to ensure alignment of the cognitive model with the intended purpose and use of the assessment as well as with all other design, scoring, reporting and interpretation decisions to yield evidentiary coherence. (p. 401)

In contrast, assessment programs that employ PAD in some way tend to have test specifications that integrate the content and skills to be measured in ways that make transparent the assessment designers' perspective on what is valued in the domain. The NAEP Technology and Engineering Literacy assessment specifications are a great example of this approach. Figure 7.11 presents a snapshot of a rich set of assessment specifications that integrate the content and skills that are valued in the classroom and discipline (National Assessment Governing Board, 2018). Note that each content area (columns) is crossed with the practice (rows), which gives rise to a differentiation in the

**Classification of Types of Assessment Targets in the Three Major Assessment Areas
According to the Practices for Technology and Engineering Literacy**

	Technology and Society	Design and Systems	Information and Communication Technology
Understanding Technological Principles	Analyze advantages and disadvantages of an existing Technology Explain costs and benefits Compare effects of two Technologies on individuals Propose solutions and alternatives Predict consequences of a Technology Select among alternatives	Describe features of a system or Process Identify examples of a system or Process Explain the properties of different Materials that determine which is suitable to use for a given Application or product Analyze a need Classify the elements of a system	Describe features and functions of ICT tools Explain how parts of a whole Interact Analyze and compare relevant Features Critique a process or outcome Evaluate examples of effective Resolution of opposing points of View Justify tool choice for a given Purpose
Developing Solutions and Achieving Goals	Select appropriate technology to Solve a societal problem Develop a plan to investigate an Issue Gather and Organize data and Information Analyze and Compare advantages and disadvantages of a proposed Solution Investigate environmental and Economic impacts of a proposed Solution Evaluate trade-offs and impacts of a proposed solution	Design and Build a product Using appropriate processes and Materials Develop forecasting techniques Construct and Test a model or Prototype Produce an alternative design or Product Evaluate trade-offs Determine how to meet a need by choosing resources required to Meet or satisfy that need Plan for durability Troubleshoot malfunctions	Select and Use appropriate tools to Achieve a goal Search media and digital resources Evaluate credibility and solutions Propose and Implement strategies Predict outcomes of a proposed Approach Plan research and presentations Organize data and information Transform from one Representational form to another Conduct experiments using digital Tools and simulations

targets of measurement that exist at the intersection of content and skills, presenting the item writer with a more detailed set of expectations to guide their work.

Using RPLDs to Guide Assessment Design

The second area of integration that is a hallmark of PAD is using RPLDs as an essential element of assessment design. Recent reviews of testing programs' use of PAD (Huff et al., 2017) indicate that the use of RPLDs to guide design is still nascent at best, although using them has been long called for in designing assessments for which the primary purpose is to reliably classify students into a proficiency level and support valid inferences about what they know and can do (Bejar et al., 2007; Huff & Plake, 2010a; Luecht, 2013, 2019; Perie & Huff, 2016).

In conventional approaches to assessment design, articulation of PLDs of any sort does not occur during the design process; rather, the development of PLDs is considered the first step of the standard-setting methodology, which occurs after the

first test administration. In contrast, in PAD the items are designed to elicit evidence for a particular performance level (or, more specifically, for a particular claim about students where the claims are arranged along a performance continuum as expressed in the RPLDs).

This intentional, *a priori* match of an item to a specific performance level has several benefits. First, the claims about what students know and can do in each performance level are inferences that require an evidential argument that can be evaluated. To have reasonable confidence that inferences about what students know and can do are valid, this evidential argument must be compelling. Designing items from the outset that target specific performance levels seems to be an inherently plausible, commonsensical approach. The alternative argument—that items designed *absent* RPLD inputs will yield valid evidence helpful for classifying students based on what they know and can do—seems whimsical at best. A second, related benefit is that when items are designed to target specific RPLDs, we are essentially engineering the desired scale properties from the beginning, creating a coherence and integration between item design and psychometrics that is fragmented in conventional approaches to test design. Third, when items are targeted to specific claims about students organized as RPLDs, there is an opportunity to engineer cut scores rather than have standard setting be a completely *ad hoc* process (Huff & Plake, 2010b; Lewis & Cook, 2020).

Resistance to targeting items to specific performance levels is typically rooted in the observation that the intended progression of items does not turn out perfectly when reviewing the observed difficulty statistics for the item. For example, suppose there is an assessment that is intended to have three performance levels that are represented by the item response theory–based scale scores, as shown in the first column of Figure 7.12. Items were designed to align to performance levels, as shown in the second column. However, after data were collected from students in initial field trials and the items were analyzed and placed on the scale according to their estimated difficulty parameters (third column), there was a mismatch for many of the items. Some would use these mismatches as evidence that attempting to target items to specific performance levels is too imperfect of a science to be of utility. However, the mismatch of observed difficulty to intended difficulty is not a new problem—conventionally developed norm-referenced tests overdevelop item pools for precisely this reason, where crafting intended scale properties is mostly achieved through careful selection from an item pool after field testing, rather than designing the fit of items to scale intentionally from the beginning. But others argue—including the authors—that the process of targeting items to specific performance levels, reviewing data from field tests, hypothesizing on the cause of the mismatches, and revising items when needed—is simply best practice in the spirit of continuous improvement and iterative design (Kaliski et al., 2011; Lewis & Cook, 2020; Luecht, 2013, 2019; Schneider et al., 2013).

In the spirit of PAD, assessment designers have advocated seeing these mismatches as an opportunity for discussion and learning rather than dismissal of the entire process. Indeed, they contend that these discussions should occur in relation to all items,

not just the ones that are mismatched (Huff & Ferrara, 2010; Lewis & Cook, 2020). The following three questions should guide the evaluation of items: (a) Does the item placement along the scale support or detract from the assumptions as articulated in the domain model essential elements (approach to cognition and RPLDs) and the design patterns (task features, difficulty drivers)? (b) Do any assumptions or design features need to be revised? (c) What can we assume about opportunity to learn (OTL), and how does that influence the data for the items? For items that are intended to be rather simple in complexity and the statistics on the item support this intention, like Item 1 from Figure 7.12, it is usually assumed that most students have had OTL to learn the knowledge and skills tested by the item and that students in the *Basic* category have some barrier to OTL (e.g., do not have the prerequisite skills to access this grade-level content). These same types of discussions should happen with items at the other end of the spectrum, like Item 9 from Figure 7.12. The item was intended to be complex and the item location along the scale seems to support the assumptions that went into the RPLD and item design. However, the design team reviewing the item and resulting statistics should not discount the counterhypothesis that the item is complex as the result of some flaw (e.g., construct-irrelevant variance) or that our assumptions about the complexity of the target of measurement are flawed and the main reason that the item statistics are showing the item as hard is that very few students have had OTL. The role of OTL is especially critical to consider for items that are mismatched: All of the assumptions that go into the item design can be supported by research and expert judgment, the item can be free of flaws, and the item can still locate on the scale in an unexpected way because of a lack of OTL (making the item seem more complex than it is had students had the OTL for the targeted knowledge and skill), widespread

RPLD and Scale Score Range	Intended RPLD	Observed Placement on Scale
Basic 350–450	Item 1	Item 1
	Item 2	Item 4
	Item 3	Item 3
Proficient 451–550	Item 4	Item 2
	Item 5	Item 5
	Item 6	Item 8
Advanced 551–650	Item 7	Item 6
	Item 8	Item 7
	Item 9	Item 9

FIGURE 7.12

Hypothetical Comparison of Intended Performance Levels and Item Scale Placement

Note. RPLD = range performance-level descriptor.

exceptional instruction in a particular area (the targeted content and skill is very complex and sophisticated, but most students are getting the item correct because they have had effective instruction and OTL), and/or more nefarious reasons such as item exposure or cheating (making complex items seem easy).

The mismatch between items and intended performance level needs more attention because understanding these mismatches helps us make better assessments and, in turn, may help us better understand—and improve—the assumptions about the construct of interest, student cognition, the underlying performance continuum as expressed by the RPLDs. It is in this process that our assumptions are either confirmed or disconfirmed and thus revised. This is the messy business of reasoning from imperfect evidence that is at the heart of PAD.

Using PAD to Engineer Desired Scale Properties

Tests for which the primary purpose is to provide norm-referenced information, such as a percentile rank, or tests for which the primary validity evidence is the strength of the prediction from a score to a criterion, such as grade point average, do not require sophisticated psychometric specifications. Typically, for these kinds of tests, psychometricians give very little direction to item writers in advance other than general advice to make sure there is a range of difficulty in items. It is assumed that high-quality items will produce an appropriate range of item discrimination and very few items will be flagged for differential item functioning. The goal of the psychometrician for these kinds of tests is to keep reliability high and maintain the unidimensional scale over time as new items are added and the population shifts. Norms and predictions are monitored and updated on a routine but not annual basis. The scale is reset as infrequently as possible because maintaining historical trend is of utmost importance to the score user. In this context, the psychometric team will review test specifications upon development or revision in conjunction with the item-writing team to ensure that there are enough items of various characteristics (e.g., algebra or geometry, multiple-choice or short constructed response) to accomplish these goals. However, in conventional testing programs, psychometricians do not become heavily involved in the design of the assessment or items until there are field test data to analyze. As Luecht (2019, p. 8) lamented,

The fundamental dilemma seems to stem from the way that we design and implement operational testing programs and ultimately develop our score scales. Most test forms and the score scales are usually constructed in siloed procedures, carried out by different groups within an organization doing different things at different times without extensive coordination nor careful integration when it comes to validity and score use. [Item writers] tend not to worry about the statistical properties of the scale, psychometricians often view test content as an annoyance that gets in the way of optimizing certain statistical scale properties, and end users must then rely on PLDs and standard setting and ad hoc score reporting techniques to build some semblance of meaning into the score scales.

For tests that need to support inferences about student proficiency in regard to a set of learning standards, we argue that psychometricians and item writers must be close collaborators from the beginning and throughout the design process, as part of an interdisciplinary team with representatives from other, related fields, such as but not limited to classroom teachers and learning scientists, long before test specifications are developed or items are field tested. Through this collaboration, the intended scale properties can play a central role in the design process. Specifically, assessments that will require performance standards—or cut scores—so that each student can be classified into a proficiency level require sufficient measurement information to distinguish students who are, for example, *Basic* versus *Proficient* versus *Advanced*. For this reason, item writers need to change their perspective from writing items that span a wide range of difficulty to targeting the items to distinguish between performance levels, which requires the RPLDs to inform assessment design and item writing. The criticality of doing so must be understood by psychometricians and item writers alike for the scale to support a successful standard setting (Huff & Plake, 2010b; Lewis & Cook, 2020; Luecht, 2013, 2019) and for the resulting inferences to have compelling evidentiary argument that leads to validation of the inferences about what students in each performance level know and can do. The intentional relationships among our research-based assumptions about student cognition, the latent proficiency continuum as expressed in the RPLDs, task features, difficulty drivers, and the resultant scale properties of the assessment should result in a strong body of evidence to support valid inferences about what students know and can do.

One hypothetical example of what an integrated set of content and skills to be assessed and psychometric specifications could look like is provided by Luecht (2019) in Figure 7.13. In this example, Luecht used the NGSS to illustrate that when appropriately engineered, design patterns (see the term *task model* in Figure 7.13) will produce measurement information that is located on a deliberate range of the scale to support intended inferences. This can only happen when RPLDs—composed of claims about student proficiency that integrate skills and content and reflect a progression of student cognition—and the desired scale properties are understood by the full interdisciplinary team to be complementary components and are used as the basis of the assessment design from beginning to end.

SUMMARY

PAD helps us integrate and create coherence where conventional approaches to assessment design are fragmented. Three areas of integration were discussed in this section: first, test specifications that integrate content and skills in meaningful ways to reflect the hypothesized learning trajectory articulated in the RPLDs and serve as the basis for the eventual inferences about what students know and can do; second, the use of RPLDs as the basis for iterative item design and development; and third, the integration of item

Generating Performance-Level Descriptors for the Strengthening Claims-Based Interpretations and Uses of Local and Large-Scale Science Assessment Scores Partnership

Note. From “Strengthening Claims-Based Interpretations and Uses of Local and Large-Scale Science Assessment Scores (SCILLSS): The Role of Performance Level Descriptors for Establishing Meaningful and Useful Reporting Scales in a Principled Design Approach (White Paper)” by R. M. Luecht, January 2019, Nebraska Department of Education. https://www.scillsspartners.org/wp-content/uploads/2019/02/SCILLSS_PLD_WhitePaper_V1812-02_FINAL_2_7_19.pdf

design and scale design. These three related levels of integration require collaboration across an interdisciplinary team from the beginning and throughout the iterative design and development process, especially by those responsible for designing and developing the items and those responsible for designing and maintaining the scale through psychometrics. It is this same partnership that is required to articulate a robust inferential argument that is supported by evidence and supports valid interpretations of what students know and can do.

The integrations discussed in this section have profound impact on how we think about the inferential and validation arguments. With PAD, we have the opportunity to develop a validation argument that is shaped by the deeper notion of coherence, rather than the typical superficial alignment, and includes evidence to support our intended

interpretations of student performance that is generated from the beginning of the design process, not post hoc validation studies.

THE EVIDENTIARY ARGUMENT IN PAD

One hallmark of PAD is that the evidentiary argument (which is defined as the evidence to support the inferential argument) and the validation argument (which is defined as an evaluation of how compelling the evidence supporting the inferential argument is) are central components of the iterative design endeavor, rather than a series of post hoc analytical exercises to be documented in a technical manual. For the purposes of this chapter, we posit that:

1. A Kanesian perspective on assessment validation (Kane, 2006, 2013) complements both a theory of action framework and the PAD framework.
2. A *theory of action* (TOA) is required to frame the evidentiary and validation arguments for assessment in the larger educational context.
3. The evidentiary argument and the validation argument are composed of a series of claims and evidence that are hierarchical, nested, and represented in many forms and in many grain sizes. For example, the *evidence model* in ECD is an evidentiary argument for specific targets of measurement, but only a subcomponent of the larger evidentiary argument supporting score interpretation, which in turn is only a subcomponent of the larger evidentiary argument supporting the effectiveness of score use as framed by the TOA.
4. The educational assessment industry needs to hold itself accountable for the decisions made throughout the assessment design process that either support or hinder the intended inferences about what students know and can do through the production of *procedural validity evidence for assessment design*.
5. Given this context, in PAD, many post hoc “validity studies” become obsolete. We use post hoc alignment studies as the prime example.

We discuss each of these propositions in turn in the following section.

Assessment Validation

As discussed previously, Toulmin’s (1958, 2006) thinking on the use of practical arguments, rather than formal logic, played an influential role in the evolution of PAD. The extension of the use of practical arguments to assessment validation processes has been an integral part of PAD from the outset. Kane (2013) described an argument-based approach to validation as requiring that

the claims based on the test scores be outlined as an argument that specifies the inferences and supporting assumptions needed to get from test responses to score-based interpretations and uses. Validation then can be thought of as an evaluation of the coherence and completeness of this interpretation/use argument and of the plausibility of its inferences and assumptions. (p. 1)

In PAD, we think of the evidentiary argument as the evidence used to support the inferential chain of reasoning threaded throughout the design components of the assessment. What evidence do I have to support that the approach to cognition is appropriate for this domain? These grade levels? What evidence do I have that the RPLDs follow a reasonable progression of student learning from novice to mastery within a given grade and domain? What evidence do I have to support that the design patterns and resulting items will yield evidence of where along the latent proficiency continuum a student most likely resides? What evidence do I have that the resulting performance-level classifications support intended inferences given the stated purpose and use of the assessment? The answers to these questions—and many more like them—constitute the evidentiary argument. The validation argument is an evaluation of how compelling the evidentiary argument is. It is incumbent on the test publishers to provide the evidentiary argument. The potential test users determine the persuasiveness of the evidentiary argument by their decision to use or not use the test for its stated purpose and use. However, that decision does not constitute a “validation” of the test. Validation would require an external review of the evidentiary argument that evaluates the documentation of the design process and the articulated answers to all of the questions that arise through that process, as well as a determination of whether the evidentiary argument is, indeed, compelling and coherent.

Theory of Action

Since 1992, states have been mandated by the U.S. Department of Education to test, on an annual basis, certain subjects in certain grades for various accountability purposes and with some promise that these assessment results can also inform decisions at various levels of the educational system (federal, state, district, building, classroom). For example, when the No Child Left Behind Act became federal law in 2002 (No Child Left Behind Act, 2002) and extended the requirement from the previous law (Improving America’s Schools Act, 1994) that state assessment results be disaggregated by various subgroups, states used those data to make decisions about how to allocate funding for curricular supports, professional development, and other services. Districts also administer a variety of assessments throughout the school year for various purposes and uses, as do principals at the school level and classroom teachers. When thought through with purpose, these assessment endeavors complement each other in a balanced assessment system (Marion et al., 2019; Perie et al., 2009). When not coordinated as a system, this results in a proliferation of redundant testing that can have many negative, unintended consequences on teaching and learning. (See Ho & Polikoff, this volume, for additional discussion of test-based accountability in K–12 education.)

Bejar (2010), building on work from Bejar et al. (2007) and Mislevy and Haertel (2006), suggested that when PAD is employed, it is incumbent on the designers to consider both construct representation and convergent and discriminant validity evidence. Bejar (2010) highlighted the latter

because test scores, certainly those of high visibility, do not live in isolation and have consequences, intended and unintended, for students and their parents. Such consequences can be thought of as part of the evidence for and against a particular assessment. (p. 381)

Bennett (2015) further extended this notion of examining consequences by postulating that in a teaching and learning context, assessments are a form of treatment and the intended effects of the assessment must be examined through the lens of efficacy or TOA.

Figure 7.14 provides a sample TOA for an interim assessment for which the primary purpose and use are to help teachers identify gaps in student learning in a particular domain of interest (e.g., fourth-grade learning standards for measurement and geometry) and to support changes in instructional practice with the intended outcome of improving student learning. From this perspective, both the evidentiary argument and the validation argument are subsumed by a broader TOA for the role that the interim assessment plays in teaching and learning.

In this example, evidence to support fidelity of implementation is a key component of the TOA. For example, although the score reports may be optimally designed to inform instructional actions, without the appropriate support systems in place the reports may not be used as intended. One can imagine several systemic actions that would need to be evaluated: Was adequate professional development provided to

FIGURE 7.14

Sample Theory of Action for Interim Assessment

Note. TOA = Theory of Action.

support appropriate interpretation and use of the reports? Were teachers given timely access to the reports? Were teachers provided time to review the reports and plan accordingly? Do teachers have access to curricular and instructional supports that cohere with the assessment results? When not implemented with fidelity, it is unlikely that an assessment designed to adjust instructional practice will result in efficacious student learning gains.

Research that examines the impact of the interim assessment as a “treatment” should occur to determine whether the actions made based on the score report result in improved achievement for students (Brookhart, 2009; Nichols et al., 2009; Shepard, 2009). There is a growing body of research suggesting that teachers often struggle to determine next instructional actions to take (Heritage et al., 2009; Ruiz-Primo et al., 2010; Schneider & Andrade, 2013; Schneider & Gowan, 2013; Schneider & Meyer, 2012). In light of this finding, if a testing program’s claim that the intended purpose and use of the assessment is to inform instruction, this must be supported by assessment designers’ documented work with an interdisciplinary team—expert teachers, learning scientists, score report designers, to name a few—to develop instructional recommendations. To return to Figure 7.14, score interpretations must be supported by evidence that supports their accuracy (evidentiary argument) and instructional recommendations should be supported by evidence that demonstrates that faithful implementation of the recommendations results in student learning gains (efficacy research).

Most testing programs focus on the evidence to support score interpretation in the lower right box of Figure 7.14 to the detriment of other sources of evidence. Gathering and documenting evidence to support score interpretation is usually treated rather mechanically, as demonstrated by the routine structure of most technical manuals that include a predictable series of psychometric analyses. When PAD is used, we argue that a rich and coherent evidentiary argument is articulated by the very nature of the design process itself.

Claims and Evidence

Assessments are a type of evidentiary argument (Kane, 1992; Messick, 1989; Mislevy, 1994). As our claims about what students know and can do become more complex and the uses of assessment results become more varied and complex, the burden on our evidentiary argument increases. Simultaneously, as educational tests come under greater scrutiny, it is incumbent on test makers to ensure that the evidentiary argument supporting the inferences we are making about students is both clear and compelling. There are at least two ways that PAD differs from conventional test development that help tremendously with creating a clear, compelling evidentiary argument. First, the inferential argument is defined up-front, used as the basis of design, documented clearly throughout the design process, and updated during assessment development; this documentation serves as both design tools (i.e., the essential elements of PAD) and the evidentiary argument that supports the inferential argument. Second, one way that evidence is conceptualized in PAD is the

observable manifestation of what the student knows and can do, and the articulation of that which is observable is used as a design element throughout the assessment development process. Collecting and curating these elements of the evidentiary argument throughout the design process contrasts with conventional approaches to test development, in which “evidence” is narrowly defined as the collection of empirical data that can only happen when design is complete and scores are analyzed.

Under PAD, the term *evidence* is used in different contexts to reference various aspects of the larger body of evidence. Evidence is used broadly to refer to the evidentiary argument that captures the comprehensive set of claims that begins with the definition of the construct and ends with the use of the test score information to accomplish the intended purpose of the assessment. During design, development, and administration, these claims are supported by the collection and documentation of design process artifacts, including but not limited to the essential elements and empirical data. Psychometric evidence is collected to support claims that items are appropriately designed and scored to locate students along the performance continuum as articulated by the RPLDs. In addition, evidence also refers to the data, warrant, and backing supporting a claim of the TOA. Table 7.3 gives examples of how claims and evidence are used in nested levels within PAD as design features as well as components of the evidentiary argument.

In Figure 7.15, we show the hierarchical and nested nature of the claims that constitute the evidentiary argument for an examination program designed to award college credit and placement.

Procedural Validity Evidence

PAD, as described in the previous section, evolved from a rich history of the role of evidentiary reasoning in assessment; a natural consequence of engaging in PAD is the documentation and use of several layers of the evidentiary argument in the form of the various artifacts that represent the essential elements of PAD, for example, prioritized knowledge and skills in the domain (domain analysis), the approach to cognition and RPLDs (domain model), and the task features and difficulty drivers (design patterns). Nichols et al. (2017) posited that to achieve the intended purpose and use of an interim or summative assessment in the educational system, coherence must exist in the design process in at least two ways: (a) All design elements must be informed by theories of learning and cognition, and (b) procedural validity evidence must be collected to demonstrate that the assessment designers followed the process and used the design elements as intended. If the intended process was followed, then the procedural validity evidence will be natural artifacts of that process.

PAD starts with an assessment design plan that explicates in detail the processes that will be followed during design, the points of iteration, the artifacts that will be produced, and the key attributes of those artifacts. In this way, procedural validity evidence for the claim “The intended assessment design process was followed” can be collected and evaluated. Such a notion may seem novel in assessment design, but it is not. We

Table 7.3 Claims and Evidence in Principled Assessment Design

Grain Size	Claim	Example Evidence
Smallest: A single item with a particular <i>evidentiary focus</i> (i.e., target of measurement)	Student can distinguish among levels of abstraction in conflicting historical information	Task stimuli (historical text, map, and/or graphic) includes various levels of abstraction. Task prompt focuses student on distinguishing among levels of abstraction
Small: A single learning standard	Student can evaluate conflicting historical information for particular historical period and focus (e.g., pre-Columbian migration patterns)	Observable evidence has four components: • Recognition and response to conflicting information • Clear, comprehensive thesis • Significant depth and quantity of evidence to support thesis, including main concept and supporting details • Recognition of different levels of abstraction in historical information
Medium: A primary design component for the assessment (e.g., RPLDs or design patterns)	The RPLDs represent a research-based progression of proficiency that are useful both for assessment design and for making inferences about what students know and can do	Literature review on how students learn and build knowledge and skills in the domain of interest; data (survey, focus groups) that indicate educators are making appropriate inferences about what students know and can do from the PLDs; procedural validity evidence from the design pattern development and item-writing process that PLDs are being used as intended in design
Medium: One of the five sources of validity evidence cited in the <i>Standards</i> (AERA et al., 2014)	Students employ intended cognitive processes when responding to assessment items	Research report from a think-aloud study that indicates students are using the intended cognitive processes at each performance level
Large: Evidence that one or more claims in the TOA are supported	When teachers use the assessment results to drive instruction, students achieve higher gains in learning than when teachers do not	Quasi-experimental design study showing respectable effect sizes for claim that when teachers use the results of the assessment to drive instruction, students have higher gains than when assessment results are not used

Note. PLD = performance-level descriptor; RPLD = range performance-level descriptor; TOA = theory of action.

routinely articulate our intended methodologies and our rationales for every psychometric aspect of the test-making endeavor: establishing and maintaining the scale over time, equating or linking forms (or monitoring item drift), item analyses, standard setting, and postoperational validation studies (e.g., dimensionality analysis, predictive studies). These plans are meticulously detailed by the assessment provider, reviewed by independent technical advisors who provide feedback, and then reviewed and approved by the assessment client (e.g., the district or state). The assessment providers are held responsible for incorporating feedback from the advisors and client and then are held accountable for executing the psychometric plans and presenting detailed evidence of said execution. In addition, there are widely held expectations throughout the industry

FIGURE 7.15
The Nested and Hierarchical Nature of Claims

on what constitutes acceptable and thorough documentation of these psychometric methods and analyses, which for federally mandated state summative tests are, in fact, externally audited via peer review. The whole of assessment design and development should be held to the same rigorous expectations of making a plan, executing it, and providing evidence that it was executed as intended.

An assessment design plan outlines the design and development process in detail, as well as what evidence will be produced that demonstrates that the plan was executed. Given that most of design and development relies on human judgment, assessment designers should be held accountable for providing procedural validity evidence. When PAD is engaged, procedural validity evidence is a natural by-product of the process as documentation of the assumptions and rationales undergirding each decision is used as design tools (e.g., the approach to cognition, design patterns). It is also helpful to be explicit in the plan on the role and nature of iteration, especially regarding the use of field test data to refine RPLDs and design patterns.

Table 7.4 contains a proposed set of validation criteria for PLD development expanded to include criteria for design patterns and item development. Huff and Plake (2010b) adapted these criteria from what are typically required of the standard-setting process. There is no reason that we should not apply the same high expectations to assessment design and development.

Hendrickson et al. (2013) offered two sets of checklists for use in the PAD endeavor. One is a set of criteria that can be used to evaluate design pattern quality. The criteria are based on assumptions that the items are written to discern between increasing levels of performance as articulated in the RPLDs and that there will be iteration of either or both RPLDs and design patterns after field testing. The second example from Hendrickson et al. (2013) is a checklist regarding iteration for PAD design components that relies heavily on iteration and consensus across various stakeholders on an interdisciplinary team. How do we know when we are done and can move forward to the next phase?

A final example in Figure 7.16 represents an item specification checklist to help ensure that the item writer is keeping critical design elements in mind. Notice how the checklist requires the item writer to indicate whether the item is to discern between students who are at the lower end of the proficiency continuum (Performance Levels 1 and 2: identify) or between students who are at the upper end of the proficiency continuum (Performance Levels 3 and 4: analysis) and how those items have different characteristics related to student cognition. It is easy to see from this example how a design tool can also serve as procedural validity evidence and evidence to support an inferential argument that makes explicit the relationships among approach to cognition, RPLDs, design patterns, items, and inferences about what students know and can do.

Alignment

Alignment of test specifications and item content to the learning standards is a key tenet of content validity for educational assessments. In conventional approaches to test design, alignment is conducted after item writing is complete. We contend that when

Table 7.4 Validation Framework and Criteria for Performance-Level Descriptors, Design Patterns, and Item Development

Category of Evidence	Criterion	Potential Evidence for PLDs
Procedural	Care in selecting panelists	Qualification and representation of panelists to support claims panel has expertise in how students learn and progress in domain and what it looks like as students reach proficiency and beyond
	Justification for PLD development framework	The approach chosen should be justified and the learning science paradigm made explicit
	Panelist training	Surveys indicate panelists understand the framework and have been sufficiently trained
	Appropriate contribution from panelists	Panelists' contribution, discussions, points of consensus, and compromise should be documented; panelist surveys
	Proper implementation	Documentation of implementation compared to workshop design: agenda, panelist surveys, PLD creation development templates; training framework
	Panelist confidence	Survey at end of panelists' confidence in process, quality, and successful implementation of development framework
Internal	Sufficient interpanelist consistency	Points of disagreement among panelists should be addressed and effectively moderated to achieve consensus or compromise
	Decreasing variability across rounds	Panelists' judgments should converge throughout the PLD development process via consensus building
	Consistency across independent panels	PLDs from two independent panels should have multiple points of consistency and few points of difference; document through qualitative comparison
	Consistency across panel subgroups	Reasonable panelist characteristics (e.g., teacher vs. researcher, assignment to different discussion groups during PLD session) should not impact
External	Expert reviews	Expert reviews should confirm evidence from learning sciences is found within PLDs; expert reviews of PLDs should confirm utility for item writing
	Teacher review	Resulting PLDs should be reviewed for interpretability by a separate panel of teachers or through a public review
	Reasonableness	Overall, is the process reasonable, defensible, and free of fatal flaws?
Procedural	Care in selecting designers	Qualification and representation of panelists to support claims that panel has expertise in how students learn and item design
	Justification for task model development framework	The approach chosen should be justified and the grain size of and intended design patterns for item types made explicit in cases where design patterns are not created for all item types
	Designer training	Surveys indicate that designers understand the intended goals and outcomes of design patterns and have been sufficiently trained

Category of Evidence	Criterion	Potential Evidence for PLDs
	Appropriate contribution from designers	Designer contribution, discussions, points of consensus, and compromise should be documented; designer surveys
	Proper implementation	Documentation of implementation compared to planned design: agenda, surveys, creation of design patterns; training framework
	Designer confidence	Survey to assess designers' confidence in process, quality, and successful implementation of development framework
Internal	Sufficient consistency	Points of disagreement among designers should be addressed and effectively moderated to achieve consensus or compromise
	Increased confidence across iterations	Iterative feedback should increase in perceived utility for consensus building
	Consistency across subgroups	Designer characteristics (e.g., teacher vs. researcher, assignment to different grade levels) should not impact quality of outcome
External	Expert reviews	Expert reviews should confirm that evidence from learning sciences is found within design patterns; expert reviews of design patterns should confirm utility for item writing
	Reasonableness	Overall, is the process reasonable, defensible, and free of fatal flaws?
Procedural	Care in selecting item writers	Qualification and representation of item writers to support claims item writers have expertise in the item writing and subject area and grade level assigned
	Item-writer training	Item writers are trained on the use of design patterns and show evidence of being sufficiently trained (e.g., can diagnose features not included in item that should be for a specific achievement-level target) before being allowed to develop items independently
	Proper implementation	Artifacts of training implementation including training framework, practice materials, feedback, and training recordings are collected
	Item-writer confidence	Survey at end of item-writer training to show confidence in process, quality, and readiness to move forward
Internal	Sufficient intraitem writer consistency	Item writer shows evidence of developing and/or identifying intended item features to match PLDs, including appropriate item types for descriptors, and receives feedback when needed
	Increased confidence across iterations	Item writers' feedback on perceived utility should increase as process is implemented
External	Expert reviews	Expert reviews should confirm evidence of training is sufficiently robust; expert reviews of prototype tasks should confirm utility for item-writer training
	Reasonableness	Overall, is the process reasonable, defensible, and free of fatal flaws?

Note. PLD = performance-level descriptor. Adapted from "Innovations in Setting Performance Standards for K–12 Test-Based Accountability," by K. Huff and B. Plake, 2010, *Measurement: Interdisciplinary Research and Perspectives*, 8(2), 130–144.

Grade 6- RL.3 <i>Describe how a particular story's or drama's plot unfolds in a series of episodes as well as how the characters respond or change as the plot moves toward a resolution</i> <i>Analyze how and why individuals, events, or ideas develop and interact over the course of a text.</i> Central aspect: • <i>Items measure students' ability to analyze how characters change as the plot moves toward resolution. Elements may also include how a plot unfolds in episodes</i>		
Item Measuring CCLS RL.3	Yes/No	If "No," Explain or Describe
Measures central aspect: (PL 1–2) The item requires identification of the change in a character as plot unfolds. Possible stems may include: Stem: How does character X change in lines XX–XX? Stem: Which of the following best describes the change in character X in lines XX–XX? Stem: What does line X reveal about a character? OR Measures supporting aspect: (PL 3–4) The item requires analysis of change or shift in plot Possible stems may include: Stem: The change/shift in lines XX-XX develops the plot by Stem: Which lines from the story show the character's change from X to Y?		
The item stem does not reveal: • the interaction of elements • the key change/development of characters Unless the interaction is identified in the stem intentionally		
The analysis in the item is supported by the text (i.e., there is development of story elements)		
The item requires students to comprehend the majority of the passage to answer the item correctly		
THE ITEM MEASURES THIS STANDARD

Note. From “Large-Scale Standards-Based Assessments of Educational Achievement,” by K. Huff, Z. Warner, and J. Schweid, in A. A. Rupp & J. P. Leighton, (Eds.), *The Handbook of Cognition and Assessment: Frameworks, Methodologies, and Applications* (pp. 397–426), 2017, Wiley–Blackwell.

PAD is employed, post hoc alignment studies are largely obsolete because the evidence of alignment is produced as part of the design process.

For example, in PAD, items are designed to measure a specific performance level of a learning standard in the RPLDs, and this level is documented. It is best practice that after items are developed, they are reviewed by parties external to the design team, such as some combination of classroom teachers, content domain experts, pedagogy experts, accessibility experts, and experts in cultural and linguistic responsiveness. As part of their review process, the experts could indicate with which RPLD level the item best aligns. These data could be analyzed for interrater reliability. This alignment evidence can also serve as a way to identify areas where more work may be needed; for example, low interrater reliability estimates for particular items can spark the same types of discussions among the design team as when psychometric analyses reveal where along the scale the item locates and whether that location is as intended.

Post hoc alignment studies may still have a defensible role in instances where assessment items were originally designed to meet one set of learning standards, and because of cost and/or time constraints, the items need to be examined for alignment to a revised or different set of learning standards. This is especially true in the state testing context because learning standards tend to change frequently, in either superficial or meaningful ways, as a consequence of leadership changes and political reasons rather than in response to new learning science research. Most states require alignment studies that show that items designed for a previous or different set of learning standards can be used with confidence to assess their new or revised learning standards because assessment design is expensive, and in the K–12 context, the cost ultimately falls on the shoulders of taxpayers.

In addition, many states—even if alignment evidence via a PAD process is compelling—may still require an alignment study conducted by an independent evaluator using conventional alignment methodologies in the short term, such as Webb (2005). No matter whether alignment is engineered from the outset or a study is done post hoc, the notion of what constitutes alignment needs to broaden to one of coherence across all aspects of assessment design: learning standards, RPLDs, item design specifications, scale properties, and interpretations about what students know and can do.

Evidentiary Argument Summary

In summary, when we engage in PAD we are defining our inferential argument and collecting evidence for our evidentiary argument from the beginning of the design process, which makes creating and collecting evidence for our validation argument an ongoing endeavor, rather than a set of post hoc analyses. In PAD, evidence comes in a variety of forms and represents a broader conception of evidence than the conventional narrow definition that evidence is equivalent to the data that are collected from administered items and analyzed psychometrically. We assert that the assessment industry should hold the assessment design process to the same kinds of scrutiny that we do our psychometric analyses and other judgmental-based processes, such as standard setting.

ASSESSMENT DESIGN: LOOKING AHEAD

Assessment designers and measurement professionals in the early 21st century are extremely fortunate to have several challenging and interesting problems to solve with emergent innovations. As demand grows for more rapid feedback that supports valid inferences about students and is instructionally actionable, there is growing interest in “stealth assessment,” smart games, and other mechanisms by which to leverage technology to seamlessly integrate learning and assessment in engaging ways for students (DiCerbo, 2014; Hong et al., 2019; Kim & Shute, 2015; Petrusel, 2014; Shute & Ventura, 2013; Young et al., 2011).

On a related note, at the time of this writing, the proliferation of assessment products flooding the marketplace that use one or more families of models lumped into the broad category of artificial intelligence (AI) is staggering. The models undergirding these products are developed by and large without the benefit of any assessment design

or psychometric theory and practice. The ways in which this evolution will change the field and the industry are unknown. If that were not sufficiently challenging, there is a growing desire for novel constructs to be incorporated into these blended learning and assessment systems. The scientific practices of the NGSS (e.g., developing and using models, planning and carrying out investigations) and the ACT Holistic Framework for Education and Work Success (e.g., collaborative problem-solving, sustaining effort) are examples of increasing complexity of learning and assessment needs. As the complexity of targets of measurement increases, the case for using PAD becomes stronger. It is hard to imagine a compelling validity argument without a transparent chain of inference that links all of the essential components together—for example, targets of measurement, RPLDs, items, scale properties, intended score inferences—coherently and elegantly.

Three related challenges will need to be addressed before we can realize the full potential of integrated learning and assessment and the potential of AI to revolutionize learning and assessment writ large. As we will argue, these issues cannot be addressed, much less solved, without a commitment to PAD. First is the use of accessibility features and the relationship of these features to the targets of measurement. Second is the evolution from ensuring that assessments are fair for all students and devoid of bias to assessments that reflect and value the diversity of cultures that our students represent. The third issue is the emergent focus on student motivation and engagement as it relates to estimates of their proficiency. The role of student motivation and engagement in assessment is made especially complex when considered alongside accessibility features for students with a variety of disabilities, as well as culturally and linguistically responsive assessments for students from our historically marginalized populations. These complex relationships need to be examined particularly closely for assessments that may not carry the same gravitas for students as assessments that contribute to their grades, promotion, placement, or other stakes that are important to students, such as interim assessments, assessments embedded in instruction, or other game-based or stealth assessments.

Accessibility and Cultural and Linguistic Responsiveness

It is beyond the scope of this chapter to give full treatment to the topic of accessibility, accommodations, and fairness or, as fairness is treated with a more contemporary perspective, cultural and linguistic responsiveness, in educational assessment. Other chapters in this volume are dedicated to a full treatment of these topics (see Zwick and Rodriguez & Thurlow). These issues are addressed here in light of the challenges that remain to be addressed in assessment design and development to ensure our assessments are accessible and responsive to the cultural and linguistic diversity of the students whom we serve. That said, the research and practice in these areas are developing rapidly and whatever is articulated here in 2025 is likely to be out of date in the next year or so. Nonetheless, we include examples here of how, without the precision and transparency demanded by the PAD process, incorporating accessibility and culturally and linguistically responsive features could jeopardize the validity of the inferences about what students know and

can do. As we have demonstrated in this chapter, PAD forces the detailed articulation of the assumptions about the intended targets of measurement and the intended inferences, and the resulting design specifications can be used to support decisions about accessibility and culturally and linguistically responsive features such that inferences about students from different populations are as free of interference as possible.

Let us begin with an example of an item from a standards-based, adaptive, computer-based interim assessment whose primary purpose and use is to inform instruction through categorizing students at the most beneficial point along an instructional pathway given their strengths and weaknesses in the target domain. The example item in Figure 7.17 illustrates an item designed with keen attention to both the National Center on Educational Outcomes recommendations to ensure that universal design for learning is applied to assessments and the WCAG (W3C, 2018) guidelines for accessibility features for items delivered via the Internet. These guidelines include but are not limited to simple, clear, and intuitive instructions and procedures, maximized readability and comprehensibility, and maximized legibility (National Center on Educational Outcomes, n.d.). Other features from WCAG guidelines include the following:

- strong color contrast between the shape and its background
- additional black outlining around the edges of the shape for added visual definition
- bold font used for answer selection; color contrast between black font and white background
- the mathematical expression is not an image so that an automated screen reader can read it aloud
- alternative text is included for this image so that a screen reader can be used for students who are visually challenged; for example, “A rectangular prism that is shaped like a shoebox. A legend indicates that $l = 7$, $w = 3$, and $h = 2$.”
- keyboard navigation allows the student to use the keyboard arrow keys to move from element to element in the correct order; therefore, a student using a screen reader will hear the many elements in this order and can navigate forward and backward between elements as needed:
 - the stem
 - the expression
 - the alt text describing the prism and the variable values
 - the four answer choices in the order shown on screen
- Spanish transadaptation

This example of accessibility features is rather straightforward. However, the line between accessibility and infringement on the intended target of measurement can blur, for example, with the addition of an audio option for reading aloud the text, item prompt, and response options that is included for many assessment items and available to all students—even those who do not have difficulty processing written text or visual impairment. An audio option likely would not interfere with the intended target

The expression shows the surface area of a rectangular prism with length l , width w , and height h . What is the value of the expression when the variables have the given values?

$$2lw + 2wh + 2lh$$

$l = 7$
 $w = 3$
 $h = 2$

78 82 72 84

AL_L6_677
Answer: Correct

Done →

La expresión muestra el área total del prisma rectangular con la longitud l , el ancho a y la altura h . ¿Cuál es el valor de la expresión cuando las variables tienen los valores indicados?

$$2la + 2ah + 2lh$$

$l = 7$
 $a = 3$
 $h = 2$

82 84 78 72

AL_L6_677
Answer: Correct

Acabé →

FIGURE 7.17

Example Item in English and Spanish to Illustrate Accessibility Features

of measurement for a straightforward math item like the one shown above, but would present a conflict for items that are designed to measure, for example, reading comprehension (as opposed to comprehension regardless of receptive mode). Without rigorous interrogation and documentation of the assumptions undergirding each assessment design choice, such as the kind demanded by PAD, we risk sloppy measurement and, as a result, flimsy arguments supporting our claims about what students know and can do when accessibility features are part of the item design.

Items are designed to be fair to all students (e.g., to avoid terms that privilege particular students when the concept or term is not the target of measurement) and are typically reviewed by independent panels to help ensure the items are free of sensitive topics or content (e.g., item-writing guidelines typically indicate that certain topics that could upset students be avoided, such as hurricanes or death) and bias (e.g., items do not include images or terms that portray students from marginalized communities in stereotypical or derogatory ways). At the time of this writing, our conventional notions of what constitutes fairness, sensitivity, and bias are being deeply interrogated as the assessment industry catches up with what pedagogy, curriculum, and instructional scholars and practitioners have known for quite some time: being responsive and inclusive of students' cultural and linguistic diversity matters in the learning endeavor (Gay, 2000; Hammond, 2015; Paris & Alim, 2017). In short, to be authentically culturally and linguistically responsive, we must rethink what is construct relevant and irrelevant and what is and is not sensitive to various populations (Randall, 2023; Solano-Flores, 2023). Hollie (2018) noted that Hollie (2012) defined culturally and linguistically responsive teaching as "the validation and affirmation of the home (indigenous) culture and home language for the purposes of building and bridging the student to success" (p. 23). In this context, culture has a broad definition and meaning; Hollie's work defines culture along multiple dimensions: ethnicity, sexual orientation, nationality, socioeconomic status, religion, gender, and age. For example, gardens are a favorite context for math items. Rather than having the context be a backyard (typical of suburbs) for every item that uses a garden, make sure that there is a broader spectrum of representation that includes farms (rural areas), community gardens (urban areas), and gardens from other cultures (e.g., terraced gardens from Indonesia). Another more poignant example would be to ensure that our assessment passages do not erase the lived experiences and histories of students from marginalized communities. For example, in a reading comprehension assessment where the passage topic is, for example, the 1893 World's Fair, a passage that only celebrates the wonder and achievements of the fair but fails to mention that luminaries Frederick Douglass and Ida B. Wells protested the exclusion of African Americans from exhibits (Duster, 1970) erases the history, and therefore the culture, of Black students in classrooms today. As we expand our contexts to be more responsive to and reflective of our ever-diversifying student body, we will need to

grapple with the inherent tension of attending to culturally and linguistically responsive content and contexts while simultaneously adhering to accessibility and sensitivity guidelines that steer item writers away from anything that may be potentially context rich or controversial. These debates must occur with a shared understanding of the target of measurement and what constitutes construct-relevant and construct-irrelevant variance. As these discussions become more nuanced, the precision, clarity, and transparency that are the hallmarks of PAD become more and more needed.

Engagement and Motivation

The research base on the role of student engagement and motivation in learning and assessment continues to grow. Unless students are engaged in the assessment, they will not be motivated to perform their best, and the assessment results for those students are likely underestimates of what they know and can do. This is a primary concern for many who are questioning what the lack of culturally and linguistically responsive assessments has meant for the achievement results of our students from marginalized populations (Gutiérrez, 2017; Lyiscott, 2019; Randall, 2021, 2023; Solano-Flores, 2019, 2023). For interim assessments designed primarily to inform instruction, rather than to assign grades, lack of engagement and motivation can be a real issue (Wise & DeMars, 2005). As most K–12 testing is slowly but surely moving toward computer-based rather than paper-based formats, and as the promise of blending learning and assessment to become the same endeavor unfolds, assessment design is in need of partnership with user experience designers (UX designers, UX design). User experience, in this usage, encompasses the various elements of design expertise that go into creating effective items, including interaction design, user interface design, art creation and curation, and usability.

Experts in UX design bring a perspective to assessment design that is generally not represented in interdisciplinary teams of psychometricians, content experts, educators, item writers, and learning scientists. Conventional practice would rely on illustrators or photo editors to participate in a very narrow way, such as providing a graphic as part of an item stimulus after an art specification has been defined by the item writer, which is a questionable practice given that said art specifications could benefit greatly from trained UX designers. However, UX designers, when part of the team from the start of the assessment design process, can help us think through the student experience of the assessment in new and compelling ways. The basic goals of UX design are to create an experience that identifies and meets the needs of the user. Some of the hallmarks of a well-designed experience are simplicity, transparency of goals and actions, clear communication of information, and an experience that is enjoyable to use. These goals translate to the experience of student assessment as well. There are more points of entry for UX design to partner in a computer-based test than a paper-based test, but UX designers also have perspective and expertise to offer in paper-based testing, since the goals and principles of good communication design apply to all media. In computer-based testing, UX designers are concerned

with not only the graphics required for items, but also the student navigation experience—from starting the assessment, to moving between items, to the within-item experience. The goal is to ensure that everything presented to the student and each part of the navigation process is intuitive and does not get in the way of the intended purpose: to optimally measure what the student knows and can do. In other words, the UX designer is just as committed to avoiding construct-irrelevant variance as the item writers and psychometricians. UX designers help assessment designers avoid construct-irrelevant variance through probing the assumptions that undergird item design with questions like:

- Are the interactions clear and easy to use? Are they age appropriate?
- Is the art content accessible and equitable? Does it represent the word, object, or concept in an unambiguous way the student can understand?
- Are there superfluous, decorative, or distracting elements within an artwork that may mislead or inhibit a student?
- Does the experience feel familiar and consistent from item to item?
- Are items designed in such a way that stimulus, stem, distractors, and answer areas are consistent across item types so that a student needs little time to figure out how to input their answer?
- Does the UX support taking the assessment over one session or multiple sessions?
- Does the user have appropriate context for what they are doing? Do they know why they are doing it?
- Does the hierarchy of content and images within an item inform the student as to where and how to answer the question?

With a PAD approach to assessment design, these types of questions would be considered in the development of the design patterns and the assessment delivery model. A strong partnership with the UX design team will help make these models better.

CHAPTER SUMMARY

Industry Inflection Point for PAD

What might be the future for the use of PAD? Andy Grove, Intel's former chief executive officer, observed, "When spring comes, snow melts first at the periphery, because that is where it is most exposed" (McGrath, 2019, p. 14). Might the same be true of the assessment industry? We might find the future influences on PAD not in the large-scale admissions tests or the state summative assessments, but in the game-based and stealth assessments, the assessment of emerging constructs like three-dimensional science learning, and the assessment of noncognitive constructs such as social-emotional learning.

PAD has been available to the field of educational assessment for over 20 years (Mislevy et al., 2002). Prior to the work of Mislevy and colleagues, the foundational concepts

for PAD were described by other scholars working at the intersection of learning, cognition, and assessment, including but not limited to Lohman and Ippel (1993), Nichols (1994), Embretson (1998), Pellegrino et al. (1999), and Snow and Lohman (1989). The use of PAD appears to offer many benefits to assessment developers and users. Yet, PAD does not enjoy widespread use in operational educational assessment design and development. Pieces have been implemented here and there in organizations and testing programs. For example, a version of PAD (ECD) was used in the design of the National Board for Professional Teaching Standards (Pearlman, 2008a) and the Test of English as a Foreign Language (Pearlman, 2008b). It was also used in the redesign of the AP program (Huff & Plake, 2010a) and by the Cisco learning network (Behrens et al., 2010), and it was required by the 2009 Race to the Top legislation that supported the assessment consortia (U.S. Department of Education, 2010). PAD is also being used by organizations to design assessments to measure the NGSS (Harris et al., 2019; Luecht, 2019). However, at the time of this writing, the authors are unaware of any operational large-scale assessment programs that systemically implement all the essential elements of PAD. The lack of widespread PAD adoption suggests that funders and users currently perceive less value in PAD compared to conventional test development.

The popularity of PAD may be waiting for an assessment industry strategic inflection point to dramatically increase PAD's value to assessment developers and users. A strategic inflection point is a change in the business environment that throws some assumptions into question and upends the basic assumptions of a business model. When this happens, we posit that the perceived value of PAD will outweigh the perceived value of conventional assessment development. Conventional assessment development and psychometric practices yield a sufficient return on investment for test developers. What is needed is a large-scale counterexample that demonstrates that PAD maximizes return on investment in assessment development.

Leading indicators—things that are not yet undisputed facts in an industry—suggest that the assessment industry is creeping toward an inflection point for PAD. A leading indicator for this inflection point is that the constructs of interest are becoming more complex and less approachable using conventional assessment development (Nichols & Huff, 2017). In addition, educators and policy makers in states and districts are increasingly unhappy with both the amount of testing and the quality of educational assessments. As such, we expect educational assessments to simultaneously meet multiple purposes and uses and to be more transparent with regard to their quality and meaningfulness in teaching and learning. Finally, assessment designers are under pressure, and rightfully so, to make sure our assessments are accessible to all students, are culturally and linguistically responsive, and are engaging to boot. The testing industry has the power of technology on its side in meeting these challenges, especially as it becomes easier for interdisciplinary teams to collaborate remotely. In addition, learning science research is occurring at a rapid rate that helps us design assessments that better support inferences about what students know and can do. Taken together, maybe there is an inflection point on the near horizon.

The arrival of inflection points is difficult to predict. For example, Reed Hastings, the founder of Netflix, waited and waited for the inflection point for the online streaming model. As Hastings explained,

In 1997, we said that 50% of the business would be from streaming by 2002. It was zero. In 2002, we said that 50% of the business would be from streaming by 2007. It was zero. . . . Now streaming has exploded. . . . We were waiting for all these years. Then we were in the right place at the right time. (McGrath, 2019, p. 79)

Similarly, Mislevy et al. (2002) were anticipating an inflection point in the testing industry over 20 years ago:

Standard procedures for designing and carrying out assessments have worked satisfactorily for the assessments we have all become familiar with over the past half century. Their limits are sorely tested today. The field faces demand for more complex inferences about students, concerning finer grained and interrelated aspects of knowledge and conditions under which this knowledge can be to bear. Advances in technology can provide far richer samples of performances, in increasingly realistic and interactive settings; how can we make sense of this complex data? And even with familiar assessments, cost pressures from continuous testing and social pressures for validity arguments demand more principled assessment designs and operations. (p. 126)

The philosophical orientation, practices, and procedures of PAD must be fully embraced and operationalized by each organization and each individual within who is responsible for designing and developing assessments of educational achievement, whether blended with instruction, interim, or summative. Our students, parents, teachers, principals, district staff, state educational leaders, and the public whom we serve deserve our best efforts to support the educational endeavor. Conventional approaches to educational assessment do not represent our best thinking and our best work; we can do better and we must.

ACKNOWLEDGMENTS

The authors would like to thank the editors and reviewers for their thoughtful comments and questions that made this chapter—and our thinking—crisper and clearer. Special gratitude goes to our mentors and pioneers in assessment design Mari Pearlman, Linda Steinberg, Ric Luecht, Steve Ferrara, and Bob Mislevy. We are grateful to Eli Mintzer for formatting the figures.

NOTES

1. We believe that classroom assessments could also benefit from principled assessment design principles and practices, but that is beyond the scope of this chapter.
2. For the purposes of this chapter, we are addressing students who take generalized assessments. Alternate assessments for students with the most significant cognitive disabilities are discussed elsewhere in this volume, including by Lane and Marion (in relation to validity) and Rodriguez and Thurlow (in relation to fairness).
3. For the purposes of this chapter, *task* and *item* are used interchangeably.
4. This chapter uses the term *item writer* to refer to all contributors to item development; however, in practice item writer generally refers specifically to those who write initial drafts of items. Most of the work attributed to item writers in this chapter is performed by content development professionals who shepherd those initial item drafts through the full item development process, which includes an iterative cycle of review and editing. These educational measurement professionals often have titles like *content specialist* or *editor*.
5. “Off the shelf” is an industry term that refers to tests developed for use in any state, regardless of the learning standards in the state.

Test Administration and Scoring

Mark D. Shermis

Performance Assessment Analytics

Allan S. Cohen

University of Georgia

Jordan M. Wheeler

University of Nebraska–Lincoln

The first four sources of validity evidence described in the *Standards for Educational and Psychological Testing* (Standards; American Educational Research Association [AERA] et al., 2014) focus on test content, response processes, internal structure, and relations to other variables. Each of these sources is heavily dependent on test administration and scoring. During test administration, the test taker interacts with the test; the presentation of the items should reflect the test content as intended by the test developer. And the test-taker interaction with the test should support the expected response processes. Item scoring should also align with the expected scoring behavior by the test developer and enable the analysis of data in support of validity. Ultimately, test administration and scoring procedures should support the intended interpretation of test scores. When test administration or scoring problems occur, they can undermine the validity of score inferences.

This chapter focuses on current and emerging practices in test administration and item-level scoring. We start by addressing the role of test administration in the assessment process and how to maintain the integrity of test administration through test security. Then, we discuss the role of human and machine-based scoring systems, provide examples of several machine-based scoring systems, and illustrate new technologies for determining text and speech content. Finally, we provide research results on machine scoring systems, suggest how to frame issues of reliability and validity for machine scoring systems, and reference how this technology is making inroads internationally.

TEST ADMINISTRATION

Four aspects of test administration support the validity of test score inferences: (a) the role of standardization, (b) test administration modalities, (c) test accommodations, and (d) nonstandard test administration.

The Role of Standardization

Standardization means that the test administration and scoring are applied consistently across all test takers. As noted in the *Standards*, “When directions, testing conditions, and scoring follow the same detailed procedures for all test takers, the test is said to be standardized” (AERA et al., 2014, p. 111). Standardization is intended to provide all test takers the same opportunity to demonstrate their competence and ensure that the interpretation of score(s) is the same for all test takers taking the same or different forms of the test.

The *Standards* (AERA et al., 2014) also take into account, however, that not all test takers may be able to demonstrate their competencies using the same procedures. Therefore, proper interpretation of standardization acknowledges that the same testing conditions may not be appropriate for all test takers. For example, test takers who receive extended time or have someone read the items to them as a test accommodation do not have the same testing conditions as test takers who do not receive these accommodations. In such cases, it is critical to specify, support, and ensure testing procedures

that provide all test takers with an opportunity to demonstrate the same knowledge, skills, abilities, or other competencies concerning the construct being measured. That is, ensuring the same construct is measured under such necessary differences in testing procedures is a significant concern. It is the responsibility of the test developer and administrator to anticipate such differences and to analyze their impact on the interpretation of test scores (see, in this volume, Huff et al., Zwick, and Rodriguez & Thurlow).

Standardization is intended to reduce construct-irrelevant variance due to differences in test administration procedures. For example, suppose familiarity with equipment or items used in the test administration is not part of the measured construct but may impact test takers' ability to demonstrate their competency. The principle of standardization requires that test takers be familiarized with the equipment or items prior to taking the examination. Further, it is necessary that those administering the test be familiar with the equipment or items and be trained to provide test takers with experiences that familiarize them with the equipment or items. Even when testing programs have attempted to make performance comparable across different testing environments, such as paper-and-pencil versus computer administration, meaningful differences may persist (Mazzeo & Harvey, 1988).

If appropriate variations in testing procedures cannot be supported, then it is possible the test may not measure the same construct(s) across test takers, thereby affecting the interpretation of results. The test developer and administrator need to anticipate such differences and, where necessary, provide appropriate interpretation modifications. Under the conditions for which this cannot be done, the test developer needs to note that standardization is likely to be affected; differences in interpretation should be described in the construct(s) being measured and interpretative materials should be provided recognizing such differences.

Test Administration Modalities

The typical steps involved in administering a group-based standardized assessment include some or all of the following: assigning test takers to tests; securing testing space, materials, and staff; staff training including proctoring and test administration procedures; checking in and seating of test takers; storing electronic or paper exam materials before administration; administering the test; monitoring and proctoring of test takers, including managing breaks and emergencies; checking test takers out from their session; irregularity reporting; distributing, collecting, and storing electronic or paper exam materials following the examination, and test item scoring and test scoring (Cohen & Wollack, 2006). Until recently, most large group testing programs used some type of paper-and-pencil administration. Computer-based testing, while not a new field (e.g., Jensema, 1974; Lord, 1977; Schmidt et al., 1978) has more recently begun to be implemented in an increasing number of large-group standardized testing programs. Developments in the statistical foundations for computer-adaptive testing (e.g., S. Wang et al., 2019), for example, have resulted in increased use in large-scale testing (S. Wang et al., 2016), as has the availability of computers and Internet access.

Despite the differences in test administration modality, however, there are variations in administering a large-group computer-based testing program compared to those in previous paper-and-pencil testing programs. These variations may come in the form of longer testing windows, standardization across multiple testing platforms, training of test administrators, use of technology-enhanced and -enabled test items, automated tools around accommodations, dynamic forms design via adaptive testing or linear on the fly, more sophisticated cheating detection algorithms, the development of procedures to handle situations where testing is interrupted (i.e., electrical outages), computer-based scoring and distributed scoring, and faster reporting. Most large-scale testing programs have a computerized version of their assessment (Mills et al., 2005). Importantly, the use of computer-based testing supports innovative item types and thereby the ability to assess test takers against the construct in ways that paper-based methods cannot support; these item types may better assess the intended constructs and expand the constructs being assessed. The use of innovative item types may align with the increased use of computers in test taker's daily lives as well as increase test takers' engagement and interest in the test. This may in turn result in test results that better reflect test takers' knowledge, skills, and abilities.

Monitoring of test takers has typically been done in person. However, the testing industry is increasingly relying on technology to assist with proctoring because it provides the ability to expand the pool of proctors and because it offers additional tools to detect potential cheating behavior. Some testing organizations (e.g., Prometric Testing, Pearson VUE) use video cameras for monitoring test takers. Video cameras allow in-person proctors and off-site proctors to monitor test takers, thereby expanding proctors' access to the test administration process. Technology is increasingly being used to monitor and record test takers' responses and to identify potential test security concerns, such as impersonation, accessing unauthorized materials, item theft attempts, or communicating with others (Dendir & Maxwell, 2020; Weiner & Hurtz, 2017).

Testing Accommodations

Issues regarding testing individuals who cannot be fairly tested under the usual administration conditions are covered by Zwick and by Rodriguez and Thurlow (this volume). In this chapter, we briefly discuss the necessity for recognizing that one set of administration conditions may not necessarily provide a fair opportunity for all individuals to demonstrate their competence. For accommodations to successfully level the playing field, in other words, they must be administered according to best practice as defined by research. This chapter focuses on the most common testing accommodations and refers to Zwick and Rodriguez and Thurlow for a fuller discussion.

Testing accommodations are provided to test takers as assistance in overcoming the effects of disabilities that are not part of the measured construct (Sireci et al., 2003, 2005; Thurlow et al., 2006). Corrective eyeglasses, for example, are an accommodation, although they are rarely considered a testing accommodation. Yet, when a test taker with poor vision is tested without corrective glasses, the measured ability is likely to be

confounded with construct-irrelevant variability due to poor vision. When a necessary accommodation is not provided, construct-irrelevant variability will confound the interpretation of scores to the extent of the impact of the disability. It is important to note that the set of accommodations typically depends on the subject and construct being measured, and the accommodations assigned to an individual test taker can differ based on the subject.

Extended testing time is the most commonly provided test accommodations (Gregg & Nelson, 2010; Lovett, 2010) and one of the most widely studied (Zenisky & Sireci, 2007). Other accommodations such as Braille, large print, sign language interpretation, and having questions read to a test taker are also commonly provided (Bolt & Thurlow, 2004).

Guidelines for the amount of extra time given to accommodate test takers have been provided in the Americans With Disabilities Act (U.S. Government Accountability Office, 2011). How the provision of extra time is handled during test administration is also covered by these guidelines. For example, extended time accommodation for tests using conventional paper-and-pencil format may require separating those receiving the accommodation into a different testing space so that proctors can easily keep track and monitor the students who received extra time. In contrast, computer-based tests can sometimes provide accommodation without moving the test taker to a separate testing room since computer-based tests can incorporate the appropriate amount of time for each student and exit the test once the allowed time is reached.

English language learners with limited English proficiency typically receive some type of accommodation when the language of the test is different from their native language (J. W. Young & King, 2008). J. W. Young and King noted, however, that there does not appear to be a commonly accepted set of accommodations (see also Rodriguez & Thurlow, this volume). One adaptation that is sometimes made in this regard is to provide a version of the test in the native language of the test taker (Buxton et al., 2014; Lazarin, 2006). This may be accompanied by either a translated version of the test or a dictionary that translates words in the test into the native language. This kind of accommodation assumes that the test taker will be able to understand the question if it is stated in their native language. One concern with this kind of accommodation, however, is that it could introduce construct-irrelevant variance because the language used for instruction is typically different from the language used for the test, which could potentially cause confusion if ideas and concepts cannot be directly translated.

Differential performance of test takers with and without accommodations may be caused not necessarily by the accommodation itself, but by the ability or level of competency of the test takers (Cohen et al., 2005). Evaluating the assessment of the construct needs to be done under each of the different administration conditions for which interpretations of the score are to be made. That is, it needs to be shown that the same construct is measured under each of the administration conditions. The purpose of the evaluation for each of the different administration conditions is to ensure

the comparability of scores obtained from the two administration conditions. For example, the scores produced by students who are given extended time need to be evaluated and compared to the scores produced by students who are not given extended time. Evaluating the effect accommodations have on measuring the construct is a crucial component of establishing test validity and fairness. A variety of methods are used to assess the effect of accommodations, including score-based prediction, differential prediction, differential validity, and criterion-related validity (see Cleary, 1968; Marini et al., 2019; Saka et al., 2022). Ultimately, test developers and test users are responsible for determining the impact of nonstandard procedures on the measurement of the underlying construct.

TEST SECURITY

Test security and detection of cheating are essential in ensuring fairness and supporting the validity of test scores. Violations of test security typically fall into four areas: (a) cheating by test takers and administrators, (b) exposure/disclosure of secure test material, (c) inappropriate test preparation, and (d) inappropriate test administration (Fremer & Ferrara, 2013). Of course, prevention is the first step in maintaining good test security. Having written policies, training test administrators, positively identifying test takers, and creating a secure test environment go a long way toward limiting cheating. In the next section, we briefly review current efforts at detecting threats to test security and different types of cheating.

Statistical Approaches to Detection of Cheating

Generally, a well-prepared test taker should not be surprised at the content on a test (Stroud, 1946). However, cheating could easily arise if the test taker feels unprepared for the test. Cheating is intended to provide the test taker with an unfair advantage, resulting in an inaccurate assessment of the test taker's proficiency (Cizek & Wollack, 2017). Cheating is not new and has been a concern in testing programs for over 2,000 years (DuBois, 1970). In ancient China, which is most probably where large-scale examinations were first administered, test takers used to write answers to questions on undergarments and refer to them during the examination. Most of the research on cheating has focused on high-stakes tests, with somewhat less attention paid to cheating on lower stakes tests.

Wollack and Schoenig (2018) described statistical detection of three types of cheating: (a) answer copying and collusion, (b) preknowledge, and (c) test tampering. Important in all methods for detecting cheating is the consideration of error rates and the recognition that statistical evidence alone is insufficient to support convicting a test taker of cheating. Despite a substantial and ongoing effort at studying methods for detection of cheating, there is no consensus on how to investigate potential misconduct on tests, particularly as it relates to the inclusion of statistical evidence. In this regard, it is crucial to understand the necessity for reporting error rates and aggregating

across multiple sources of evidence rather than sanctioning test takers solely based on statistical information.

Wollack and Schoenig (2018) described five broad categories of cheating detection: (a) person fit indices, (b) copying detection and similarity, (c) score differencing, (d) erasures and answer changes, and (e) response time methods. Cheating detection using person fit indices involves a statistical approach to identifying test takers who do not fit the psychometric model well (e.g., incorrectly answering items the psychometric model expects them to answer correctly and correctly answering items the psychometric model predicts them to answer incorrectly). Copying and similarity detection involve flagging test takers who have suspiciously similar response patterns. Score differencing utilizes compromised test items by identifying test takers whose performance differs between the subset of compromised and uncompromised items. Erasures and answer changes involve identifying test takers who change their answers more often than expected. Finally, response time methods use models to determine the necessary amount of time to answer an item and identify test takers with irregular response times.

Research on person fit indices has tended to show poor power in areas such as detecting answer copying. As a result, relatively little research on cheating has focused on these indices. An alternative to person fit is to compare the similarity of response strings for possible answer copying or collusion. Some of these methods compare only incorrect responses, and others compare the complete response string. In addition to detecting cheating among test takers, some work has been reported using response similarity and integrity of testing rooms or facilities. One caveat with similarity analysis is that it can be challenging to distinguish colluding test takers and test takers who have received the same instruction. Erasure detection methods are only applicable to paper-and-pencil tests, although answer changes have been studied for paper-and-pencil and computer-based tests. Computer-based testing also offers the possibility of providing log-file information that can accurately indicate answer changes.

Response time, initially studied for use in improving item parameter estimates (van der Linden, 2007), has also been studied for possible use in detecting cheating, as in the form of item preknowledge (Meijer & Sotaridona, 2006). One approach using this technique considers the residual estimated response time compared to the actual response time. The assumption in the use of response time is, in part, that a speedy response, given the item and ability characteristics, may indicate item preknowledge.

One variant of preknowledge is inappropriate access to test content. This occurs when test takers harvest or access harvested items from a previous administration of the examination. It can happen when test takers simply write down questions they remember after taking a test and then either use them to prepare for a retest or provide them to other test takers who are preparing for the same or an alternate form of the test. This latter action is considered theft. This is also the case when it occurs as plagiarism (see section “Machine Learning Approaches to Detection of Cheating”). One manifestation of harvesting items occurs when test takers share testing materials in some electronic format, such as from chat rooms or group social media accounts. In

addition to statistical methods for detecting cheating, other approaches such as web crawls, hotlines, auditing test centers, and logging and monitoring systems also have been used (Cizek & Wollack, 2017). These kinds of methods are sometimes helpful to detect some types of cheating, such as harvesting.

Machine Learning Approaches to Detection of Cheating

Some research is beginning to report the use of machine learning methods to detect cheating. Response similarity is one area in which this approach is being reported. Much of the early work on the use of machine learning for cheating detection began in the context of online games (Galli et al., 2011). Cheating in online games is a concern because games can often provide a substantial income stream for game developers (Yeung & Lui, 2008). Blackburn et al. (2014) surveyed STEAM, a large digital game delivery platform, and reported that approximately 6% of the 12 million users had been flagged as possible cheaters. STEAM developed and supports a cheating detection component called valve anti-cheating (“Valve Anti-Cheating Software,” 2020). Cheating is a concern in online games because honest players leave the game site when cheating is present (Alayed et al., 2013).

The increasing use of technology in education and society, in general, has led to the development of serious games (Abt, 1970). Game-based learning provides an important new platform for instruction and testing (Walker & Engelhard, 2014). Serious educational games developed out of this effort (Annetta, 2008) and contain testing components used to assess the game performance of the learner (Annetta & Bronak, 2011). Although some approaches have begun to be developed for detecting cheating in serious educational games (Rosyid, 2018), this is still a relatively new research area that is needed to address the security issues involved.

Recent work on cheating has focused on detecting plagiarism in constructed response items, most notably writing samples. Plagiarism detection is of interest because it is a form of answer copying. It differs from academic research in that use is made of another person’s work (e.g., writing, research) without appropriate attribution, whether done with or without modifying the actual words but retaining the meaning (zu Eissen & Stein, 2006). The possibilities for plagiarism have increased substantially over the years because of the very large number of machine-readable documents available on the Internet that can be used as sources (Alzahrani et al., 2012).

The availability of machine scoring (see section “Machine-Based Scoring Systems”) makes inclusion of constructed response items increasingly accessible for large-group testing. In this section, we consider recent work in machine learning that has focused on detecting plagiarism in documents that are in a machine-readable form. A number of these methods are available via online web applications, some of which are free and some which are not. Because the list of available methods for plagiarism detection is continually changing as machine learning and natural language processing methods evolve, we do not present a list of available methods. However, we suggest that a simple search on the Internet will yield multiple sites with plagiarism detectors.

Plagiarism detection methods generally use some form of document comparison against a database of documents, often using machine learning. In an early work on machine-based plagiarism detection, Shivakumar and Garcia-Molina (1995) described a word frequency method, which compared a new, possibly plagiarized document against a known record. These methods tend to work well when the comparison is made of directly copied text (zu Eissen & Stein, 2006). The use of intelligent plagiarism, whereby portions of the original text have been modified to retain the same meaning but with different words, is more difficult to detect (Alzahrani et al., 2012). Mozgovoy et al. (2010) described an application of a topic model to identify documents that contain a large amount of paraphrasing.

A careful consideration of error rates can often be missing from plagiarism detection sites. For example, academic work in a discipline may use the exact words and phrases as previously published research. Journals sometimes use plagiarism detection software to ensure that manuscripts accepted for publication do not plagiarize the work of others. Common wording is characteristic of much research that focuses on the same problem area; however, plagiarism detection methods that make use of common words or strings of words to detect plagiarism can sometimes erroneously result in a finding of plagiarism. As we suggested, software using older plagiarism detection methods can sometimes be circumvented by changing the wording or ordering of concepts.

In the next section, we focus on scoring systems, beginning with human scoring and then moving on to machine-based scoring systems.

HUMAN-BASED SCORING SYSTEMS

Complex items, such as constructed-response and performance-based tasks, often require human raters to score each response following a rubric or guideline. These scores are either assembled with other test scores, provided to the test taker, or used to train automated scoring engines so that not all responses need to be seen and scored by humans. The scores given to these items, however, are subjective by nature since raters need to judge the quality of the responses. When human raters are used to score these types of items, the raters become an essential component for ensuring the reliability, validity, and fairness of scores (McClellan, 2010). Human raters, therefore, often go through rigorous training protocols and methods to ensure that scores are accurate and reflect the construct being measured by the item (Glazer & Wolfe, 2020). Rater training protocols help assessment systems reduce construct-irrelevant variance among scores and increase the consistency of scores across raters (see ETS, 2021; Ricker-Pedley et al., 2020).

The level of rigor applied to rater training methods and protocols depends on the implications of the assessment results. High-stakes assessments often require a rigorous training protocol and different operational raters to score the same response to reduce construct-irrelevant variance, maintain high interrater reliability, and ensure the validity of scores.

General Steps for Rater Training Methods and Protocols

Rater training methods and protocols differ among systems, assessments, and items. These differences are based on multiple factors and include things such as the item type(s), the number of score categories (dichotomous or polytomous), the number of test takers, the context (i.e., low stakes versus high stakes), and the number of resources available. Developing a successful rater training protocol requires careful consideration of the intended use of the assessment because the training protocol will become part of the validity argument for the complex items.

The rigor of rater training methods and protocols depends on the implications of the assessment results. High-stakes assessments often require detailed training protocols and different operational raters to score the same response to reduce construct-irrelevant variance, maintain high interrater reliability, and ensure the validity of scores within and across test administrations (if applicable). However, the rater training methods and protocols follow a few general characteristics/steps (Wolfe & McVay, 2010). These methods and protocols are generally led by experienced raters and involve iterations of facilitated reviews about the correct application of scores. First, raters are provided information regarding the item, prompt, and related material(s). Next, raters review the scoring rubrics and anchor responses that have been annotated and scored. The anchor responses are typically created by content/domain experts for all possible score categories or selected from responses during the pilot phase of an item. Content and domain experts spend considerable time reviewing and discussing anchor responses since these responses serve as validity evidence and reference materials for scoring future responses. The qualifying exams are assessed by comparing the degree of raters' exact agreement and adjacent agreement with expert raters (e.g., 70% exact agreement and 100% adjacent agreement). Typically, raters must complete the training method and protocol to become an operational rater for a particular assessment or item (Bernardin & Buckley, 1981).

Materials and Information Regarding Prompt

Background information about the prompt and item is provided to the raters to ensure that they have a sufficient amount of information regarding the construct(s) being measured by the item. The information provided should demonstrate the breadth and depth of the construct and give raters an idea of the scope of the construct being measured. In addition to information and materials about the construct, raters are provided with materials that may be present in the item, such as source passages, figures, and tables. It is expected that raters fully understand the prompt and any supplemental materials, what is being asked, what construct is being measured, and how provided materials relate (and should be used) to the construct and scores.

Overview of Scoring Rubrics and Examples

Raters are provided with the scoring rubrics for the items and details about each of the score categories. Furthermore, raters are provided with example responses, often called anchor responses, to illustrate each score category on the rubric. These examples

provide adequate detail about the different aspects of the response and how they affect scoring. It is essential that the example responses not only provide information regarding each score category but also provide a wide variety of responses that illustrate the range of quality within a scoring category. Additionally, example responses that are confusing or unscorable are provided to prepare raters for identifying aberrant and unusual answers. These example responses serve as references, or anchors, for the raters as they score new responses.

The raters view the example responses, annotations, and score categories and discuss them, typically in a group setting, with a trainer or an expert rater. This process can take a considerable amount of time and requires strong facilitation skills by the trainer. It is at this stage where raters are being *calibrated* against the rubric.

Practice Scoring Responses

Once raters thoroughly understand the materials related to the prompt, the rubric, and example responses, they apply their trained scoring knowledge to practice responses. The set of practice responses covers all score categories and represents the range of responses within each score category. Each practice response has been previously rated by expert raters, and the scores provided by the raters in training are compared to the scores provided by the expert raters. In addition, the raters are also asked to provide rationale for their score assignment, which is compared to the rationale of the expert raters. During the practice scoring part of rater training, raters are given feedback regarding potential personal biases (e.g., personal feelings toward the question or personal feelings toward a given response) to reduce the construct-irrelevant variance due to these personal biases.

Qualifying Exam

Raters must pass a qualification exam to score responses in an operational setting. The objective of the qualifying exam is for raters to demonstrate that they can accurately and consistently provide scores across all score categories. The qualification exam often consists of a set of responses that aligns with each of the score categories. The set of responses and their alignment to the score categories are determined by experts and typically gathered in field testing or piloting of the item. Raters must achieve a certain level of agreement with the experts to pass the qualification exam (Van Moere, 2013). In essence, the goal of the qualifying exam is to ensure raters are calibrated to the rubric scale. Qualifying exams are often given to raters regularly to ensure that they continue to provide reliable and accurate scores. These exams act as a calibration and monitoring tool for raters and realign their scoring with the rubrics. The qualifying exam is a crucial component in providing a validity argument for the scores because it helps reduce the construct-irrelevant variance caused by raters.

Monitoring Operational Raters

Once a rater completes the training protocols, they are typically monitored in the operational setting through the use of blind validity checks and read-behinds to ensure raters are producing accurate and reliable scores (Engelhard, 2002). Blind read-behinds, or

backscoring, occur when operational responses are randomly selected and routed to expert judges/raters to ensure that the operational rater is providing reliable and consistent scores. If the operational scores differ from the expert raters' scores, the rater is removed from the operational setting and returned to the training protocol.

In addition to blind read-behinds, raters are often monitored over time through performance data and metrics. Validity responses is one monitoring method used at different points during the operational rating process (McClellan, 2010). Validity responses are responses that are scored by expert raters and then randomly seeded into an operational rater's queue. Since operational raters do not know the difference between a validity response and a regular response, the discrepancy between the score provided by the expert raters and operational raters is used as a method for continual monitoring of raters. Other metrics and data are also used to monitor raters, such as the score distributions of a rater and their agreement with other operation raters that score the same response (Engelhard, 2002; M. Graham et al., 2012). Raters can also be monitored through a re-examination of the qualifying exam at the beginning of each scoring session or at various specified time intervals.

Selecting Appropriate Raters

There are many considerations when hiring and selecting raters for particular items and assessments. Some criteria for selecting raters include educational background, subject and domain expertise/knowledge, and prior rating experience or teaching experience. The selection process of raters should also reflect the stakes of the exam. That is, the selection process should be more rigorous for exams with high stakes (Guo & Lei, 2020).

Research on Rater Training Protocols

Much of the early research on raters focused on the various aspects of the training procedure and how it affected score outcomes. Previous research indicates a few things for assessment systems to consider when developing a training protocol to lead to better future outcomes (Wolfe & McVay, 2012). It is important to demonstrate the existence of rater errors, such as leniency and severity of raters, and how to avoid these errors (Bernardin, 1978; Ivancevich, 1979; Uggerslev & Sulsky, 2008; Wind, 2019). Previous research also suggested that training protocols should directly precede operational scoring because it leads to more consistent and accurate scores (Attali, 2019; Roch & O'Sullivan, 2003; Sulsky & Day, 1994). Additionally, repeated practice scoring from the training protocols has been shown to improve the rating accuracy of operational raters (Hauenstein & McCusker, 2017). The attitudes of raters toward the training protocol have also been shown to affect the overall performance of raters (Noonan & Sulsky, 2001).

In addition to the above factors, the type of rater training method can influence rater effects. Two commonly used methods for rater training are the spiral and sequential methods. The spiral method trains raters on multiple items in a single training session.

The sequential method trains raters on a single item per training session, and every new item requires a separate training session. Moon and Hughes (2002) compared the spiral and sequential methods using a set of raters and found that, on average, the spiral method led to more accurate and reliable results from raters.

Measuring Rater Effects

Many psychometric models have been developed to measure the effects of raters, monitor raters over time, and classify raters. One of the first models to measure raters' effect from rater data was the rating scale model (Andrich, 1978). The rating scale model uses a Rasch measurement model with a facet for raters. The locations of the rater facets on the construct provide information regarding the severity of raters. Similar rater effects have also been measured through other latent trait models (e.g., Engelhard, 1994; Patz et al., 2002; Wolfe & McVay, 2012). The accuracy of operational raters can be modeled using an unfolding model known as the hyperbolic cosine accuracy model (J. Wang et al., 2016). The model uses accuracy ratings defined by the agreement between operational and expert raters to identify groups of raters that score similarly. In some cases, rater effects are measured over time by measuring the change in levels of accuracy of a rater or measuring how raters change their use of the score categories (e.g., Myford & Wolfe, 2009; Wolfe et al., 1999). These measurements are known as rater drift effects and are used to monitor operational raters throughout the scoring process.

MACHINE-BASED SCORING SYSTEMS

Machine-based scoring systems run the gamut from mark-sense readers to programs containing sophisticated scoring models of written or spoken work. None of these is “smart” in the sense that it can reason, problem-solve, create, and conclude. But most contain programming for relatively focused tasks that are reliable, modeled after expert (or human) behavior, and very efficient. For mark-sense readers, the programming is associated with determining the location of a “mark” (usually a bubble filled in with a No. 2 pencil) and associating it with a correct or incorrect response. It is sophisticated in that it can adjust for minor location deviations, can determine an intended mark from a stray one, and may be able to ascertain whether the pattern of marks is similar enough to another pattern in the batch to flag it for possible cheating. Algorithms that score essays compare a candidate essay against a model developed from a sample of essays that human raters have scored. The model may contain elements that evaluate grammar, organization and development, mechanics, syntax, and content. It may also be able to detect essays written in bad faith, ones that are plagiarized or off topic, or ones that present threats to self or others.

In this section, we will turn our attention to machine-based scoring applications and technology associated with tests, assessments, and surveys. Investment in this technology is designed to evaluate performance in a valid, reliable, and cost-effective

manner. Much has been accomplished, but there is a long way to go. The fourth edition of this volume reviewed the development of mark-sense readers, optical mark recognition, optical character recognition, and intelligent character recognition (Microsoft Corporation, 2022), and the reader is referred to that edition for more information on these long-standing devices. Consequently, we begin with a short review of more recent unique technologies that can assist in the delivery and data collection of performance assessments.

Data Capture

Many entry modes exist for written responses to an assessment. For computer-based assessments, the traditional mechanism is to type an answer on the keyboard. However, this requires that test takers have the ability to type. A tool for converting text into electronic forms is entry via tablets or touchscreen computers. In this case, a user would write the (block-written or cursive) text using a stylus on a screen that is simulated to look like paper or a test form. The text is then postprocessed and converted to electronic format. There are two advantages of using this approach over processing paper-based written text through intelligent character recognition. First, the response is converted directly to text rather than undergoing a separate scanning procedure to convert it to a scanned image for intelligent character recognition. Second, and importantly, the test taker can review and edit the results of the text conversion. Third, the design of the simulated paper corrects for skew or layout challenges. Most programs check for transcription errors through spellcheck, though sometimes errors can be introduced or inappropriately flagged by machines. For example, it is not uncommon for young children in the United States to write exclusively in block text (Loewus, 2016). Many of these individuals will write in all capitals. Spellcheck may flag words written this way as incorrect. Once converted, the text can be self-edited by the test taker, reducing errors that might be inadvertently introduced by postprocessing.

With speech recognition technology, dictated speech is converted into text as part of a transcription process or as part of the construct itself (e.g., English learner speaking assessment). This may be done as a testing accommodation or in generating a report that might, in its original form, be oral in nature (e.g., dictating the results of a dissection while the dissection is occurring). Alternatively, it may allow those who do not possess sophisticated keyboarding skills (e.g., young children) to express their performance orally but be processed or audited in written form. Many word processors support dictation (e.g., Microsoft Word), which has reasonable recognition accuracy rates (W. Xiong et al., 2018). The accuracy rate may be improved by “training” the processing engine to adapt to the speaker’s pronunciation and meter. The engine’s performance may also be enhanced by providing supplemental dictionaries. So, for instance, the dictation programs for radiology may have increased recognition rates by focusing on a more restrictive or specialized vocabulary (Ghai & Singh, 2012).

Data Integrity

The technologies described above come with varying degrees of accuracy and reliability. While long-standing devices such as mark-sense scanners are highly reliable, it is possible to introduce artifacts with even something as simple as this technology. The scanner may pick up stray marks made by the test taker, or the medium used for marking the answer sheet may be inappropriate (e.g., using a red pen instead of a blue or black pen). It is possible that the test taker changed their answer but did not erase the original answer thoroughly. Consequently, the machine picks up two responses instead of the intended one and has to be programmed for what to do in that situation. This can negatively impact the validity of score interpretation if the programming selects the unintended answer. The printing of the form itself may be skewed so that none of the answers can be accurately scanned. The best first step here is to visually inspect all the answer sheets to ensure that test takers conformed to the marking guidelines. A second check would involve a data validity check. Once the information has been processed, a follow-up can be made to establish that test takers marked their responses within an acceptable range. For example, the scan sheet may allow responses from a to f, but the test only had a response range from a to d. If a test taker marked alternative e, we would conclude that the individual made a mistake, but perhaps for a different reason than if they had selected an incorrect alternative in the range of a–d. A third check would be one that would address the possibility of cheating. In an earlier section of this chapter, we described security software that would estimate at a particular confidence level whether the answers had been copied.

Many data capture mechanisms perform a quality assurance check in the processing software. If the processing/scoring software encounters a character it does not recognize, it will flag it, display the original handwriting, and ask an operator how to proceed with processing the response (Microsoft Corporation, 2022). The optical character recognition operator will then supply the correction. It is possible to take samples of the same writing sequence and ask multiple operators to correct the same sequence of “flags” as a measure of agreement. Even then, those scoring the written responses may have to make a series of deliberate decisions about how best to modify (or not) the writing for scoring. For example, part of the algorithm that prompts the software to flag a response may be word misspellings if it took the most likely character representation as the correct one. Alternatively, the expected language for transcription might be English, but the writer included Spanish words or phrases. These words or phrases would likely be identified as errors unless a correction (or compensating algorithm) is in place. An important decision affecting the construct measured is whether spelling and punctuation errors are corrected or maintained during transcription or whether spelling and punctuation are even part of the construct. When handwriting is transcribed through a tablet, the test taker has the option of self-correcting words through immediate feedback. However, the question of how the writing might be modified to process it for scoring remains the same.

Processing oral (i.e., dictated) responses has its own data integrity challenges. The tolerance levels for accents differ depending on the software used, the spelling of the response is assumed to be correct, and each language has its quirks. For example, English requires the transcription software to determine the unique context of homonyms (e.g., to, too, two). In other languages, the same word can mean multiple things depending on the speaker's inflection. Moreover, it is important that punctuation be accurately accounted for so that the beginning of sentences is properly accounted for. The only way to determine the machine transcription or scoring accuracy is to validate it against a human rater or have the speaker review the transcription and make corrections. The software employed to transcribe or score responses from handwritten or oral responses can usually place a confidence estimate as to how likely the response was transcribed or scored accurately. These estimates can be validated against empirical evidence collected from human-scored responses for reliability and/or validity estimates. There is some evidence that children with learning disabilities benefit from dictating their responses rather than typing or writing them, especially for extended responses (MacArthur & Graham, 1987).

Interactive Computer-Based Systems

Computer-based innovative test items are designed to achieve a variety of outcomes. They may have a performance-based component that cannot be captured through a more traditional display of items (e.g., math items with formulas or graphing items), they may be designed to be more engaging or motivational, or they may be created to capture a repetitive behavior or action that could not otherwise be obtained (Parshall & Harmes, 2014). Scores may be validated using processes such as *rubric validation*, whereby content experts interact with the item to understand how it is scored or observe patterns of scoring in live data either randomly and/or in a targeted manner to determine how outliers are managed and typical responses are managed, etc. Scoring rules are defined by content experts and tested by them.

In a “hot spot” item, the test taker is asked to click on or touch the screen area that represents his/her response to a question or task. This is illustrated in Figure 8.1.

Figure 8.2 is an example of a “drag-and-drop” type item. It is similar to matching-type questions, except that it relies on a visual stimulus as the stem. Its main advantage is that test takers can visually confirm their choices, and the task is slightly more enjoyable than simply matching two columns of information.

Audio prompts can be used interactively with a computer in various settings. For example, audio prompts are employed in the College Board Advanced Placement Music Theory Exam, where the test taker is played a short music sequence and asked to transcribe it to a staff (College Board, 2021). Used in this way, the audio prompt played from a computer may facilitate the individualization of the process compared to playing the music to a group of test takers from an MP3 player.

A video prompt may use video imagery to convey prompt content in a way that would not adequately be described or addressed by words alone. In Figure 8.3, the student is

**FIGURE 8.1****An Example of a Hotspot Question**

Note. From "Improving the Quality of Innovative Item Types: Four Tasks for Design and Development," by C. G. Parshall and J. C. Harnes, 2014, *Journal of Applied Testing Technology*, 10(1), p. 7.

asked to imagine that they have been shrunk inside their classroom. You might elect to use a video-based stem if you believe that the imagery conveyed the situation or task more clearly. Or perhaps the modality would make the task more accessible if you thought that performing it would be hindered by an overreliance on reading ability.

It could be argued that the text sufficiently defines the writing task asked of test takers as a writing prompt. However, the video prompt may provide additional context when the experience to be related is uncommon, new, or foreign. Even though the formats we have described have many compelling advantages, multiple-choice items are still the most common type of items administered on computer-based systems (Parshall et al., 2000).

Simulations as a Rehearsal or Demonstration of Skill

While the video prompt may serve as a setup for a performance assessment, it does not provide a responsive environment to demonstrate the desired or proxy skill. Simulations do. Simulation is the imitation of the operation of a real-world process or system over time (Banks, 1998). Simulations may be beneficial when exhibiting the actual skill is costly, dangerous, or may simply require much practice before it is acquired. Airline pilots will show that they can take appropriate steps in an airplane simulator during an emergency rather than employing an expensive aircraft containing live human beings.

Identify the features in this cross-section by dragging the labels into the boxes.

Use the mouse to drag the boxed words into the empty boxes. Alternatively, use the tab key to select an empty box, then use the space key to cycle through the options.

Check

FIGURE 8.2

An Example of a Drag-and-Drop Question

Note. From *Drag and Drop Onto Image*: Screenshot by Moodle, https://moodle.org/plugins/qtype_ddimageortext

In the education environment, science students may practice a frog dissection using simulation software before they perform the actual procedure. Knowing where to make an incision, how to identify and harvest the frog's organs, and techniques for moving from one part of the frog to another are skills that can be realistically simulated and assessed on software before beginning the actual work. The software practice can reduce mistakes and raise the probability of a successful authentic performance. Scoring a simulation can provide more realistic measurement, but only if carefully and properly conceived. Scoring is based on expert-driven rubrics that consider the consequences of making mistakes. Figure 8.4 shows a screenshot of a frog dissection simulation.

Serious-Based Games

As discussed earlier, a serious-based game achieves a learning goal through the demonstration of acquired or refined performance (Krath et al., 2021; Landers, 2014). The term *game* implies that the activity is fun, but the expression *serious* indicates that the purpose of the activity is educational or otherwise enlightening. Assessment data collected through serious games have some advantages over traditional tests in that one can document performance change over time, there are repeated samples of similar behavior, and feedback is immediate. The main drawback is that nonrelevant skills may impact performance. The ability to respond may require computer skills (e.g., ability to use a mouse or keyboard) that are irrelevant to the construct being assessed.

**BOX 1**

A TRANSCRIPT OF THE VIDEO PROMPT

Tell this story.

It's a Friday afternoon and you and two friends walk into the classroom to check on your science experiment. But when you touch the liquid, it bubbles over and instantly shrinks all three of you down to two inches, or about 5 centimeters.

Describe what you will do to survive the weekend.

Where will you find food and water?

How will you seek out shelter?

Will you create a structure? If so, what classroom materials will you use? Will you create your own miniature city?

What hazards do you need to avoid?

What challenges will you face as a tiny human?

What will you do when you're bored? Maybe ride a paper airplane? Create your own sport with string and tape and leftover cardboard?

Describe your adventures as a mini-student. Be sure to use vivid imagery. And consider all the ways you can be creative with your classroom setting.

FIGURE 8.3**A Screenshot of a Video Prompt**

There are five elements of a serious-based game (<https://www.game-learn.com/all-you-need-to-know-serious-games-game-based-learning-examples/>). These include the development of a story, a conversion of the situation to a game, the provision of immediate and individualized feedback, a simulation of engaging behavior, and a learning goal.

An example is the adventure game *80 Days*, as illustrated in Figure 8.5. Loosely modeled after the Jules Verne novel *Around the World in 80 Days*, the players learn geography by traveling around the world, having to plan their trip, making route adjustments as necessary, buying and selling materials in different markets, making health decisions, and achieving their goal in “80 days” or fewer. The degree to which gamers follow the rules of the game and make good decisions is the basis for scoring. “Goodness” may be based on expert-driven rubrics or on some other basis (e.g., efficiency).

ARTIFICIAL INTELLIGENCE SCORING

Artificial intelligence (AI) scoring is the ability of computer technology to evaluate and make score predictions for some type of open-ended performance. The most common machine scoring assessment is for written prose (Shermis et al., 2013), but it has been expanded to short-form constructed responses and speech. The examples in this section are based on these three response modalities. The scoring technology to accomplish this has come under several different names, including its original incarnation, automated essay grading, and one that has been in place since the early 2000s automated essay scoring (AES). It is also referred to as automated essay evaluation or automated writing evaluation. The latter terminology suggests that the technology

**FIGURE 8.5**

A Screenshot From the Serious-Based Game *80 Days*

Note. *80 Days* [Screenshot]. Copyright 2014 by inkle. Reprinted with permission.

can do more than just score essays. For example, several systems are supplemented with natural language processing (NLP) capabilities that can analyze the structure of writing and provide qualitative feedback (e.g., “Your essay appears to be about the role of media in a democracy”) that may or may not be a component of the scoring process. Most of the initial applications have been in English, but development has been reported in multiple languages, including, for example, Japanese (Ejima & Takeuchi, 2022; Ishioka & Kameda, 2006), Chinese (Chang & Lee, 2009; Qian et al., 2020), and Swedish (Lilja, 2018; Östling et al., 2013). (See also Table 8.2 for a more comprehensive list of non-English AES scoring engines.) All but the most enthusiastic proponents of AES suspect that there are forms of writing that will always be difficult to evaluate (e.g., poetry). However, the technology has been applied to the score predictions of multiple genres and populations at various writing levels with some degree of success (Shermis, 2014). It is important to note that machine scoring models may employ some aspects of artificial intelligence in their algorithms or they may be based on static data models (Mayfield & Black, 2020).

In the United States, the technology was spurred on by the initial adoption of the Common Core State Standards (Porter et al., 2011), where one of the goals was to develop assessments that would address higher order thinking skills and encompass more writing. While most states eventually walked back their commitments to the Common Core State Standards and the consortia that promoted them (i.e., Partnership for Assessment of Readiness for College and Careers [PARCC] and Smarter Balanced), many states began to incorporate the general principles of the Common Core in their state standards. This meant that the amount of writing assessed increased and the need

to come up with an economical way of evaluating large volumes of writing came into demand. The first widespread demonstration of the AES technology began with the Hewlett trials of 2012. The Hewlett trials are described in a later section; they marked a new wave of development for AES technologies.

For the most part, AES models are based on human ratings of a sample of essays either generated from a specific prompt (e.g., “prompt-specific”) or accumulated across essays within a particular writing genre and grade (e.g., “generic”). To better understand this process, reviewing an example of a human writing model is helpful.

Rubrics

One of the challenges in creating AI models is that rubrics are often hard to define, vague, and incomplete. In this context, AI refers to the ability of a computer to emulate intelligent human behavior (Simon, 2019). A search for a conceptual definition of “good writing,” for example, is broad and imprecise, and those who assess in that domain end up using operational definitions grounded in rubrics. For the most part, the rubrics are based on characteristics of writing (traits) or components of writing (i.e., analytic scoring; Stiggins & Bridgeford, 1983). One trait rubric is the Common European Framework of Reference for Languages (CEFR; Council of Europe, 2002). The CEFR was formally introduced in 2002 as a collective project of the European Union to establish criteria and assessment procedures for evaluating individual language performance. The CEFR describes language proficiency in reading, writing, speaking, and listening on a six-level scale. It is used for instruction and assessment to create a system that has similar meaning across all languages covered by the European Union. The CEFR is just one popular conceptual framework; there are many others with their associated rubrics (Shermis, 2022).

AES

In these next sections, we discuss products from ETS for automated essay and speech scoring. They were chosen because they are well documented, used in a number of different applications, and highly researched. Table 8.1 lists other English AES systems that are available for use and may incorporate other features. e-rater is an automated essay evaluation by ETS (Attali & Burstein, 2006; Burstein et al., 1998; Burstein, Tetreault, & Chodorow, 2013). The e-rater engine first became operational in 1999, when it was deployed to provide one of two scores for essays on the writing section of the Graduate Management Admissions Test, a high-stakes, large-scale assessment. In conjunction with human ratings, e-rater is also currently used for the computer-based Test of English as a Foreign Language Internet-Based Test (TOEFL iBT) and as a check score (i.e., score from a second rater) for the GRE. In the Criterion Online Writing Evaluation service—a web-based writing tool that helps students plan, write, and revise their essays—e-rater is used to foster the best instructional and assessment practices (Burstein, Tetreault, & Madnani, 2013).

Table 8.1 Comparison of English-Based Automated Essay Scoring (AES) Systems

AES System	Developer	Technique	Main Focus	Instructional Application	Number of Essays Required for Training	Language
AutoScore	American Institutes for Research (now Cambium Assessment)	Natural language processing (NLP)	Style and content	N/A	2,000–3,000	English
Bookette	CTB McGraw–Hill	NLP	Style and content	Writing Roadmap	250–500	English
CRASE	Pacific Metrics (now ACT) (Lottridge et al., 2013)	NLP	Style and content	N/A	100 per score point	English
e-rater	ETS (Burstein et al., 1998)	NLP	Style and content	Criterion	100–1,000	English
Intelligent Essay Assessor	Pearson Knowledge Technologies (Landauer et al., 1997)	LSA	Content	N/A	100–300	English
Intellimetric	Vantage Learning (Elliot, 2003)	NLP	Style and content	MY Access!	300	English Chinese Hebrew Bahasa Malay
Lexile Writing Analyzer	MetaMetrics (Burdick et al., 2011)	NLP	Style and content	N/A	None—uses a fixed model	English
LightSIDE	Teledia Laboratory (Mayfield & Rosé, 2013)	Statistical	Content	N/A	300	English

Note. Adapted from “State-of-the-art Automated Essay Scoring: Competition, Results, and Future Directions from a United States Demonstration,” by M. D. Sheremis, 2014, *Assessing Writing*, 20, 53–76, p. 63 (<https://doi.org/10.1016/j.asw.2013.04.001>).

One of a family of scoring engines used at ETS, e-rater aligns a defined writing construct with NLP methods to identify linguistic features in student and test-taker writing for scoring and evaluation (e.g., diagnostic feedback). Consideration of aspects of the writing construct in earlier system development (Attali & Burstein, 2006; Burstein, Tetreault, & Madnani, 2013) and more recent research and development support the enhancement of the system’s construct coverage about the structure of argumentation (Beigman-Klebanov et al., 2013), discourse coherence (Burstein, Tetreault, & Chodorow, 2013), and vocabulary usage (Beigman-Klebanov et al., 2013). The e-rater software currently identifies and extracts several feature classes for model building and essay scoring using statistical and rule-based NLP methods. These feature

sets are proxies for the more conceptual attributes of a human-based writing construct (Attali & Burstein, 2006).

Feature development and re-evaluation are dynamic, and specific feature variables may vary as the system is updated with new releases. Individual feature classes represent an aggregate of multiple features. The feature classes—the variables of writing that constitute the construct model developed for score prediction—include the following: (a) grammatical errors (e.g., subject–verb agreement errors), (b) word usage errors (e.g., *their* versus *there*), (c) errors in writing mechanics (e.g., spelling), (d) presence of essay-based discourse elements (e.g., thesis statement, main points, supporting details, and conclusions), (e) development of essay-based discourse elements, (f) style weaknesses (e.g., overly repetitious use of vocabulary), (g) two content vector analysis-based (Wolfe & McVay, 2012) features to evaluate topical word usage, and (h) a feature that considers correct usage of prepositions and collocations (e.g., *powerful computer* vs. *strong computer*; Futagi et al., 2008) and sentence variety. The set of features in (h) represents positive features, rather than errors in conventions. Because proper usage of English prepositions and collocations is especially difficult for English learners, the addition of these features also expands e-rater’s ability to recognize characteristics of writing that are important for assessing nonnative writers. Figure 8.6 illustrates the breakdown of the e-rater model. More details about specific features aggregated within a feature class may be found in Attali and Burstein (2006).

Human-assigned scores are used to build e-rater models and are the basis for building models for most of the other automated scoring engines. A randomly selected training sample of at least 250 human-scored essays is processed through e-rater, extracting the features described above. Features are aggregated into conceptually related groups and converted to a vector (Downey et al., 2008) of numerical feature values. Using a regression modeling approach, the values from this sample are used to determine an appropriate weight for each feature (Attali & Burstein, 2006). The same process is performed vis-à-vis feature extraction and conversion of features to a vector format to score a new, unseen essay during a test administration. To compute the final score prediction, these values are then multiplied by the weights associated with each feature, and a sum of the weighted feature values is calculated (Attali et al., 2010). In addition to providing holistic scores using construct-aligned language features, e-rater provides advisories for detecting such construct-irrelevant elements and attempts to enhance the overall score (Higgins et al., 2006). Many features used for e-rater scoring are also used for feedback in Criterion, a portfolio program used for writing instruction. These include the grammar, usage, mechanics, and styles features and the organization and development features described above.

More recently, other scoring engines have incorporated additional feature sets to include predictors such as n-gram vectors (i.e., content), latent Dirichlet allocation (i.e., topic modeling), deep neural network embeddings, Bidirectional Encoder Representations from Transformers (BERT), and passage similarity metrics as ways to improve outcomes (Lottridge et al., 2020a).

FIGURE 8.6

Organization and Construct Coverage of e-rater Version 19.1, Released in 2019

Short-Answer Scoring

With AES, the models are formulated through an assemblage of features and the process then compares a candidate essay against the model and predicts a score. The mechanical aspects of writing are often expressed as a ratio of the propensity of mechanical errors to the volume of writing, while the content may be expressed as “distance” between the semantic dimensions of the model to the semantic dimensions of the candidate essay.

With short-answer scoring, the focus tends to be more on evaluating the content of what was written rather than the response’s style. Two different approaches are taken for model building. In the older approach, answers, answer variants, answer ranges, and sometimes wrong answers are programmed and compared against a candidate response. The closer the match, the higher the score. Answer variants are sometimes linked to a corpus of synonyms so that the word “ruler” or “monarch” might be considered (or not) equivalent to the word “king.” If answers are modeled on human responses, it is usually helpful to establish the range of responses or test out possible exceptions to the programming. Some scoring engines have routines to help evaluate the candidate answers in the context of using passive voice (e.g., “Carthage was destroyed by Rome” versus “Rome destroyed Carthage”; Leacock & Chodorow, 2003).

A more recent approach employs the multiple feature extractions mentioned earlier, including latent semantic analysis and n-gram vectors for content, latent Dirichlet allocation for topic modeling, deep neural networks and machine learning, BERT, passage similarity metrics, and a variety of linguistic variables. These features are then compared against a rubric and a score is predicted. Figure 8.12, which illustrates the process graphically, is referenced later in the section on the validity of machine scoring. For more modern scoring algorithms, the process for scoring short-answer questions and more extended essays is essentially the same. Topic modeling, for content, is addressed in the next section of this chapter (Ormerod et al., 2022).

The National Assessment of Educational Progress (NAEP) program recently ran a competition on the automated scoring of short-form constructed responses for NAEP Reading in Grades 4 and 8. Twelve competitors were provided item materials, a randomly selected training and validation set, and asked to make predictions for a test set where only the text of the response was provided using the NAEP 2017 Reading data. In these trials, human rater performance was $\kappa_w = .91$; for the competition winners, the scoring performance was $\kappa_w = .89, .88$, and $.87$. Competitors were also asked to submit reports on the fairness and transparency of their models (Shermis, 2024).

Automated Speaking Assessment

Automated scoring of speech grew out of the need to address the volume of second-language (L2) learners trying to acquire English-speaking skills (Howson, 2013; Zechner & Loukina, 2020). As discussed earlier, the European Union uses English as the official language of commerce and employs an assessment framework that can rely on both human and machine scoring of speech tasks (CEFR; Council of Europe, 2001; Green, 2013).¹

Most people have had casual interaction with an automated speech recognition (ASR) system either through digital assistants (e.g., Alexa, Siri, Google Assistant) or by dictating into a speech-to-text translator program. These applications are different from speech scoring systems in that they are optimized for native speakers or can be adapted through training and software settings (i.e., to account for dialects). Even with highly sophisticated ASR systems, there are subtle indications that they may be less than perfect. For example, you may ask a digital assistant to turn *out* the lights when the programmed protocol is to turn *off* the lights. Alternatively, you may dictate, “The rain in Spain falls mainly on the *plane*” when you meant “The rain in Spain falls mainly on the *plain*.”

Automated speaking assessment follows a paradigm similar to that of AES. Language- and speech-related features are extracted, and a scoring model is used to compute a score based on a combination of these features. The main difference between text and speech is that the word identities are unknown in speech and an additional component is needed—the ASR system—to generate a word hypothesis from the test taker’s digitized spoken response to an item prompt. This process is illustrated in Figure 8.7. In addition to L2 assessment, automated speech scoring is used in related applications such as the automated assessment of job interview performances (L. Chen et al., 2016) and automated evaluation of oral presentations (Ramanarayanan et al., 2015).

Word error rate (WER) is a standard metric for measuring speech-to-text accuracy of ASR systems.² WER uses the Levenshtein distance to determine the fewest number of steps needed to convert the engine-transcribed text to the target (human-transcribed) text. For native adult speakers, WER is relatively low. For example, Microsoft claims its ASR system has a word error rate of 5.1%. Google reports a WER of 4.9%. For comparison, human transcriptionists average a word error rate of 4% (H. Chen, 2021). However, WERs for spontaneous nonnative speech are substantially higher, on the order of 20%–30% or more. Factors that affect recognition accuracy include the variation in native languages of the test takers, variations in their speaking proficiency, suboptimal recording conditions (e.g., environmental noise, background talk), and speaker idiosyncrasies (some speakers are inherently harder to recognize by ASR systems than others; Hsu et al., 2021; Shermis, Burstein, et al., 2015; C. Wang et al., 2021).

FIGURE 8.7
Standard Process Approach for Automated Speech Scoring

Note. Adapted from “Overview of Automated Speech Scoring,” by K. Evanini & K. Zechner, in K. Zechner & K. Evanini (Eds.), *Automated Speaking Assessment: Using Language Technologies to Score Spontaneous Speech* (pp. 3–20), 2020, Routledge.

ASR is typically trained using machine learning algorithms that are based on large amounts of speech data. The process of training an ASR system involves several steps, including:

1. **Collecting speech data:** The first step in training an ASR system is to collect a large amount of speech data. These data can come from a variety of sources, such as audio recordings of human speech, transcribed audio recordings, or text-to-speech data sets.
2. **Preprocessing the data:** Once the set of data has been collected, it must be preprocessed to prepare it for use in training the ASR system. This can involve tasks such as converting audio files to a standard format, removing background noise, and segmenting the audio into smaller chunks.
3. **Feature extraction:** The next step is to extract features from the speech data. These features may include things like pitch, duration, and frequency of the sound waves in the audio. The goal is to extract features that are relevant to the task of recognizing speech.
4. **Training the model:** With the preprocessed and feature-extracted data, the ASR model can be trained using machine learning algorithms such as deep neural networks. During training, the model is exposed to large amounts of labeled speech data, and it learns to recognize patterns in the data that correspond to different words and phrases.
5. **Evaluation:** After the model has been trained, it is evaluated using a separate data set of speech data. This evaluation is used to determine the accuracy of the model and identify areas where it may need to be improved.
6. **Fine-tuning and optimization:** Based on the results of the evaluation, the ASR model may be fine-tuned and optimized to improve its accuracy. This may involve adjusting various parameters of the model or collecting additional data to retrain the model.

Overall, the process of training an ASR system is iterative, and it may take many rounds of training, evaluation, and fine-tuning to develop an accurate and reliable system (Evanini & Zechner, 2020).

SpeechRater

SpeechRater is a product of ETS that was deployed to score the speaking section of TOEFL Practice Online in 2006. SpeechRater is used here as an example, but there are many commercial systems available (Cheng et al., 2014; Pearson, 2017). This system helps students prepare for the TOEFL iBT. Unlike most other speech scoring systems, SpeechRater is intended to provide scoring for assessments that elicit a wide range of evidence of speaking proficiency (i.e., not only pronunciation) and to elicit spontaneous and natural speech from the test candidates as opposed to mere reading or repetition (Zechner et al., 2009).

The tasks scored by SpeechRater are modeled on those used in the speaking section of the TOEFL iBT. These tasks ask the test taker to provide information or opinions on familiar topics based on their personal experience or background knowledge and respond to reading or audio stimuli related to campus life and academic situations, such as lectures. The speaking time per item is about 1 minute. Test takers are scored on a scale of 1 (lowest proficiency) to 4 (highest proficiency), with a score of zero assigned to responses that do not address the task.

The recorded spoken response of the test taker is first sent to an ASR system, which generates a hypothesis, a string of words along with timestamps, that provides its best estimate of what the speaker said. Next, several feature extraction programs generate a vector of features indicative of various aspects of speech, such as fluency, pronunciation, prosody, vocabulary, and grammar, as exemplified in the TOEFL rubric (ETS, 2013). Finally, the features are combined in a scoring model to predict a score for each spoken response. The six-item scores of the test taker are then aggregated and scaled and placed in a score report for the test taker, along with information about how to interpret the score.

The TOEFL rubric specifies three dimensions of attributes that contribute to the score of a response:

- delivery (low-level technical features of speech production—e.g., pronunciation and fluency),
- language use (formal cues of linguistic competence—e.g., grammar, diction), and
- topic development (higher level semantic, pragmatic, and organizational aspects of the response).

Delivery features can be extracted most easily directly from the output of the speech recognition system, while language use is more difficult to address, given the constraints of recognition accuracy. The appropriate development of the topic is even more challenging to assess without an accurate response transcript.

Most of the features used in the early versions of SpeechRater addressed the delivery aspect of the TOEFL speaking construct (i.e., fluency and pronunciation). More recently, extended sets of features were developed and added to SpeechRater, including features measuring aspects of rhythm (L. Chen & Zechner, 2011), vocabulary (Yoon et al., 2012), grammar (Bhat & Yoon, 2015; Chen & Zechner, 2011), content (Xie et al., 2012), and discourse (X. Wang et al., 2016). The statistical model SpeechRater uses to predict the score based on these features is a multiple linear regression model. However, promising experiments have been performed using decision trees as well (Xi et al., 2008).

Like the advisories generated by e-rater, SpeechRater has a so-called filtering model that can identify responses that should not be scored automatically because of certain deficiencies or anomalies (Higgins et al., 2011; Yoon et al., 2011). Compared to

written texts, such nonscorable responses comprise a much more comprehensive range of phenomena—for example, low audio quality due to technical issues in the recording process, background noise, background talk by other test takers, or non-English responses. The reliability and validity of SpeechRater is discussed at the end of the chapter.

AI Scoring Conclusion

Since 2004, the progress in automated speech evaluation methods and systems has been substantial, and state-of-the-art speech scoring systems can measure certain aspects of speech proficiency quite reliably, particularly when the spoken test responses are somewhat constrained and predictable. For more spontaneous and open-ended responses, progress has been slower, and automated speech assessment systems are currently unable to evaluate all the aspects of speaking proficiency that human expert raters are trained to consider and evaluate. This is largely because of limitations in current speech recognition capabilities when applied to nonnative speech by speakers with a broad range of speaking proficiencies.

Some areas for future work include the conceptualization and development of features in the domains of the speaking construct that have not yet been adequately addressed, improvements to the speech recognition system, and research into more challenging but more natural item types, such as dialogues.

TOPIC MODELING OF CONSTRUCTED RESPONSE ITEMS

As briefly mentioned in the previous section, various topic models are used to extract features that are then used as covariates in many machine learning algorithms for scoring short-answer items and essays. Topic models are mathematical and statistical models used to analyze sets of documents (i.e., corpora) and were initially developed as an indexing technique to summarize, compare, and classify large sets of textual data. The primary objective of topic models is to discover topics and the usage of topics within a corpus (Chemudugunta, 2010). Topics are textual features that occur across all documents and can often be thought of as latent clusters of words. The usage of topics is a textual feature that occurs within an individual document and expresses the use of topics within the document.

Although the use of topic models was initially developed outside educational measurement, they have been shown to be useful methods for a variety of applications related to scoring and test security, such as feature extraction for automated scoring engines, improving ability estimation under an item response theory framework, discovering topics that are elicited by different items, identifying misconceptions, detecting complex forms of cheating, and providing feedback to students (e.g., Foltz et al., 1999; Gierl et al., 2020; Mozgovoy et al., 2010; Wheeler et al., 2022; J. Xiong & Li, 2023). Many applications of topic models in measurement utilize the latent seman-

tic analysis (Deerwester et al., 1990) and latent Dirichlet allocation (Blei et al., 2003) models and their variants.

Latent Semantic Analysis

Latent semantic analysis (LSA) is one of the earliest topic models and was originally designed for indexing and comparing text from a corpus. LSA is similar to factor analysis and principal component analysis in that it extracts latent components (i.e., topics) from a corpus and detects the relationship between each document and each word with respect to those components (Landauer et al., 2013). Applying LSA requires a matrix representation of the corpus, which is referred to as the document-by-word matrix where each row belongs to a distinct document in the corpus, each column belongs to a word from the vocabulary (i.e., the set of all unique words that appear in the corpus), and the cells contain the occurrence of each word in each document. Figure 8.8 displays a document-by-word matrix for a corpus that contains D documents and W unique words.

The document-by-word matrices are typically sparse (i.e., they contain many zeros) because most documents use only a small subset of words from the vocabulary. This tends to cause meaningless comparisons between documents directly using the document-by-word matrix. LSA, therefore, applies singular value decomposition (Golub & Reinsch, 1971), a linear algebra technique, to the document-by-word matrix. Singular value decomposition calculates the observed variation across documents with respect to latent components by decomposing the document-by-word matrix into three orthonormal (orthogonal and standardized) matrices: a document matrix, a topic matrix, and a word matrix. The document matrix contains the relationship between each document and the latent components, the word matrix contains the relationship between each word and the latent components, and the topic matrix contains the relative weights of each latent component. Multiplying the three matrices results in the original document-by-word matrix, as shown in Figure 8.9.

The three orthonormal matrices constitute the underlying semantic space of the corpus. The semantic space of a corpus is defined as the mathematical representation for the meaning of words and documents that is captured by the co-occurrence of words

	Word 1	Word 2	...	Word W
Document 1	0	1	...	2
Document 2	0	0	...	0
⋮	⋮	⋮	⋮	⋮
Document D	2	0	...	0

FIGURE 8.8
An Example of a Document-by-Word Matrix

across documents. The objective of LSA is to reduce the underlying semantic space by removing components with relatively small weights from the document, word, and topic matrices (Deerwester et al., 1990). That is, the components that explain the least amount of variation across the documents are removed from the semantic space (Dumais, 1994). Selecting an appropriate number of components to remove depends on a variety of factors, including the number of documents, the number of words, and the intended use (see Wild, 2016, chap. 7).

After the components are removed, the matrices can be multiplied together to obtain a reduced document-by-word matrix, as shown in Figure 8.10. The reduced document-by-word matrix approximates the original document-by-word matrix, meaning the cells of the matrix now contain approximate values for the occurrence of words in each document. Additionally, the reduced matrix is no longer sparse (i.e., it now contains only a few zeros). This provides a richer representation of the corpus, which allows for more meaningful comparisons between documents (Landauer et al., 1998). Calculating the cosine similarity between rows of the reduced document-by-word matrix yields a useful measure of textual coherence between the documents (Foltz et al., 1998).

FIGURE 8.9
Illustration of Singular Value Decomposition on a Document-by-Word Matrix

FIGURE 8.10
Illustration of Latent Semantic Analysis Dimensionality Reduction

LSA is used in a variety of ways for AES, since the features and topics extracted from LSA essentially reflect the language patterns used by students when responding to an item. For example, the document and topic matrices extracted from singular value decomposition can be used as a set of input variables for scoring algorithms. The similarity measures between documents can also be used to create textual features for scoring algorithms. Coh-Metrix (McNamara et al., 2014), a computer program for analyzing and extracting features from a set of documents, utilizes LSA to produce various metrics for written and spoken texts that are then used as covariates in scoring algorithms. Although LSA has been successful in providing features for automated scoring algorithms, applying LSA to unseen documents containing words that were not in the original corpus used to fit the model can be difficult and can cause the algorithms to underperform.

Latent Dirichlet Allocation

Latent Dirichlet allocation (LDA) is a probabilistic mixed membership model used to analyze sets of documents (i.e., the corpus). LDA aims to estimate three sets of parameters: topics, topic proportions, and topic assignments. Topics are latent clusters of words and are defined as a probability distribution over all the unique words within the corpus (i.e., vocabulary). The topic distributions are corpus-wide features that express the probability of each word in the vocabulary occurring within the given topic. Topics identify common themes seen across all documents in a corpus. Topic proportions are latent clusters of topics and are defined as a probability distribution over all the topics. The topic proportions are document-wide features that express the usage of each topic within a document. Topic assignments are classifications that assign each word in a document to one of the topics (Blei et al., 2010).

Figure 8.11 displays a graphical representation of LDA. The graphical model has three rectangles, or plates, representing the textual data's replications or levels. Documents are considered replications since there are multiple documents within a corpus. Words are considered replications nested inside documents because documents contain multiple words. Topics are considered replications since there are multiple topics within a corpus. The circles represent the variables of the LDA model, and their placement within the plates shows the level at which the parameter occurs. Shaded circles

FIGURE 8.11
Graphical Plate Representation of Latent Dirichlet Allocation

indicate observed variables, and unshaded circles indicate latent variables. The topic proportions are located at the document level because each document is given a set of topic proportions that represent its use of each topic. The topic assignments are located at the word level because each word is given an assignment to a topic. The word probabilities are situated at the topic level because each topic is a probability distribution over all the words. The arrows represent the directional relationship between each variable. The variable at the head of the arrow (i.e., where the arrow ends) depends on the variable at the tail of the arrow (i.e., where the arrow originates).

Assuming the number of topics a priori, the LDA model assumes a generative process for constructing each document within a corpus. That is, given the number of topics, LDA assumes a document is generated using the following process (Blei et al., 2003):

1. Select the number of words from a Poisson distribution.
2. Select the topic proportions from a Dirichlet distribution.
3. For each word in the document:
 - a. Select a topic assignment, given the topic proportion, from a multinomial distribution.
 - b. Generate a word, given the topic assignment and topics, from a multinomial distribution.

This process is used to develop estimation algorithms to infer the topic, topic proportion, and topic assignment parameters of the model from the observed words.

Applying LDA to a set of documents is an exploratory approach because the number of latent topics is assumed before the model is estimated. Therefore, selecting an appropriate LDA model requires researchers to fit multiple candidate models using a different number of topics and then compare each model based on statistical fit indices and interpretability. Additionally, when LDA is used as a feature extraction technique for automated scoring, the number of topics can be selected based on various performance metrics. The number of topics that provides the most parsimonious model is usually chosen as the best-fitting model (Mardones-Segovia et al., 2023).

Considerations for the Application of Topic Models

Before fitting a topic model and extracting features from textual data, the documents must go through data cleaning steps (Boyd-Graber et al., 2014). First, all punctuation is removed and all words are converted to lowercase, ensuring that the model is not counting the same word twice because of capitalization. For example, the word *dunes* and *Dunes* should only count as one unique word rather than two. Next, the words go through a stemming process that involves retrieving the base meaning of a word from its different tenses. For example, the verbs *swim*, *swims*, *swimming*, and *swam* all carry similar meaning and might be converted to a single word, *swim*. This process also involves nouns; for example, *teen*, *teens*, *teenager*, and *teenagers* all have a similar meaning and could be converted to the word *teen*. The stemming process is intended to increase the clarity of the topics by using a single unique word. In this way, it enables

the model to cluster words with similar meanings together, thereby enhancing the interpretability of the topics (Schofield et al., 2017). The process of stemming also involves changing misspelled words into their correct forms. This process is context dependent, meaning there is no universal list of stemming words, and it is often tailored to the corpus.

The last data cleaning step is the removal of stopwords. Stopwords are common words that carry little information about the topics (Wilbur & Sirotkin, 1992). Stopwords tend to occur with high frequencies, and if they are not removed, they will tend to dominate the latent topics, reducing the interpretability of the topics (Choi et al., 2017). Generally, stopwords lists include words such as *the*, *a*, *are*, and *they*. There is no theoretically grounded approach to choosing and removing stopwords. Many techniques, however, aid in selecting stopwords, such as custom rules (Schofield et al., 2017), which are developed by researchers for their specific application. These allow the researcher to create a unique stopwords list specific to the intended analysis of the corpus. The TF-IDF index is another method for selecting stopwords (Robertson, 2004). This index uses term frequencies to decide whether a word is being used too often. Finally, the general stopwords rule (Manning et al., 2008) combines statistical approaches and customization to define stopwords. Previous research suggests customized stopword lists are needed for analysis of extended-response items (Choi et al., 2017).

Applications of Topic Models in Educational Measurement

Topic models are widely known in educational measurement as a feature extraction technique for automated scoring algorithms. For example, commonly used machine scoring programs, such as the Intelligent Essay Assessor (Foltz et al., 1998), Coh-Metrix, and Autoscore (Lottridge et al., 2020b), use LSA to extract meaningful document features. LDA has also been used to assess the viability of using topic proportions as covariates in a scoring algorithm. However, results showed that LDA methods performed worse than LSA methods (Kakkonen et al., 2006; H. Xiong et al., 2019).

The utility of these models, however, lies beyond automated scoring and in analyzing test-taker text for themes. For example, Shin et al. (2019) used LDA to analyze written responses to test questions to identify common misconceptions that could be used to develop distractors for multiple-choice items. Wheeler et al. (2024) demonstrated that LDA could be used to extract and summarize information about test takers' reasoning when responding to constructed response items. The results suggested that LDA can be used to provide validity evidence for test developers and provide educators with information to inform instructional approaches for essays. Duong et al. (2019) used LDA to analyze answers to an essay test requiring integrative borrowing. Responses of students taught to use instructional conversation (a form of collaborative learning) were compared to responses of students who had not. Results indicated that answers of students taught to use instructional conversation expanded beyond the characters and settings in the prompt and expressed an understanding of multiple perspectives compared to the answers of students who had not had an instructional conversation training. Students

who had not had instructional conversation training simply restated the prompt, did not change the setting, and only took a single perspective into account in their answers.

Choi et al. (2017) used LDA to detect latent topics to aid in identifying the semantic and thematic structure of students' writing. Topics that differentiated the types of words and the latent themes in good versus poor writing were detected. Kim et al. (2017) found that two of the three topics in the topic model of answers to a test of science inquiry knowledge corresponded to academic language and discipline-specific language as reflected in the use of scientific words such as *measure*, *effect*, and *hypothesis*. Answers making use primarily of the third topic used mainly everyday language. Kwak et al. (2017) reported a change in the use of topics detected by LDA in essay test answers as a result of instruction.

The differential use of topic proportions in the instructional setting has been shown to identify the quality or track the improvement in students' writing (Choi et al., 2017). Choi et al. reported that some students switched in the proportions of topic use from everyday language to academic language following instruction, although the rubric-based scores of their answers did not show any change. Topic proportions, however, also can be used to indicate topics that are highly related to scores. Kwak et al. (2017) found that one of the latent topics, characterized as *discipline specific words*, had a significant positive correlation with the score on the essay test ($r = .70$).

The benefit of LDA is that it provides additional and easy-to-understand information about the content of the essay. Results from Kim et al. (2017) showed that the topic structure from LDA models yielded similar results to a qualitative analysis of the same essays. This suggests that these topic models have the potential to provide constructive feedback in real time to students beyond just a score.

Additional Topic Models

While LSA and LDA are the most commonly used topic models, other topic models have shown promise in modeling text. These are supervised LDA, the bigram model, autoencoders, and word embeddings.

Supervised LDA

Supervised LDA (sLDA; McAuliffe & Blei, 2007) is a variant of LDA that uses a dependent variable to help infer the topics, topic proportions, and topic assignments of the model. The dependent variable is modeled jointly with the LDA model by regressing the dependent variable on the topic proportions (Perrote et al., 2011). The joint modeling framework makes the topic proportions more predictive of the dependent variable. For example, McAuliffe and Blei (2007) found that when trying to predict movie ratings, the sLDA model outperformed the LDA model, followed by regression. Additional covariates, such as document length, can be added to the sLDA, which is referred to as an sLDA with covariates model (Wilcox et al., 2020). When sLDA and the sLDA with covariates model are applied to constructed-response items, the dependent variable is typically a score category or classification of the test taker.

Bigram Topic Model

The bigram topic model (Wallach, 2006) is an extension of the LDA method that incorporates partial order of the words by considering adjacent words. Under the bigram model, each topic is represented as a set of distributions rather than a set of probabilities associated with words. The distribution the topics represent is the combinations of words that occur adjacent to each other. For example, in the sentence *The green ball flew across the sky*, the word combinations of *green ball*, *ball flew*, *flew across*, and so on are considered the bigram terms (i.e., tokens). The bigram topic model uses a similar structure as LDA; however, the model assumes that words will occur adjacently multiple times. That is, essential combinations of words will appear across the multiple documents. For example, it is safe to assume the word *united* and the word *states* will appear next to each other in a single bigram *united states*. If the documents being analyzed do contain words that will appear adjacently across multiple documents, then the bigram topic model will not produce useful information beyond that of the unigram LDA about the text data.

Autoencoder

An autoencoder is a type of artificial neural network used to approximate data by reducing the underlying dimensionality of the data set. The autoencoder extracts features from the data through an unsupervised learning algorithm that contains three major parts: an input layer, a hidden layer, and an output layer. The input layer is a vector representation of the original text, the hidden layer is a reduced vector space, and the output layer is an approximated vector representation of the original text. The length of the vectors from the input and output layers are the same; however, the vectors obtained from the output layer approximate the vectors used in the input layer. There are a variety of autoencoder algorithms for analyzing and extracting features from textual data, including the General Language Understanding Evaluation (A. Wang et al., 2018), the bidirectional encoder representations from transformers (Devlin et al., 2018), and many more (e.g., Y. Chen & Zaki, 2017; Vaswani et al., 2017; Wu et al., 2019; Zhai & Zhang, 2016).

Word2vec and Doc2vec

The word2vec (Mikolov et al., 2013) and doc2vec (Le & Mikolov, 2014) are NLP topic models used in linguistics to find the meaning of words. The word2vec uses one of two algorithms: a continuous “bag-of-words” algorithm and a skip-gram algorithm. These two algorithms are simple neural networks and derive the meaning of words based on the context words surrounding them. The word2vec model assumes that the meaning of words is determined by the words that appear near them. The doc2vec extracts features (i.e., topics) from documents by using the words that appear in them and the meaning of words derived from the word2vec algorithm. In this way, the doc2vec represents an abstract meaning of a document based on the word meanings that word2vec numerically represents. These two models differ from autoencoders in that the order of the text is not considered.

ASSESSING THE VALIDITY OF SCORES THROUGH AUTOMATED ASSESSMENTS

One of the most common uses of topic models is through automated scoring assessments. This section considers how scores predicted by AI assessments may differ from those that humans assign through either a grading or a rating process. Note that human score assignment may not necessarily be the standard through which an AI model is constructed, but for most performance assessments, it is the standard approach. Additionally, it is important to note that general information about validity is addressed elsewhere by Lane and Marion (this volume), and issues related to the use of technology-based assessment are described by Bennett et al. (this volume).

Technology-Based Assessments

Tentative guidelines for technology-based assessments have been drafted by the International Test Commission and Association of Test Publishers (2022), the *Guidelines for Technology-Based Assessments*. This document subsumes what used to be referred to as computer-based testing but now includes testing that might be administered through the Internet, on tablets, on phones, and through speech recognition and the like. These guidelines are based on the *Standards* (AERA et al., 2014) but address issues that may be unique to technology-administered assessments. So, for example, some test takers may lack the background experience to effectively enter their responses on a computer keyboard (a construct-irrelevant factor). The validity concerns in this document are focused on construct underrepresentation and construct-irrelevant factors. The guidelines also cover recommendations for test development, test design and assembly, test delivery environments, scoring, digitally based results reporting, data management, psychometric and technical quality, test security, data privacy, fairness, and accessibility.

Automated Scoring

In his defense of AES, Page (2003) offered the Turing test as a benchmark by which machine-predicted scores might be judged. The test goes something like this: If you hand essays to a scorer behind a screen and cannot tell the difference between those scores assigned by the human scorer and those predicted by a scoring algorithm, then you should treat the two sets of scores as the same. AI-assigned scores generally meet the Turing test (basically a *reliability* argument) but not the test of *transparency*, which most argue is an essential element to establishing the validity of a score (Bejar et al., 2017; Ramineni & Williamson, 2013). The argument here is that if the scoring algorithm gets to the same score using a process different from that of the human scorer, the score will lack some dimension of validity.

The problem is that human scorers can also arrive at the same score using different processes, so the human scoring enterprise is often guided by *rubrics* and *expertise* of the scorer to help define what humans should be attending to when assigning scores. The purpose of the rubric is to define the domain being assessed and articulate the elements

of performance that make it better or worse, complete or incomplete. The challenge is that by restricting the focus of attention to specific aspects of performance, other aspects of performance may be ignored or undervalued (construct underrepresentation). If reliance on expertise is involved, scoring a performance may be influenced by the amount and types of expertise possessed by the human scorer (Wolfe & McVay, 2012). This simply means that AI models based on human scores will inherently possess varying degrees of unreliability. To establish the validity of AI-predicted scores, the twofold goal is to maximize the reliability of scores and conformance to the underlying rubrics or processes used by experts.

Williamson et al. (2012) discussed the interpretational context of using automated scoring in a high-stakes testing environment. The article addressed five areas that should be systematically evaluated before concluding that the use of the technology might be appropriate. These include construct relevance and representation association with human scores, association with independent measures, generalizability of scores, impact on score use, and decisions and consequences. For instance, human raters and machine scoring algorithms may have high agreement on assigned and predicted scores but come to this outcome using different mechanisms. Suppose the machine scoring algorithm is a reliable proxy for the human process under a known range of conditions and meets the criteria listed previously. In that case, it may be acceptable to employ the technology in a high-stakes environment. If it is unreliable and its restrictions cannot be mapped, then the utility of machine scoring will be limited. Given such outcomes, it could even be argued that machine scoring works well for evaluating certain kinds of expository writing for a heterogeneous mix of U.S. school children in Grades 6–12 but does not seem to perform adequately in evaluating poetry or other kinds of stylized writing or does not work well in grades where keyboarding skills have not yet been mastered.

With regard to the evaluation of writing, the current algorithms are used to predict score assignments based on human raters' scores over a variety of academic writing genres. To make significant improvements in the technology, the writing community will have to develop an accepted operational definition of what constitutes "good writing," and computational linguists will have to articulate what they can emulate well and what aspects of writing evaluation require more development.

One common approach to establishing score validity is to employ evidence-centered design (Mislevy et al., 2006). Evidence-centered design is based on a tripartite model that is composed of a construct model, a task, and evidence that "defines rules and criteria for interpreting observations, test taker responses, and processes that can be used to relate observations to the latent constructs in the constructed model and accumulate evidence from responses to tasks" (Ercikan & McCaffrey, 2022). In the case of writing, an argument might be made based on an interpretation of a rubric and the accumulation of sufficient evidence that a score has some particular meaning. The problem is that there are varying degrees of clarity regarding rubrics, processes, and decisions based on the score. (See also ETS, 2021, for a discussion of the collection of validity evidence for the use of automated scores.)

When Rubrics, Processes, and Decisions Are Clear

One of the more popular automated assessment devices used in golf is a technology called Trackman (n.d.). It is usually combined with cameras to show the effectiveness of a golf swing when using specific clubs (e.g., a driver). The Trackman device is placed behind the golfer. It employs Doppler radar to measure multiple aspects of swing performance, including club speed, ball speed, ball spin rate, launch angle, attack angle, swing direction, club path, face angle, ball distance, and ball carry, among others. These attributes are very clearly defined. While there is no perfect golf swing, there are swing models that experts consider as being better than others. For example, if you want to hit a golf ball straighter, you want your swing to align with an ideal swing plane and hit the ball squarely at impact. The goal is not to hit the same shot on every swing, but rather to control the swing to adapt to the situation. For instance, there are times when a golfer might want to shape the ball to go to the right or the left.

The validity issue is whether the measurements taken by Trackman (n.d.) constitute the relevant components of a golf swing and whether the measures taken are accurate and reliable. The accuracy and reliability of the measurements can be confirmed using other tools besides Doppler radar. The relevancy of the measurements can be demonstrated experimentally using golf swing machines. For example, if one wants to hit the ball farther, one can increase the clubhead speed while keeping other “variables” constant. Johansson et al. (2015) used Trackman data with random forest models to accurately predict the handicap (skill level) of a sample of 275 golfers. As is always the case, getting a good golf result with a bad swing is possible, but not likely. It is also possible that there may be other attributes of performance that have not yet been envisioned. Still, for the moment, there seems to be general satisfaction that Trackman and similar instruments result in valid swing assessment scores.

For kinesthetic assessment, there are automated scoring models used in dance (Faridee et al., 2019; Joshi & Chakrabarty, 2021), boxing (Perkins et al., 2017), gymnastics (Shimamoto et al., 2013), and diving (Kramer, 2017), to cite a few areas. These performance domains are similar in that the rubrics for scoring are clear, are well defined, and require expertise or technology to score in real time. The instruments used to aid in the assessment are reliable, but not always perfect. For example, to use automated scoring in boxing, participants must wear specialized jerseys embedded with sensors. During the development of the technology, it was discovered that loose-fitting jerseys resulted in false positives (recording a “hit” when no hit was observed). The experimenters found that in the looser jerseys, the sensors were hitting against each other. The modification ensured that the jerseys had to have a tighter fit (Perkins et al., 2017).

When Rubrics and Processes Are Clear (But Maybe Incomplete) and Decisions Are Muddy

In their treatment of fairness as a component of score validity, Huggins-Manley et al. (2022) illustrated the use of automated video interviews (Hickman et al., 2021) as a mechanism for hiring into a potential job opportunity. During the automated video

interview, the job candidate is presented with a video-taped interviewer, provided with a question or prompt, and then asked to respond. The automated scoring algorithms consider the responses, the length of the answers, the manner in which the response was given, and several other attributes of interaction. Different kinds of employment data were recorded, such as age, race, gender, and level of education, to control for background differences. In the article, Huggins-Manley et al. (2022) advocated using validity arguments to evaluate fairness akin to the kinds of performance statements generated with evidence-centered design. For example, suppose the job in question was someone working as a manager in a call center. In that case, there is no theoretical reason why hiring rates for males and females should be different in terms of their anticipated performance on the automated video interview, assuming that the questions themselves were unbiased. This expectation would result in a formal statement as such.

What Hickman et al. (2021) found, however, was that these expectations can be influenced by confounding effects such as self-selection bias (i.e., the proportion of women and/or men who apply for the job and how to treat those who identify as nonbinary. Surprisingly, Hickman et al. (2021) also found that the scoring technology predicted better decisions when trained interviewers answered as proxies for the applicants rather than the applicants themselves.

When Rubrics, Processes, and Decisions Are Muddy

Shermis (2022) discussed the theoretical misalignment between the kinds of writing assessments that are common in high-stakes tests and those advocated by the writing community. Most accountability writing assessments are based on the composition-rhetoric theory of writing (sometimes referred to as the current-traditional theory of writing; R. E. Young, 1982). The key features of this writing theory include formal correctness, the elegance of style, and the modes of discourse. These are usually implemented as short writing samples suggested by a question, a series of questions, or some other prompt. The result is a writing sample that ranges from 50 to 500 words that may be scored by human raters, machine scoring algorithms, or a combination of the two.

While the composition-rhetoric theory has formed the basis for most accountability exams, the writing community has moved on to other theories of writing in which a specific product is only part of the performance that might be evaluated. For example, the cognitive process theory of writing is aimed at improving and documenting the decisions that writers make (Flower & Hayes, 1981). Participating in a brainstorming exercise or character sketching would be writing activities consistent with a cognitive process theory of writing but would not be directly reflected in a prompt response.

Alternatively, the sociocultural theory of writing stipulates that

writing is a complex social participatory performance in which the writer asserts meaning, goals, actions, affiliations, and identities within a constantly changing, contingently organized social world, relying on shared texts and knowledge. The projection of meaning and shared orientations at a distance requires making assumptions and predictions about who will be reading the texts, what

their interest and knowledge are likely to be, and how they may be using the information. (Bazerman, 2015, p. 18; see also Prior, 2006)

Implicit here is that school, along with many other institutions, is one way a person is socialized, and it is important for the writer to be cognizant of this process. With this theory, writing improves as a function of the interactions (i.e., feedback) the writer receives to achieve a set of norms. Evidence would include measures of improvement (or lack thereof) based on feedback.

The point is that what constitutes writing is different for those in the high-stakes assessment enterprise and those who actually teach writing. The one-shot 40-minute response to a prompt would not capture the evidence that those in the writing community are looking for when they assess the development of someone’s writing performance. Whether the writing is scored by humans or through AI ends up being a secondary issue.

The Transparency of Processes

The major obstacle in establishing the validity of machine score predictions most likely centers on the lack of transparency of processes. This is also a challenge for human raters even when assigning scores based on a rubric. Figure 8.12 shows the process used

FIGURE 8.12
Project Essay Grade (PEG) Model Training Pipeline

by Measurement, Inc.'s Project Essay Grade (PEG) automated scoring engine. The PEG engine was the 2022 winner of the NAEP contest to score responses to reading items in fourth and eighth grade for the 2017 NAEP test administration (Institute for Education Sciences [National Center for Education Statistics], 2022). In this particular challenge, human raters had $\kappa_w = .91$ averaged across responses to 20 reading items, and PEG score predictions came in at $\kappa_w = .89$. This scoring performance represented a considerable improvement from a similar contest conducted in 2012 (i.e., the ASAP trials).

In 2012, most competitors, including PEG, used parser-tagged linguistic variables, LSA, and the ability to assess passage similarity in what was referred to as a bag-of-words approach (Deerwester et al., 1990) to modeling. Since then, many prediction models have added n-gram vectors, LDA for topic modeling, BERT, and deep neural networks (i.e., machine learning). For example, using the bidirectional encoder representations from transformers allows the language model to be automatically encoded from left to right or right to left. A language model is a type of AI model that is trained to predict the likelihood of the next word in a sequence, given the preceding words in that sequence. It is designed to understand and generate human language and can be used for applications such as speech recognition, machine translation, and text generation. Recent research has shown that a language model that is bidirectionally trained can have a deeper sense of language context and flow than single-direction language or no-direction models (Devlin et al., 2018).

However, outside the field of applied linguistics, these techniques might seem foreign and even unrelated to the process a human rater would go through to assign a score to a writing sample. Shermis (2022) proposed to use either the 6 + 1 Traits or the CEFR (Shermis, 2018) as a way to establish a crosswalk between the concepts employed in AI scoring and the vocabulary used by the writing community to describe their processes. PEG processes align reasonably well with five of the six 6 + 1 Traits (development of ideas, organization, word choice, sentence fluency, conventions). For example, PEG LDA is reasonably well aligned with the trait development of ideas. Without some sort of crosswalk, the measurement and writing communities will find it hard to establish common ground in their description of writing processes.

Finally, Ferrara and Qunbar (2022) suggested that some AI processes will likely remain *unknowable* until we have more experience with machine score prediction algorithms. In refining a score prediction, AI might employ one of many machine learning techniques. Why one of these techniques would perform better on a particular writing sample can be documented but probably not well explained. Much more research is needed to establish the efficacy of some of the tools used in AI score prediction. Still, many parts of the algorithms align well with vetted rubrics used by human rating enterprises. We document elsewhere in this chapter the kinds of possible bias and errors committed by human raters.

Validity and Reliability Evidence for SpeechRater

SpeechRater's score reliability is assessed by first training a multiple linear regression scoring model on a set of about 1,200 responses and corresponding scores assigned by human + expert raters and then evaluating the trained model on an unseen test set of about 300 test takers who have a complete set of six scores (about 1,800 responses total). For each speaker, the sets of six human and automated scores are each summed to obtain an aggregated speaking score. The aggregate speaking scores from human raters and SpeechRater are compared using the Pearson r correlation and quadratic weighted kappa metrics. The correlation between aggregated speaker-level SpeechRater scores and human scores was $r = .61$, and the quadratic weighted kappa was .53. In comparison, the human interrater correlation on the same data set was $r = .63$, and the quadratic weighted kappa was 0.57 (Shermis, Burstein, et al., 2015).

As for possible construct (under-)representation, a validity concern (AERA et al., 2014, chap. 1), the features of SpeechRater are mainly focusing on the construct dimension of "delivery" (e.g., fluency, pronunciation, prosody) and, to a lesser extent, on aspects of "language use" (e.g., vocabulary diversity, grammatical accuracy). Features related to the response content are currently not used in SpeechRater operationally, although recent research has resulted in features associated with this dimension as well (M. Chen & Zechner, 2012; Xie et al., 2012). To represent a comprehensive subset of the construct of speaking proficiency as defined in the TOEFL rubric, a significant amount of additional research and development is still required.

In addition to these considerations of validity, a study on criterion-related validity was conducted by Bridgeman et al. (2012). In this study, 555 U.S. undergraduate students who were native speakers of English were asked to listen to TOEFL iBT responses given by 184 test takers taking one of two distinct forms. The researchers then examined correlations between multiple-choice comprehension scores (based on these listening exercises) and human and SpeechRater scores of the same test takers' responses. They found that the correlation between human expert raters and undergraduate listeners' comprehension scores was higher (.97 and .81 for the two forms, respectively) than for SpeechRater (.55 and .37). The main reason for this discrepancy is very likely that SpeechRater is covering only a subset of the construct, with most of its features focusing on the delivery dimension, few on language use, and none as of yet on topic development.

EMPIRICAL WORK: THE HEWLETT TRIALS

The Hewlett trials, sponsored by the Hewlett Foundation, were conducted in the spring of 2012 as a test of machine scoring for the PARCC and Smarter Balanced consortia (Shermis & Hamner, 2012, 2013). These two entities had responsibility for helping states implement and assess reforms consistent with the Common Core State Standards. The trials consisted of three studies—a commercial vendor demonstration for AES, a worldwide competition for AES, and a worldwide competition for short-form constructed responses.

The first two studies employed eight different essay sets drawn from six states representing the PARCC and Smarter Balanced consortia. In the first two studies, four of the essays were “source based.” A student was asked to read an artifact and then write an essay. The remaining four essays were based on more traditional prompts (i.e., those requiring narrative, descriptive, and persuasive writing). For the first study, over 17,000 essays were randomly divided into two sets, a training set ($n = 13,336$) on which the vendors had 1 month to model the data and a test set for which they were required to make score predictions. The training set essays were each initially scored by two human raters. Significant discrepancies in these scores were then resolved by calling in additional ratings, a so-called resolved score, and the text of the essay. The resolved score reflected the final score assigned by the state. To resolve differences between the two human raters, states applied a set of adjudication rules (e.g., ask a third rater to evaluate the essay) that may or may not have reflected the judgments of the original human raters. The test set consisted only of the text of the essay. Six of the eight essays were transcribed from handwritten documents using one of two transcription services. Accuracy rates were estimated to be over 98%. The challenge to the nine teams was to produce automated scores that best predicted those assigned by human raters.

Performance of automated scoring systems was evaluated on five different measures using the Kaggle platform (onward Kaggle Inc., 2010). The first two measures reflected the distributional properties of the essay scores, mean and standard deviation. The remaining five measures addressed how well the machine scores agreed with those assigned by the human raters (e.g., the resolved score). These included exact agreement, exact + adjacent agreement, kappa, quadratic weighted kappa, and the Pearson product-moment correlation. The AES engines performed well on the distributional measures. With a high degree of consistency, all nine demonstrators in the first study were able to replicate the means and standard deviations for the scores assigned by the human raters. With regard to agreement measures, there was some variability, but the AES engines performed well on three of the five measures (exact + adjacent agreement, quadratic weighted kappa, correlation). On the two measures where the performance was not as high (exact agreement and kappa), there was also high variability among the human raters. In addition, scaling artifacts attributable to the way the state scores were adjudicated may have contributed to the relative lack of precision on predicted scores. In sum, on five of the seven measures, machine scores reasonably approximated those of human raters and, on a few of the data sets, even performed better than their human counterparts. The conclusion of that study was that with additional work, AES could be a viable solution in some aspects of evaluating high-stakes long-form writing assessments. The study did not evaluate the potential for score bias in group differences (i.e., no investigation of differential item functioning), used existing paper-based essays from states as the source of information rather than obtaining text as a computer-administered assessment, and contained a restricted range of evaluation criteria as part of its design.

The second study was very similar to the first, but with some important differences. First, it was conceived as a \$100,000 competition involving 158 teams of data scientists

from around the world. Some of the competitors included a few vendors from the first study who were ineligible to win the monetary prize. Second, the data scientists had 3 months to create and refine their models, whereas the vendors only had 2 weeks. Third, the data sets from the first study were anonymized using the Stanford Named Entity Recognizer (Finkel et al., 2005) so that the likelihood of identifying an individual through persons, organizations, or places was minimized. A study was conducted to determine what, if any, impact might occur through anonymization. On the three measures that were chosen to evaluate impact (mean, standard deviation, quadratic weighted kappa), only minor differences were observed for both NLP- and non-NLP-based scoring engines (Shermis, Lottridge, & Mayfield, 2015). Finally, with the exception of commercial vendors, the competitors were required to produce their algorithms and a white paper that explained how they modeled the data. Results showed that the top international competitors performed slightly better than the commercial vendors. Analysis of the algorithms revealed that the data scientists did not introduce any new techniques, but rather resequenced existing techniques to extract additional explained variance.

The third study compared short-form constructed responses evaluated by both human raters and machine scoring algorithms. As before, both public competitors and commercial vendors vied to develop machine scoring algorithms that would match or exceed the performance of operational human raters in a summative high-stakes testing environment. Data ($N = 25,683$) were drawn from three different states, employed 10 different prompts, and were drawn from two different secondary grade levels. Samples ranging in size from 2,130 to 2,999 were randomly selected from the data sets provided by the states and then randomly divided into three sets: a training set, a test set, and a validation set. Machine performance on all of the agreement measures failed to match that of the human raters. While machine-human agreements were as high as they were for the essay scoring competitions, agreement among human raters was even higher, so that machine performance did not reach the threshold of human raters. The study concluded that additional development had to take place before machine scoring of short-form constructed responses could be commercially viable.

INTERNATIONAL WORK IN MACHINE SCORING

As mentioned at the beginning of this section, there has been an expanded interest in machine scoring beyond the English language. In assessing language differences, three salient dimensions may impact how effectively writing in different languages can be evaluated with automated systems. The first dimension pertains to differences between written and spoken language (e.g., writing complexity), the second dimension addresses dialectical or regional differences within a language (e.g., different words for same object or action), and the third dimension focuses on distinctions among different languages (e.g., different alphabets). Moreover, a few languages are managed by academies (i.e., a formal body admits new words, adjusts the meaning of existing words, and affirms grammatical expressions into the language) while most are not. All of these can impact the efficacy of machine scoring models (Shermis, 2020).

Early efforts focused on using established U.S. English-based scoring engines to score different languages by simply replacing the English parser and tagger with that of the targeted language (Ishioka & Kameda, 2006; Schultz, 2013; Vantage Learning, 2001). Many of the foreign-language scoring engines are, at this point, simply proofs of concept and are typically a combination of a statistical models used in conjunction with LSA or some variant of it (e.g., LDA). They usually employ a weighted linear combination of a subset of parser variables (i.e., metavariables) in addition to a distance metric derived from the LSA component. These tend to work surprising well (i.e., with quadratic weighted kappas sometimes in the low 80s) given that the training set was often small or employed corpora that were only tangentially related to the essay topic. The foreign-language scoring engines are generally an assembly of tools rather than a complete system. As such, they typically require manual handling from one step of the process to the next, rather than as an embedded set of linked steps. Only a few systems included NLP programming to evaluate the more mechanical aspects of writing. Table 8.2 lists several foreign-language AESs.

Table 8.2 Comparison of Non-English-Based Automated Essay Scoring (AES) Systems

AES System	Developer	Technique	Main Focus	Instructional Application	Number of Essays Required for Training	Language

FEEDBACK FOR FORMATIVE ASSESSMENT

Ellis Page originally envisioned AES as a “teacher’s helper” to provide the extensive feedback that classroom teachers did not have the time to give when faced with grading 125 papers (5 classes × 25 students/class) for each writing assignment (Page et al., 1994). Receiving ample and significant feedback in time to improve writing performance is closely related to improved levels of writing performance (Biber et al., 2011; Landauer et al., 2009). Recent meta-analyses of high-quality research studies have identified writing instruction practices that can best improve student reading and writing performance. The studies—*Reading Next* (Biancarosa & Snow, 2004), *Writing Next* (S. Graham & Perin, 2007), *Writing to Read* (S. Graham & Hebert, 2010), *Informing Writing* (S. Graham et al., 2011), and *The Effectiveness of Feedback for L1-English and L2-Writing Development* (Biber et al., 2011)—provide a range of practices, as well as the statistical effect size (an estimate of the magnitude of the instruction) on student learning, that may serve as a guide to best instructional practices: providing feedback, developing inquiry activities for a particular writing task, encouraging self-assessment, using student evaluation of writing using scales, fostering sentence combining instruction, monitoring of writing progress by the instructor, study and emulation of good models of writing, and promoting free writing. There are also cautions regarding allowing students to write using paper and pencil when they are inexperienced in word processing and the exclusive use of grammar instruction that has not been demonstrated to be an effective treatment. Such empirical findings have allowed the development of a set of best principles for writing instruction: the creation of a supportive writing environment, instruction in writing strategies, knowledge acquisition of effective writing, and attention to foundational skills (S. Graham et al., 2013).

CONCLUSION

The research and work discussed in this chapter have demonstrated the profound impact that technology has had on test administration and scoring. The technology extends from how we administer and score assessments to the detection of possible cheating. Some of these developments have opened adaptations for individuals with special needs in a way that was not possible with traditional paper-and-pencil tests. However, the scoring technology does not always follow the same process or logic human evaluators use when making judgments and sometimes lacks transparency. It is incumbent on those who develop automated scoring processes and those who use them to ensure that the technology does not introduce construct-irrelevant variance in interpreting test scores. Guidelines have been developed to help those engaged in this enterprise, but it is always incumbent to provide evidence that the resulting test scores are appropriately interpreted.

ACKNOWLEDGMENTS

The authors would like to thank Drs. Susan Lottridge and Peter Foltz for their insightful comments and constructive suggestions. We also appreciate the thoughtful recommendations and remarkable editorial work of the book's coeditors, Drs. Linda Cook and Mary Pitoniak.

NOTES

1. The CEFR is used to evaluate other languages besides English.
2. Word error rate = (substitutions + insertions + deletions)/number of words spoken, where errors are:
 - substitution: when a word is replaced (for example, “shipping” is transcribed as “sipping”),
 - insertion: when a word is added that was not said (for example, “hostess” is transcribed as “host is”), and
 - deletion: when a word is omitted from the transcript (for example, “get it done” is transcribed as “get done”).

Technology- Based Assessment

Validity, Modeling, and Analysis Issues

Randy E. Bennett
ETS

Michelle LaMar
ETS (Retired)

John Mazzeo
ETS (Retired)

In this chapter, we focus on validity, modeling, and analysis issues in technology-based assessment. For present purposes, we define *technology-based assessment* (TBA) as a measurement used for decision-making primarily in education, but also in the workplace, that employs digital computing in most, if not all, aspects of its creation, delivery, presentation, scoring, or reporting.

As of this writing, TBAs were being used for consequential decision-making purposes widely in the United States, as well as in some other countries and in some international assessments. Among the more prominent of such programs are the National Assessment of Educational Progress (NAEP), the Programme for International Student Assessment (PISA), the Australian National Assessment Program, the GRE, the TOEFL, the Graduate Management Admission Test, the United States Medical Licensing Examination (USMLE), the Law School Admission Test, and the California Assessment of Student Performance and Progress (CAASPP). CAASPP is particularly notable because of its test-taker volume, which may be the largest of any such measure. On a single day, June 7, 2019, that volume exceeded 670,000 students, with well over 3 million individuals taking the examinations in the spring 2019 cycle (Johnson, 2019). Although many testing programs, especially those outside the United States, continue to test on paper, the number of major testing programs that have become digital, coupled with the large size of CAASPP, demonstrates that technology delivery is feasible at scale. The transition has proven to be, as one of the authors of this chapter had earlier suggested, “inevitable and inexorable” (Bennett, 2002).

What is motivating this transition? Briefly stated, the most salient reasons revolve around three areas. First is the need to align the medium of testing with that of learning and of the information economy’s workplace. Absent that alignment, assessment runs the risk of appearing, and becoming, irrelevant to its constituents. The second reason is the belief that assessment processes can be conducted more efficiently, with savings in time and cost. Scores, for example, can in some instances be generated and reported immediately. Third is the measurement of constructs that are impossible to evaluate in traditional testing modes. Examples include using technology tools for such activities as reading in hyperlinked environments, information search and synthesis, writing, modeling, and collaborative problem-solving (Institute for Education Sciences, n.d., 2018; Mullis & Prendergast, 2017).

The transition that has occurred since the 1990s in the United States and elsewhere can be described at a high level in terms of three stages or generations (Bennett, 1998, 2010a). The first generation is essentially an infrastructure-building effort. The cost and time required to put that infrastructure into place are typically substantial, involving obtaining hardware and software, hiring personnel, providing training, and creating myriad new processes and procedures. To control cost and complication, tests in this generation often look little different from paper assessments in their realized design and question format. This generation’s tests primarily serve institutional purposes like school accountability, leverage technology minimally (e.g., through incremental advances like adaptive testing), and are generally organized as singular events (e.g., for state accountability purposes, as annual, end-of-year administrations).

In the second generation, goals begin to shift toward achieving some degree of qualitative change and to leveraging the technology more effectively for efficiency improvement (Bennett, 1998, 2010a). With respect to the former goal, a diversity of less traditional item formats may be employed, including those sometimes called “technology-enhanced” (e.g., involving multimedia stimuli, dragging and dropping onscreen text or objects, highlighting segments of text). Additionally, new constructs may be introduced (e.g., writing on computer), so that what is assessed begins to change fundamentally. Efficiency improvements extend beyond delivery via automated approaches to item generation (Gierl & Haladyna, 2013; Irvine & Kyllonen, 2010), test assembly (Veldkamp & Paap, 2017), and scoring (Shermis & Burstein, 2013; see also Shermis et al., this volume), as well as to using the Internet for such processes as item review, standard setting, human online scoring, reporting, and other communications with test users.

Reinvention characterizes the third generation of assessments (Bennett, 1998, 2010a). What in the two earlier generations was an evolution dictated primarily by technology now shifts to one driven by substance. In this generation, theory-based models and cognitive principles combine with more traditional content considerations to provide the substantive basis for assessment design (see Huff et al., this volume). Second, these assessments integrate the needs of individuals more fully with those of institutions. A special case of this development is greater integration with instruction, including the repeated sampling of performance over time. Third and finally, the use of complex simulations and other interactive performance tasks allows new skills to be measured and traditional ones to be evaluated in more meaningful ways.

Of note with respect to the focus of this chapter is that the *Standards for Educational and Psychological Testing* (Standards; American Educational Research Association [AERA] et al., 2014) contains no section or set of standards specifically devoted to technology-based assessment. The document does, however, make clear that “computer . . . tests need to be held to the same requirements of technical quality as other tests” (p. 197) and that the “interpretation of scores on technology-based tests are evaluated by the same standards for validity, reliability/precision, and fairness as tests administered through more traditional means” (p. 188). In this sense, an assessment’s purpose, with its attendant claims for score interpretation and use, remains the central consideration in determining the appropriate level of technical quality.

With the above as an introduction, the goals of this chapter are to present (a) major issues in validity, modeling, and analysis for TBAs and (b) potential approaches to addressing those issues. The chapter is organized as follows. The first section centers on assessments used to support consequential purposes. This class encompasses decisions that, as singular instances, may have highly significant impact on individuals, groups, or institutions and that are often difficult to reverse. Examples include school admissions, promotion and graduation, educator evaluation, school accountability, intranational and international comparisons, and job licensure and certification. In this section, the history and current landscape are described for technology-based tests of this type.

Discussed are innovative tasks and item types, comparability, the analysis of response processes, and the automated scoring of complex constructed-response tasks.

The second major section covers assessments employed for in-the-moment instructional decisions or for describing what a student knows and can do so that near-term (but not necessarily real-time) instructional next steps can be taken. As singular instances, these decisions usually have less dramatic impact on individuals and are more easily reversed than decisions we have termed *consequential*. This section also begins with a review of the history and current landscape that includes brief consideration of common technology-based assessment designs and task types, response processes, and scoring methods. This section closes with a discussion of psychometric models for assessment embedded in instructional and learning systems.

The chapter's last major section explores the third-generation idea of combining both assessment purposes—that is, consequential decision-making and instructional support—in the same assessment. We conclude the chapter by summarizing key points, giving recommendations for research, and speculating on future directions.

ASSESSMENTS USED TO SUPPORT CONSEQUENTIAL PURPOSES

In this section, we outline the landscape regarding TBAs used for consequential purposes in education, as well as in the professions and occupations. We include tests used to make consequential decisions about individual test takers, as well as state, federal, and international measures intended to provide results for various monitoring and accountability purposes. In doing so, we trace major milestones in the development and operational deployment of TBAs.

Even prior to the widespread availability of desktop computers, the potential benefits of testing by computer were relatively obvious. Such delivery offered the possibility of immediate scoring and reductions in cost associated with the elimination of printing and shipping of test materials. Throughout the 1970s and into the 1980s, advances in psychometric research and theory by Lord (1970) and Weiss (1976) revealed how more powerful psychometric models, coupled with alternative test delivery schemes enabled by computer, could also improve quality. Computer delivery that moved beyond simple, linear, preassembled test forms to the use of sequential and computer-adaptive tests (CAT) offered the potential of increased measurement precision throughout the proficiency range, as well as increased efficiency (i.e., better precision for a fixed amount of testing time; Lord, 1980; Weiss, 1982).

The operationalization of TBA required an infrastructure to deliver tests securely on a large scale. As described by W. D. Way and Robin (2016), this infrastructure first emerged, surprisingly, from the University of Illinois's efforts to expand computer-assisted instruction (CAI) as implemented in its Programmed Logic for Automatic Teacher Operations system. That system was further developed and commercialized by Control Data Corporation. In partnership with the National

Association of Securities Dealers, the Control Data Corporation used this system, circa 1978, to offer what was most likely the first proctored TBA for consequential decisions, in this instance for licensure and certification.

One of the earliest entities interested in the potential convenience and efficiency of TBA—in particular, through adaptive testing—was the U.S. military (Sands et al., 1997). Military institutions sponsored considerable research and influential conferences on this topic that advanced the measurement field substantially (Weiss, 1978, 1980, 1985). In 1979, a feasibility study was launched to develop an adaptive version of the military's selection and placement test battery, the Armed Services Vocational Aptitude Battery. This test was developed, evaluated, launched for operational testing in 1992, and adopted fully in 1996.

One of the earliest efforts to deploy TBAs for consequential decisions in education—in this case, college placement decisions—began in the mid-1980s, when the College Board introduced its computerized-adaptive College Placement Tests (CPTs). The CPTs, delivered on microcomputers, were intended for use at 2- and 4-year institutions to help identify incoming students requiring remedial education in English, reading, and mathematics. The development and validation of these tests is described by Ward (1988) and Ward et al. (1986). The College Board's current college placement test—Accuplacer—is a direct descendant of the CPTs.

A subsequent major milestone was the development and introduction by ETS (Educational Testing Service) in 1993 of a CAT version of the GRE General Test, for use in graduate admissions decisions (Mills, 1999). Designed to award scores that were comparable to its paper-and-pencil predecessor, this work produced a key innovation: an item-selection algorithm capable of balancing psychometric considerations with constraints related to item content, format, and exposure, including dealing with passage-based items (Stocking & Swanson, 1993). This innovation helped to ensure that GRE CAT scores not only were psychometrically efficient but also met the content validity and fairness criteria important to consequential use. In this same decade, ETS followed with computer versions for other postsecondary admissions programs, including the adaptive Graduate Management Admission Test and the TOEFL CBT, with both adaptive and linear sections.

Whereas the introduction of these TBAs was a notable advance, it also surfaced some unanticipated challenges (Wainer & Eignor, 2000). Paper-and-pencil tests could be administered to large numbers of students on a few days per year, requiring only a small number of different forms. In contrast, because of infrastructure limits, TBAs had to be delivered in small centers to fewer students on a more continuous basis. Since demand tended to peak at particular times, problems quickly arose with test-taker access to centers. As important, it soon became apparent that initial plans for item pool sizes and item exposure controls were inadequate to maintain security. Dealing effectively with these problems substantially increased the costs of CAT TBA relative to paper-and-pencil administration. Additional problems emerged with respect to preventing students from learning how to “game” the CAT (W. D. Way & Robin, 2016). The vast

majority of these problems have been ameliorated over time, with increased access, use of alternative models such as multistage adaptive testing (MST), and enhanced schemes for exposure control. As of this writing, the two major undergraduate college admissions programs (ACT, formerly American College Testing; and SAT, formerly Scholastic Aptitude Test) have begun to offer TBA versions, with the SAT having become all digital as of 2024 (College Board, 2024).

The first forays into TBA consisted largely of adaptively delivering multiple-choice items, the staple of paper-and-pencil testing programs. Relatively little was done to leverage the affordances of TBAs for presenting more complex tasks focused on measuring a broader set of competencies. While this eventuality may have been partly due to the limitations of the available computer technology, other contributing factors included cost, limits on available testing time, score reliability, comparability with paper versions, and fairness concerning the use of performance testing generally.

It is perhaps not surprising, then, that early attempts to introduce performance tasks occurred with licensure and certification testing, where longer testing times, costs that could be passed on to the test taker, and reduced need to maintain comparability with prior versions made such innovations more tractable. For example, in the 1990s the National Council of Architectural Registration Boards introduced an automatically scored, performance-based design section into its licensure examination (Bejar & Braun, 1999). Similarly, the National Board of Medical Examiners incorporated computer-based patient management cases into the USMLE (Margolis & Clauser, 2006). Finally, the American Institutes of Certified Public Accountants began to administer TBAs containing performance tasks (Breithaupt et al., 2006). It is noteworthy that all these examinations retained very substantial, complementary multiple-choice sections to achieve the reliability and generalizability levels needed for licensure decisions. (See Margolis et al., this volume, for a comprehensive review of testing in licensure and certification.)

The first waves of consequential TBA testing—in the military, in university placement, in graduate admissions, and in licensure and certification—occurred with TBAs delivered on mainframes, then on stand-alone desktop computers in college placement offices, and next via networked machines at vendor testing centers (e.g., Prometric and Pearson VUE) and in university labs. Hardware and software could be reasonably standardized, and the use of data networks to transmit test content and response data allowed security to be maintained. For K–12 education, in contrast, the use of TBA for state-mandated accountability tests, high school end-of-course measures, and graduation examinations awaited development of a more pervasive infrastructure that could accommodate machines resident in the schools. (See Ho & Polikoff, this volume, for a comprehensive discussion of assessment for accountability in K–12.)

With the evolution of the Internet and the proliferation of laptops and tablets, TBA became increasingly practical for state-mandated accountability tests. This history dates to about 2000, when Oregon, Virginia, and a few other states each began pilot TBA programs (Bennett, 2002). Those pilot efforts gradually expanded so that by

2007, Oregon, for example, had received approval for a computer-adaptive version of its federally mandated K–8 summative assessment (W. D. Way & Robin, 2016). The passage of the American Recovery and Reinvestment Act of 2009, and in particular the Race to the Top Assessment Program (U.S. Department of Education, n.d.), gave a dramatic boost to development by funding several testing consortia, including the Smarter Balanced Assessment Consortium and the Partnership for the Assessment of Readiness for College and Careers (PARCC). Smarter Balanced and PARCC developed TBAs aligned to the Common Core State Standards in English language arts and mathematics. The tests made use of adaptivity (Smarter Balanced), items that employed technology affordances (technology-enhanced items [TEIs]), and more innovative performance tasks to measure writing, research, and problem-solving skills. The tests were first administered operationally in 2015 in a substantial number of states. By the 2015–2016 school year, between the adoption of the consortia tests and states that had implemented their own TBAs, EdTech Strategies (2015) estimated that 85% of the accountability tests in Grades 3 to 8 would be delivered online. Moreover, although many states were using both online and paper-based tests, only three states were not using some form of TBA. Primarily a result of political pressures, state membership in the consortia has waned substantially, with many states since choosing to implement their own TBA programs. Despite the reduction in consortia membership, most states continue to use TBA in whole or in part for their state-mandated accountability assessments (Olson, 2019).

Progressing alongside the development of TBA for state accountability was incorporation into the U.S. national assessment. In 1999, NAEP began a series of studies to facilitate its transition to TBA. NAEP is a congressionally mandated assessment and differs from typical testing programs in that group-level results, rather than scores for individual students, are reported for the nation, states, selected demographic groups, and some large-city school districts. Results are based on samples of schools and students, with a highly efficient matrix-sampling design employed to cover a broad content domain while minimizing testing time for any individual. Although the results do not carry direct consequences for schools or students, NAEP results receive much press coverage and are highly influential in shaping national, state, and big-city education policy.

The NAEP TBA studies investigated the delivery of traditional NAEP paper-based assessments in mathematics and in writing via computer (Bennett et al., 2008; Horkay et al., 2006; Sandene et al., 2005). Computer delivery occurred on desktop computers via the Internet or on disconnected laptops. These studies, which involved administering the assessments in both modes to randomly equivalent samples, examined issues related to comparability of results between computer and paper administration and between laptop and desktop administration, as well as issues related to differential subgroup performance and the role of computer familiarity. Results were largely favorable, suggesting the prospect of transitioning NAEP to TBA while maintaining trend comparisons to previous paper results. A third study explored the use of innovative interactive tasks

to examine problem-solving in technology-rich environments (Bennett et al., 2007, 2010). This study also yielded promising results.

Based on this early work, subsequent research, and developments in technology and testing, as of this writing, the NAEP program has almost completely replaced its paper-based assessments with TBAs. In 2011, NAEP conducted its first operational writing TBA in Grades 8 and 12 (National Center for Education Statistics, 2012). The assessment, which was delivered on NAEP laptops, required students to compose essays in response to prompts, just as in earlier paper administrations. However, because the assessment was based on a new framework, no attempt was made to maintain trends to prior years. In 2014, NAEP conducted the Technology and Engineering Literacy assessment, designed from inception as a TBA (National Center for Educational Statistics, n.d.). This assessment included TEIs as well as scenario-based interactive tasks (see the section on “Innovative Item, Task, and Assessment Types”).

NAEP’s mathematics and reading assessments at Grades 4 and 8 were transitioned in 2017 and consisted largely of traditional multiple-choice and constructed-response items, along with a limited number of TEIs (Jewsbury et al., 2020). Plans for future assessments in all NAEP subjects presume digital delivery and the increased use of innovative item types. While the current TBAs still employ the standard NAEP matrix-sample designs, adaptive administration has also been explored (Oranje et al., 2014).

In similar fashion to NAEP, such international group-score assessments as PISA and the Trends in International Mathematics and Science Study (TIMSS), are transitioning or have transitioned to TBA. (See Braun & Kirsch, this volume, for a comprehensive discussion of assessments in the international context.) Unlike NAEP, these assessments continue to support both TBA and paper administration because not all participating education systems have the required infrastructure. Consequently, these programs work to maintain comparability of results, both to prior assessment cycles and within a cycle.

PISA, which measures the reading, mathematics, and science skills of 15-year-olds across many nations and jurisdictions, transitioned to TBA for all three content areas (plus financial literacy) in 2015 (Organisation for Economic Co-operation and Development [OECD], 2017). The assessments, which were delivered on school desktops and laptops, consisted largely of TBA analogues to existing paper item types. In 2018, the reading TBA was converted to an MST, whereas the mathematics and science assessments remained linear tests.

TIMSS, which assesses the mathematics and science skills of eighth graders, was also in the process of transitioning to a digitally based version (Mullis, 2019). As of 2019, TIMSS was administered via computers or tablets, as well as in its paper format, with about half of participating education systems utilizing each mode. In addition to traditional items, the eTIMSS digital version included innovative tasks designed to simulate real-world and laboratory situations where students can integrate and apply processes and content knowledge to solve mathematics problems and conduct scientific experiments.

A third international group-score assessment, the Progress in International Reading Literacy Study (PIRLS), has also incorporated a TBA, this one concentrating on the reading skills of fourth graders. In 2016, 16 of the 58 education systems that participated in the paper-based assessment (including the United States), also took ePIRLS, a supplementary measure of online reading skills (Institute for Education Sciences, n.d.; Mullis & Prendergast, 2017). The assessment, which was delivered on either school desktop or laptop computers, consisted of two tasks that required test takers to answer multiple-choice and constructed-response items pertaining to information presented on simulated web pages.

As we look to the future, it seems reasonable to assume that TBAs will move toward a more decentralized delivery model admitting a wider range of assessment devices. As seen with the consortia-developed K–12 tests, beyond requiring a minimum configuration, it is impractical to impose strict control over the delivery device. Within and across U.S. states, schools own a wide variety of equipment. Furthermore, it is not feasible for test sponsors to provide a common device at that scale. Similar considerations exist for international programs like PISA and TIMSS.

Moreover, disruptive events like the COVID-19 pandemic make it evident that consequential testing may need to be carried out remotely at times. In pandemic conditions, gathering in groups is unsafe. Thus, consequential testing may increasingly need to be administered in homes on test taker–owned equipment, where feasible and where the security conditions for such testing are acceptable to both sponsors and users. For the purposes of K–12 assessment, approaches such as remote proctoring involving live monitoring or video capture, as well as recording and analyzing process data (e.g., timing and keystroke sequences), remain controversial as of this writing.

In addition to various exogenous factors, validity and fairness concerns may be moving consequential testing toward a more decentralized delivery model. As more complex constructs are included and tasks are incorporated that require extensive use of and familiarity with the device and interface, issues of comparability and fairness might be better served by allowing test takers to work on their own equipment. In that way, score differences might be more likely to reflect differences in the target constructs rather than also reflecting familiarity with an arbitrarily imposed, standardized device configuration.

To make consequential testing possible in decentralized testing environments, current strategies for ensuring standardization, security, and fairness will need to be adapted. As for K–12 accountability testing, some control over testing conditions may still be imposed through the specification of minimum device characteristics like screen size and resolution, types of keyboards, and transmission bandwidths. Providing free online practice materials and tutorials to familiarize test takers with task types, tools, and interfaces will also continue to be important. But most likely, these strategies will need to be coupled with a careful approach to designing delivery systems, interfaces, tools, and tasks to ensure performance is device agnostic.

Innovative Item, Task, and Assessment Types

In the preceding section, we outlined the development and landscape for consequential TBA. Next, we consider the building blocks of innovation in such assessments—items, tasks, and assessment types.

Among the potential benefits technology brings to assessment design are increased construct fidelity (Russell, 2016), evoking and supporting more complex cognitive processes, and allowing greater observability of the response process. Construct fidelity represents the extent to which the response process evoked by the item accurately reflects the targeted measurement construct. Russell and Moncaleano (2019) identified two components of construct fidelity: the extent to which the problem context is consonant with domain practice and the degree to which the response interaction aligns with the interactions that would occur in a real-world situation. For most constructs, paper-and-pencil items are far from real-world applications in both respects, implying that technology enhancement might allow for increases in construct fidelity.

Complexity of cognitive process relates to the length and depth of reasoning that is required to correctly respond to the task. Criticism has long been made about traditional multiple-choice item formats because they can measure only certain types of cognition and because of the impact that focus may have on teaching and learning (Frederiksen, 1984). Technology-enabled assessments have the potential to measure constructs that involve more complex cognitive processes, such as science practices, collaboration skills, and investigative research (Bennett et al., 2010; Csapo et al., 2012). Through use of simulated problem contexts, computer-based tasks can support an extended problem-solving process more appropriate for these domains from which student cognition might be modeled at a finer grain size (Mislevy & DiCerbo, 2012).

Whereas TBA may be useful in evoking complex cognition, traditional paper-based assessments can also call on higher order response processes through the use of text and diagrams (Bennett, 2012). An advantage of computer-based assessments, however, is the ease with which evidence about response process can be captured. The more interactive an item response, the more process data can be recorded. Thus, technology makes complex response processes more observable. “Observable” does not necessarily mean scorable; as discussed in the section “Response Processes,” challenges in interpreting and scoring process data must also be overcome before this evidence can be used meaningfully.

In the following paragraphs, we examine technological innovations in four broad categories: TEIs, extended-interaction items, scenario-based tasks, and simulation-based performance tasks. The first two categories involve innovations at the item level, while the second two encompass innovations for lengthier tasks that may include interdependent components.

TEIs

The most common items used in computer-based assessments are traditional item types with constrained outcome spaces, some of which could have an exact paper-and-pencil replica. These items might take multiple-choice, matching, sorting, or short-answer

formats. They may appear as discrete samplings, independent of one another, or as part of an item set. For assessments offered on both paper and computer, items with exact or highly similar counterparts are desirable to increase the comparability of score meaning between delivery modes. Additionally, these items produce data that fit commonly used scoring and psychometric models, increasing the likelihood that results can be put on the same scale as previous paper administrations.

While the format of such items is basically traditional, technical innovations can be introduced in stimulus presentation or response process, thereby making the item a “technology-enhanced” one. For example, the use of images, audio clips, animation, and video enables a richer presentation of information, which may increase construct fidelity or evoke more complex cognitive processes, even when the response type is highly constrained (Bennett et al., 1999). Figure 9.1 gives an early example that shows how multimedia might be employed in an item stimulus as part of a test of U.S. history knowledge. The item allows the student to view and analyze a primary source in a way closer to that of a historian.

For the response process, the affordances of mouse and touchscreen technology are frequently used to enable drag-and-drop or on-screen drawing as response mechanisms (Zenisky & Sireci, 2002). Drag and drop can be used for questions that ask test takers to move objects into the correct order or for items in which test takers reposition

FIGURE 9.1

objects from one set to match objects in another set. Additionally, drag and drop can access a more continuous response space, such as putting objects onto a map or placing a marker on a spectrum (ATP, 2017; Wan & Henley, 2012).

An example is the PISA 2015 interactive science task, *Fish Farm*. In this item set, students are given a brief context statement about the need to develop a particular type of alternative seafood source and the challenges encountered in operating such a source. Following this context are three independent items (i.e., subsequent items do not build directly on preceding ones or lead to a culminating task satisfying a goal given in the context statement). One of the set's items asks students to help design a sustainable farm ecosystem by dragging organisms into the appropriate tanks (Figure 9.2). The cognitive complexity of this item is fairly high because it “requires students to understand a system and the role of several organisms within that system” (OECD, 2018). Whereas this item could be rendered on paper using a diagram and labels for the organisms, the ability to move the organisms into the fish farm allows test takers to more naturally construct, evaluate, and revise their model.

Russell and Moncaleano (2019) judged that most usage of drag and drop in TBA failed to increase construct fidelity. Interactivity, per se, does not necessarily improve the item. In the fish tank task, the graphical representation allows students to reason

FIGURE 9.2

PISA 2015 Interactive Science Item in Which Students Use Drag-and-Drop Interactions to Complete a Model of a Fish Farm

Note. PISA = Programme for International Student Assessment. From *Try PISA 2015 Test Questions* by OECD, 2018. (<https://www.oecd.org/pisa/test/pisa2015/#d.en.537240>). CC by 3.0

more directly about the placement and interactions among the organisms. Thus, the drag-and-drop functionality is used effectively to increase the similarity of the evoked cognitive process to ones that a scientist might employ, arguably enhancing construct fidelity.

Extended-Interaction Items

More innovative uses of technology have generally resulted in greater interactivity, providing support for and observation of a more extended response process but still within the context of a discrete, stand-alone item or item set. These items frequently involve constructing a complex response to solve a problem. Test takers might be asked to graphically represent a process, analyze data, or test a hypothesis using a runnable model (a function that accepts input parameters and outputs a result intended to mimic reality, as in the “running in hot weather” example that follows). This type of item is distinguished both by the multiple actions a test taker is expected to take and the depth of cognitive processing associated with those actions.

An example of this class is shown in Figure 9.3. In this PISA 2015 item set, test takers are asked to use a runnable model to answer questions about factors that increase the risk of dehydration or heat stroke for a jogger on a hot day. Test takers are expected to interact with the model, running several trials with different settings before responding

FIGURE 9.3

PISA 2015 Extended-Interaction Item From the *Running in Hot Weather* Set

Note. PISA = Programme for International Student Assessment. From *Try PISA 2015 Test Questions* by OECD, 2018. (<https://www.oecd.org/pisa/test/pisa2015/#d.en.537240>). CC by 3.0

to the multiple-choice item prompt. The interactions allow students to engage with a real-world problem, while providing evidence of solution process through event logs (discussed in the section “Types of Response Process Data”). Thus, this format permits measurement of a construct that is not possible to assess with a paper test.

Another example of extended interactivity can be found in the PISA 2018 literacy items, which provide a simulated web browser for test takers to employ in researching a topic. While the primary construct is reading comprehension, the item design requires students to follow hyperlinks and use tabs for navigation to relevant content. In this case, the interactivity is intended to increase construct fidelity by replicating the context in which one might undertake information search.

Scenario-Based Tasks

Whereas TEIs and extended-interaction items can provide richer stimuli and the opportunity to observe response processes, their design as independent items (including in sets) limits the depth and complexity of problem-solving. To tap deeper problem-solving processes, assessment designers may turn to scenario-based tasks (SBTs), as defined by Deane et al. (2018), O'Reilly et al. (2019), and others. These tasks are characterized by an overarching narrative, or scenario, which poses a goal for the test taker to achieve. The scenario presentation is followed by a sequence of related technology-enhanced and more traditional items that lead to a culminating performance in which the test taker attempts to satisfy the goal (e.g., a proposal for how a school might use a generous gift, backed by reasons and evidence from given sources). SBTs break the process leading to this goal into steps, each of which is at the same time part of the larger whole but implemented as one or more distinct items.

Some of the tasks included in the NAEP 2014 Technology and Engineering Literacy assessment offer examples. As an instance, the bike lane task consists of five items (see Figure 9.4). Students are first introduced to the motivating problem of safety when riding in a lane adjacent to automobile traffic. Initial items ask students to interact with a runnable road-sharing model that rates bike lane safety based on the manipulable parameters of automobile speed limit and lane width. In later items, students use the information gathered to create safe road designs for cyclists and ultimately to reach the goal of a bike route that optimizes safety, cost, and route length.

The SBT format, when used to measure problem-solving processes, is a compromise between the discrete items of traditional assessment and the open-ended problem-solving characteristic of an extended project. When assessing complex problem-solving, the ability to gather evidence on the process competes with the level of constraint imposed on the problem space. If we allow the student full freedom within the problem space, it is more difficult to detect, understand, and score the problem-solving process used. In unconstrained tasks, the most reliable evidence of competency is typically the outcome. Unfortunately, the outcome may offer little information with which to distinguish and subsequently guide learners within the middle and lower regions of the proficiency distribution. When the task outcome is complex enough to show

FIGURE 9.4
Selected Screens From the NAEP TEL 2014 Scenario-Based Task *Bike Lane*

From *2014 Technology and Engineering Literacy (TEL): Sample Scenario-Based Tasks*, by National Center for Education Statistics, n.d. https://www.nationsreportcard.gov/tel_2014/#tasks/bikelanes

finer gradations of competence, for example, as in an essay or lab report, making such distinctions comes at the cost of greater scoring time and effort.

If we instead discretize the problem-solving steps to allow observation of specific portions of the process, we are inevitably scaffolding problem-solving along a more constrained, and frequently more linear, path. That constraint could improve measurement or, conceivably, undermine it by giving the test taker aids not typically available in the criterion situation. Research suggests that the former situation may be the case. That is, SBTs may in some respects produce better measurement than less-structured performance tasks, particularly in more effectively aligning the processes measured with the intended construct (Guo et al. 2019, 2020; Zhang, Deane, et al., 2019). This result could be due to the initial questions in an SBT helping to activate relevant knowledge and better orient the test taker to the task at hand. In the criterion situation,

similar orientation can come, for example, from consulting with others and viewing examples of quality solutions to comparable problems.

Simulation-Enabled Performance Tasks

While SBTs scaffold the problem-solving process to enable observable evidence about the complex cognition underlying a performance, these tasks are somewhat unnatural. According to Russell's definition of construct fidelity (Russell & Moncaleano, 2019), SBTs may provide a realistic context, but because of their structure, the actions students take might diverge from those that a domain practitioner would employ in their problem-solving.

Performance assessments come closer to actual domain practice, allowing individuals to demonstrate a skill by carrying out a less structured task. A driving test offers a good example. However, although it has high construct fidelity, it requires specialized equipment (i.e., a car), a human examiner, and an individualized administration. A compromise position is offered by TBAs that employ simulation-enabled performance tasks. Such tasks attempt to represent key stimulus features of a given performance situation, calling on competencies that would be employed in that situation, but reduce the resource requirements to more manageable levels.

As an example, the USMLE seeks to assess a potential physician's ability to independently diagnose and treat a variety of patient conditions. As noted, in 1999, the National Board of Medical Examiners incorporated patient case management simulations into the computer-based USMLE (Dillon & Clauser, 2009). In each case management task, the patient's condition changes over simulated time. The test taker can engage in various actions that a doctor might take, including requesting patient history, getting the results of a physical exam, ordering laboratory tests, making a diagnosis, and prescribing treatment. While the "physical exam" is implemented using a set of checkboxes, the lab tests and treatment plan are specified using text input. This format prevents any form of prompting because the test taker will not see a list of available tests or treatment options (unless there are multiple options that match the test taker's input). While these simulations are not similar in fidelity to interacting with a real patient (they do not include any visual representation of the patient or of test results like X-rays), they replicate the main aspects of the problem-solving process used in practice. As mentioned, simulation-enabled performance tasks have also been employed in the architect and accountant examinations, among others (Clauser et al., 2016). (See Margolis et al., this volume, for more on assessment in licensure and certification.)

Less comprehensive simulation-enabled tasks can be found in school testing programs. For example, PISA 2015 assessed collaboration skills using a simulated group assignment in which the test taker negotiates with two automated agents to achieve a specified goal (OECD, 2018). In this instance, all choices made by the test taker were selected responses; however, the choices made changed the task situation.

Of special note in simulation-based performance tasks is that technology plays a key role in observing and making inferences about complex cognitive processes. That is,

the technology environment provides a reasonably realistic problem setting that allows the test taker to work through the problem in a high-fidelity manner. The test taker's step-by-step decisions can be recorded in computer log files, making inferences about their problem-solving process feasible and, in principle, scorable.

Appropriate Use of Innovative Items and Tasks

While innovative item types have important advantages, they are generally expensive to build, more complicated to administer, and less well understood in terms of measurement properties. For consequential testing, such item types should be used only when substantively appropriate, suited to the target population, and logistically feasible.

With respect to substantive appropriateness, as noted, such innovation can improve construct fidelity by enhancing problem presentation or response interaction, thereby evoking more relevant problem-solving processes. Instances include constructs that involve the use of technology itself, such as technical literacy or data analysis, as well as constructs for which the technology can provide a more faithful context for the application of skills, as in scientific inquiry, medical licensure, or remote collaboration (Bennett et al., 2010; Clauser et al., 2016; Csapo et al., 2012).

In addition to fit with the intended construct, appropriate use implies a good fit with the target population. Fit in this context means that all test takers can interact with items in ways that provide evidence of competency. Essential to this premise is an infrastructure capable of validly assessing *all* members of the test-taker population, including those with disabilities or who are English learners (see also Rodriguez & Thurlow, this volume).

Feasibility encompasses assessment design, development, administration, scoring, and reporting. Innovative items can introduce complications in any or all these phases. Design and development time and costs are frequently underestimated by staff members more familiar with traditional assessments. However, the costs tend to be front-loaded because the deployment of innovative item types requires developing or adopting new tools and processes, training assessment developers, designing for accessibility, conducting cognitive labs to evaluate whether the intended processes are evoked, etc. Once this foundation is established, the operational development of innovative items can be streamlined by using appropriate authoring tools and improved through the telemetry (i.e., process data) produced by the items. Finally, scoring and reporting requires appropriate psychometric models to facilitate defensible inferences.

Validity, Modeling, and Analysis Issues

Innovative items and tasks present new challenges for validity, modeling, and analysis, especially for tests used to make consequential decisions. Such innovations demand evidence that new presentation formats and response interactions produce meaningful inferences about the intended constructs. Studies may cover the range of evidence types recommended for validation generally (AERA et al., 2014), but with added attention to whether the response processes evoked are consistent with the target construct

and to what degree construct-irrelevant variance might have been introduced (e.g., Gallagher et al., 2002; Mislevy et al., 1999). For SBTs and simulation-enabled performance tasks, potential unfairness due to Task $\times$ Person interaction may also be present (Linn & Burton, 1994; Shavelson et al., 1993).

Task $\times$ Person interaction occurs when one test taker is more familiar with, knowledgeable about, or interested in a particular context or topic than another test taker. For shorter tasks, this effect can be easily balanced by having a variety of different contexts or topics across items. SBTs and simulation-enabled performance tasks, however, tend to take significant time, making it impractical to include more than a few tasks. For example, the NAEP Technology and Engineering Literacy assessment tasks take 10–30 minutes each, leaving little room for additional items with contextual or topical variations (a problem NAEP addresses through its matrix design and the reporting of results at the group level, rather than through individual scores).

For TEIs and many extended-interaction items, well-understood psychometric models such as item response theory (IRT) can be used because student response data can be reasonably assumed to meet the statistical assumptions of such models. Any media or interactivity, however, must be carefully evaluated to ensure that their addition does not introduce extraneous cognitive load or other forms of construct-irrelevant variance. Particularly for extended-interaction items, the ease with which the computer interface is learned and employed can significantly affect performance. To ensure fairness, assessment developers must consider the range of experience levels likely in the target population. Similarly, items that use video or audio, or that have fine-motor-skill requirements, must be created to be accessible from the outset. Universal design methodologies are the de facto standard for achieving this goal, including such features as braille, stacked multilingual translations, videos in American Sign Language, and glossaries and test directions in other languages (e.g., Smarter Balanced, 2024).

SBTs and simulation-enabled performance tasks raise significant issues for modeling and statistical inference. While SBTs often contain a set of scored items that resembles a traditional assessment, performance on these items may not necessarily be statistically independent conditional on proficiency. The overarching narrative and topic that define the SBT contribute one source of local dependence that may affect estimates of test precision under standard analysis approaches. When multiple SBTs are used within a larger assessment, a testlet model (Wainer et al., 2000) can be employed to account for the added dependencies among item responses within an SBT.

Another source of dependence might come from how items are related over the scenario. Test takers who draw the wrong conclusions in early items may carry those incorrect ideas forward. Such is particularly the case when the SBT is structured so that later items build on previous results, as in the bike lane task. The effect of previous errors can be mitigated through leveling, in which the test taker is given a correct starting value for the new item. Leveling is controversial, however, because it does not allow test takers to follow their own path, nor does it necessarily eliminate the dependency that could be caused by the test taker's memory of previous reasoning. Models that can

accommodate item dependency, such as Bayesian networks, might be suitable in this context (Almond et al., 2015).

Simulation-enabled performance tasks often have a significant number of correct responses, especially when the response process itself is key to the target construct. In such cases, the log files contain fine-grained details such as mouse clicks, keystrokes, and latencies, which on their own are likely to have very limited meaning. Lending meaning requires thoughtful planning and development, starting with task design (Clauser et al., 2016). Such an approach involves creating a task so that it elicits important features of performance, which can then be aggregated in some fashion for scoring. This approach was used in the USMLE and in the design section of the Architect Registration Examination (Bejar, 1991; Braun et al., 2006; Clauser et al., 2016). New analytic techniques, such as deep learning (LeCun et al., 2015), or novel applications of cognitive-process modeling (LaMar, 2018) may also help in meeting the scoring challenge. The use of response-process data will be discussed further in the section “Response Processes” and automated scoring will be discussed in the section “Automatically Scoring Complex Constructed-Response Tasks.”

Comparability of Results and Score Meaning

As noted earlier, many current TBAs can be characterized as first or early second generation—that is, they differ modestly from their paper-based predecessor or current counterparts with respect to item types and the competencies targeted for measurement. However, some of these TBAs also make use of innovative items. Thus, they are beginning to leverage the affordances associated with digital administration. In this section, we deal with the implications of such leveraging for the comparability (i.e., continuity of meaning) of results.

In one use case—national assessment—the comparability of results from new TBAs to prior paper-and-pencil (PBA) results is generally desired. Comparability to PBA versions is sought because one of the defining characteristics of NAEP is the ability to compare the performance of students in the early 21st century—overall and for various subgroups—to cohorts from prior decades. In another common use case, K–12 accountability as implemented through Smarter Balanced and PARCC, the TBAs replace prior, distantly related, paper tests with no expectation of comparability. However, each of these TBAs may coexist with its own PBA counterpart, the choice of examination mode being left primarily to states, districts, and schools.

In both use cases, test takers and test users alike may desire, or expect, that results obtained under either examination mode should be comparable to the other. For group-score assessments like NAEP, recent results obtained with TBA—for the United States as a whole, for demographic subgroups, and for states and districts—need to provide meaningful comparisons to the results from earlier years in which the administration mode was paper and pencil. Changes in scores need to be interpretable because of changes in the target competencies (i.e., to construct-relevant factors), not because of an artifact of the switch from paper to digital delivery. Similarly, for K–12 accountability

tests, differences in results between districts, schools, classrooms, or individual students should reflect differences in the constructs of interest, not factors related to examination mode.

Moreover, in some use cases—for example, TBAs for K–12 accountability—the TBAs themselves allow for considerable variation in administrative conditions. Both the Smarter Balanced and the PARCC tests, for example, are delivered on a range of laptops and tablets, and student responses can be input through keyboards native to the device, an external keyboard, or, in some cases, touchscreens. Despite this variability, test users and takers again expect the results—individual and aggregate—to be comparable across these variations.

The definition of what it means for scores from different versions of a test, or from different tests with similar targeted competencies, to be comparable has received much attention in the measurement literature, initially within the context of more general discussions of score linking and equating (Holland, 2007; Holland & Dorans, 2006; Linn, 1993; Mislevy, 1992; see also Moses, this volume). In this literature, comparability is viewed as a matter of degree, with the strongest level being achieved when scores from different tests can be considered *interchangeable*. Less-stringent degrees are achieved through other forms of scale alignment such as concordances, statistical relationships between the results of assessments of related constructs that hold in specific populations.

Interchangeable scores can often be obtained in the context of consequential tests, like SAT and ACT, which traditionally produced different parallel forms administered in the same mode (primarily PBA) for use at each scheduled test administration. Such forms are constructed so that the assessed content and psychometric characteristics are tightly controlled to enhance comparability. As a result, the test takers at a given level of proficiency can be expected, on average, to achieve the same test score and to be measured with the same degree of precision, regardless of the test form administered. Moreover, score meaning—in terms of the competencies measured—can also be assumed to be the same, regardless of the form given.

It is noteworthy that even within this highly constrained context, it is rarely the case that the *raw scores* from different forms (e.g., simple number-correct scores or even IRT-based estimates) can be treated as interchangeable. However, with proper data collection designs and appropriate analysis procedures, scores from these alternate forms can be *equated* (i.e., adjusted for any unintended differences in difficulty and/or expressed on form-invariant scales, like the well-known ACT and SAT scales). For most practical purposes, after equating, the resulting scale scores from different forms of the same test can be treated as interchangeable in terms of the constructs measured, as well as psychometric characteristics, when making inferences about individual test takers or groups.

In considering the comparability of scores from PBA and TBA forms, interchangeability may be a reasonable and desirable goal when the content, item types, and delivery paradigm (e.g., linear versus adaptive) of the two modes are kept as close as possible. In situations

where the identical (or nearly equivalent) set of items is being delivered, there is a long history and considerable body of empirical evidence with different kinds of tests and testing populations, often referred to collectively as *mode comparability studies*. Though findings from this body of research are somewhat mixed, the evidence suggests that—as is often the case with different PBA forms of the same test—some degree of equating adjustment to TBA raw scores may be required if results are to be treated interchangeably with those of the corresponding PBAs. Papers by Paek (2005), Kingston (2009), Drasgow et al. (2006), Lottridge et al. (2010), and W. D. Way et al. (2006) offered pertinent reviews for tests that provide individual scores. Jewsbury et al. (2020) gave an additional recent example from NAEP pertinent to group-score assessments.

In some use cases (e.g., the Smarter Balanced K–12 accountability tests and the PISA transition to TBA), design differences between PBA and TBA also exist—for example, the paper version being linear and the computer one item-level or multistage adaptive. Changes in test delivery that involve an item-level CAT or an MST could, in some cases, be expected to affect the psychometric properties of scores, usually by improving the precision of results for low- and high-performing test takers relative to test takers in the middle of the score distribution. Hence, strictly speaking, scores from the linear PBA and adaptive TBA may not be interchangeable in the same sense as scores on parallel forms from the PBA test, the differences in precision at particular ability levels being intentional and desirable. However, through the imposition of content and format constraints and the conduct of appropriately designed equating studies (see, e.g., Dorans, 2000; Schaeffer et al., 1995, 1998), adaptive versions of linear PBAs can be instantiated such that scores can be treated as equivalent measures of the same construct for practical purposes.

As of this writing, however, the TBA versions of a test can be expected to differ at least to some degree from their PBA counterparts in ways that go beyond a simple move to adaptive delivery. Even first- and second-generation TBAs frequently contain some number of TEIs for which exact PBA counterparts do not exist. As a result, subtle cross-mode differences in the assessed target competencies are inevitable. Similarly, construct-irrelevant factors—such as familiarity with and ease of working within the digital and paper testing environments, respectively—might also reduce the degree of comparability. Different approaches to scoring constructed-response items represent an additional threat to interchangeable scores. For example, absent training, human raters have been found to differentially grade handwritten versus computer-entered responses (Russell & Tao, 2004a, 2004b; Sandene et al. 2005, pp. 14–15).

The *Standards* (AERA et al., 2014, p. 105) requires a clear rationale and supporting evidence for claims that scale scores earned on alternate forms of a test may be used interchangeably. Given the goal of leveraging the affordances of digital delivery, achieving interchangeability is unlikely, perhaps unnecessary in many use cases, and probably undesirable if it limits improvements in measurement precision and better representation of important constructs. However, even when strict equivalence is not claimed, the *Standards* requires a rationale and direct evidence of the *degree* of

score comparability commensurate with intended uses and claims (p. 106). Similarly, U.S. Department of Education guidance on peer review of state assessment systems (U.S. Department of Education, 2018) suggests that when a state administers different versions of its assessment (e.g., TBA and PBA, or TBA on different devices), the state should provide comparability evidence generally consistent with the expectations of current professional standards.

What sorts of evidence traditionally have been, and should be, provided to document the degree of comparability between TBA and PBA results? Whereas the *Standards* contains no specific guidance, there is a substantial literature that addresses the topic generally. Some of this literature is located within the broader context of establishing comparability of scores obtained under standardized conditions to those obtained from test variations such as accommodations, adaptations, or different languages, where interchangeable scores are rarely practically achievable. Particularly pertinent discussions can be found in Kolen (1999), Wang and Kolen (2001), Sireci (2005), Winter (2010), Lottridge et al. (2010), Randall et al. (2012), DePascale et al. (2016), and Berman et al. (2020).

There is considerable agreement in this literature regarding the sources of evidence required. These sources include studies that examine:

- similarity of the dimensional structures;
- similarity of item-level psychometric properties (e.g., classical test theory indices of difficulty and discrimination, IRT curves, IRT model fit in cases where the TBA and PBA versions contain identical or corresponding items);
- similarity of predictive and concurrent statistical relationships between assessment scores and other related educational variables;
- similarity of measurement precision through comparisons of overall standard errors of measurement and standard error curves across the proficiency range;
- similarity of overall score distributions, including means, degree of dispersion, and shape; and
- similarity of score differences and extent of differential item functioning for important subgroups defined by gender, race/ethnicity, disability, socioeconomic status, or computer familiarity.

Whereas a comprehensive evaluation of comparability would involve all these sources of evidence listed, rarely in practice is that possible. In analogous fashion with validity, degree of comparability remains an integrative judgment by test professionals, test users, and other stakeholders as to whether claims based on comparisons of PBA and TBA versions are adequately supported.

From a fairness perspective, perhaps the most important sources of evidence for tests used for consequential purposes are associated with what Winter (2010) labeled “score-level comparability” (the last three sources listed above). Direct evidence is usually gathered from mode comparability studies in which TBA and PBA results are obtained from groups that can be assumed to be equivalent with respect to the

distribution of the target competencies associated with the test. Data from such studies serve two roles. The first role is to provide evidence of score-level comparability. The second role is to, when necessary, determine an adjustment from one or the other modes to account for the effects—that is, differences in overall test performance (means, standard deviations, or shapes). Depending on other sources of evidence, the adjustment can, in the best case, render the scores effectively interchangeable or, where claims of interchangeability are not justified, increase the degree of comparability and fairness inherent in score use.

Mode-Study Data Collection Designs

Mode comparability studies have made extensive use of the data collection designs traditionally employed for equating and linking (see, for example, Kolen & Brennan, 2004; and Moses, this volume). *Single-group designs* have many advantages, in principle. In these designs, test takers are given both the PBA and the TBA versions, usually with the order of administration randomly counterbalanced (e.g., Gallagher et al., 2002). Because the same test takers are tested in both modes, issues related to sampling variability between groups are minimized. Moreover, this design provides the most direct evidence of the construct equivalence of the TBA and PBA versions. The correlation between scores in the two modes and the similarity of internal dimensional structure, psychometric properties, and relationships with other variables can all be directly evaluated *on the same group of test takers*. If IRT methods are employed, the appropriateness of jointly scaling both tests can also be directly appraised by examining model fit.

However, there are several challenges with implementing such designs. It is often not feasible to administer tests in both modes to the same test takers because of concerns about burden and so-called *order effects* (i.e., the fact that the relationships between the TBA and PBA versions may differ depending on administration sequence). Lottridge et al. (2010) described several such studies where differential order effects were found.

A somewhat more practical alternative that offers many of the advantages of single-group designs is the *random-groups design* (i.e., where test takers are randomly assigned to administration mode). Because test takers are assessed in only one mode, issues of burden and order are not relevant. When data from large, randomly equivalent groups of test takers are available, almost all the sources of evidence recommended above can be produced, the major exception being correlations and joint IRT scaling. NAEP has relied, and continues to rely, on such designs in carrying out its transition from PBA to TBA (e.g., Bennett et al., 2008; Jewsbury et al., 2020). As part of its 2015 field test, PISA also employed this design to aid in its TBA transition (von Davier et al., 2019).

Operational research from NAEP, described in detail by Jewsbury et al. (2020), is a particularly good example. Data from the random-groups design were used to adjust for mode effects associated with TBA, as well as to provide comprehensive analyses (including classical test theory and IRT), documenting the evidence for the comparability of NAEP results across modes after adjustment. In this study, NAEP administered

the PBA and TBA versions of its fourth- and eighth-grade 2017 mathematics and reading assessments to random samples of test takers, with random assignment to mode carried out largely within each NAEP-participating school. This *within-school* design was chosen to produce highly similar samples, taking each mode at all the jurisdiction levels for which NAEP reports results (nationally, by state, and for large urban districts), and to give reasonable statistical power for detecting mode differences at the state and subgroup levels.

National-level results comparing item-level statistics across modes (biserial correlations, differential item functioning statistics, IRT parameter estimates), as well as various other psychometric characteristics (e.g., dimensionality), provided solid evidence that the two versions were measuring highly similar target competencies. However, other test-level analyses indicated that, without adjustment, results from the TBA versions of the 2017 reading and mathematics assessments would be systematically lower for both fourth- and eighth-grade test takers, with larger mode effects for fourth graders. After making a *single adjustment* to the TBA NAEP scale-score distributions to equate the mean and standard deviation for the national samples taking the assessment in each mode, results were shown to be highly similar for the major national reporting subgroups (e.g., sex, race/ethnicity), for states, and for participating large urban districts. That is, with very few exceptions, the observed differences due to mode were within the bounds of sampling error. The few statistically significant differences that were observed showed little consistency across grades and subject.

PISA employed a somewhat different approach (von Davier et al., 2019). In the 2015 field test, a number of countries provided data from randomly equivalent samples of 15-year-olds for both PBAs and TBAs of reading, mathematics, and science. The investigators combined descriptive analyses—that is, visual inspection of residual plots and indices of item-level model fit—with statistical evaluation of a series of constrained IRT models that they refer to as “mode-effect models.” The mode-effect models imposed increasing degrees of measurement invariance. These analyses identified some items for which comparable functioning could not be supported. However, for most items, the evidence suggested that the IRT parameters were equivalent across modes. These items were then treated as equivalent in the operational 2015 analyses so that results from both PBA and TBA could be reported on a common scale comparable to prior PISA assessment cycles (OECD, 2017, chap. 9).

Whereas the random-groups approach can be quite effective, it too may frequently be intractable because it relies heavily on random assignment and requires large sample sizes for sufficient statistical power. Whereas NAEP was able to achieve both requirements, those requirements may not be easily met in other operational contexts (e.g., where the test-taking population has uneven access to computers or where imposing an administration mode is not acceptable to the test taker or institution). In such situations, data collection by necessity will involve self-selected, *nonequivalent groups*, that is, groups in which similarity of the distribution of target competencies for the TBA and PBA versions cannot be assumed.

With nonequivalent groups, mode comparability studies have typically adopted one of two strategies (or their combination). The first strategy is to use statistical approaches that employ demographic and other related performance data to control for preexisting group differences in the targeted constructs. Approaches such as propensity-score matching (Rosenbaum & Rubin, 1985), coarsened exact matching (Iacus et al., 2011), or weighting-based approaches (Haberman, 2015) can be employed to create *pseudo-equivalent groups*. These matched groups can then be used to conduct the desired comparability analyses, including the calculation of any mode adjustment. Numerous examples of this approach can be found (Lottridge et al., 2010; W. D. Way et al., 2006, 2007, 2008; Yu et al., 2004).

A second strategy is to rely on *common-item assumptions*—that is, the assumption that identical or nearly identical items appearing in both modes exhibit the same psychometric characteristics (e.g., difficulty and discrimination). When employed in the context of nonequivalent groups, this strategy can be thought of as a variant of the *common-item* or *anchor test nonequivalent groups design* (Kolen, 2007). Numerous IRT methods can be applied, including concurrent calibration and approaches based on separate calibration of PBA and TBA data, followed by some form of parameter linking on test characteristic curve transformations. In addition, non-IRT methods can be brought to bear (see, for example, Kolen & Brennan, 2006, chaps. 4–6). Usually, the analyses proceed by first assuming that all identical/similar items function comparably and then selectively relaxing this assumption based on various diagnostic indices, such as model fit and analysis of outliers.

As a basis for evaluating comparability, both approaches to the nonequivalent groups situation come with challenges that can compromise their effectiveness. Statistical matching requires sufficiently strong ancillary data related to test performance that accounts for the differences between the groups with respect to the targeted competencies. When such ancillary data are not available, the matching will not produce equivalent groups. As such, conclusions regarding comparability, or adjustments to achieve comparability based on equating the score distributions in the matched groups, may be suspect. It is important to note that ineffective matching could potentially affect conclusions in both directions. That is, one could be led to conclude that scores are not comparable when in fact they are or to miss a systematic directional bias that was inadvertently removed through faulty matching.

A possible example of this situation can be seen with the PARCC K–12 reading and mathematics accountability tests, which existed in both TBA and PBA form. Though not strictly identical with respect to all item types, the two modes were intended to produce comparable results. Comparability studies were conducted based on field test data in 2014 (Brown et al., 2015) and on the first year of operational data in 2015 (Liu et al., 2016). The first of these studies was originally intended to use a random-groups design, but challenges in implementation made it necessary to rely on a post hoc matching approach. In contrast, the second study was designed to employ nonequivalent groups with propensity-score matching. In each study, a comprehensive analysis was done

using most of the generally recommended evidence types (AERA et al., 2014). Both studies presented solid evidence that highly similar constructs were being assessed by the two modes. Moreover, though small mean differences usually favoring PBA were noted for particular test subject/grade combinations, the differences in average scores between modes were, for the most part, negligible. Thus, the general conclusion was that results could be compared across modes for accountability purposes.

Despite this conclusion, subsequent studies and analyses of operational PARCC results have suggested that, in at least some districts and states, scores on the PBA version were systematically higher to a greater degree than would have been expected from the mode comparability study results (Backes & Cowen, 2018; Duque, 2017). One reason that evidence of noncomparability has surfaced may be that the earlier matching procedures did not work as intended, a possibility expressed in the 2016 PARCC Technical Report (Pearson, 2017, pp. 143–144). However, other considerations—such as differences in the relationship between TBA and PBA results across groups, states, and time—represent alternative, or at least contributory, factors. Several of these considerations are discussed in the following paragraphs.

Relying on common-item assumptions effectively assumes that, at least on average across all the items common to both modes of presentation, consistent *main effects* on item difficulty and discrimination favoring one or the other mode are negligible. Studies employing this approach are most typically carried out within an IRT framework. In one variation, IRT item parameter estimates based on data from one mode (the reference mode) are applied to the data from the other mode. Analyses of model fit are done to identify items for which the assumption of common parameters appears untenable, and these items are then deleted from the set. For these identified items, as well as items unique to the other mode, separate item parameter estimates based on data from the new mode are obtained, with the parameters for the remainder of the items fixed at their reference-mode values. The full set of item parameters is then used to produce results that are directly on the reference-mode scale.

In situations where the tests have been carefully created to measure similar constructs across modes and the assumptions of negligible main effect are tenable, this approach can achieve comparability of score distributions, as well as provide clues regarding item features that interact to introduce cross-mode noncomparability (e.g., when the mechanics of response entry for a TEI are more complicated than answering the analogous question on paper). The latter information can be quite valuable in producing future comparable versions. However, the assumption of negligible main effects cannot be effectively evaluated based on the mode-study data collected with the non-equivalent groups design. This situation stems from the fact that main effects on item parameters due to mode are not separable in the IRT analysis from group differences on the target construct since the two causes are perfectly confounded. Moving forward, these differences will manifest themselves as a systematic source of noncomparability between scores in the two modes. Attempts are sometimes made to combine the common-item approach with matching strategies to disentangle the mode effects from

group differences (ETS et al., 2016; Liu et al., 2016). However, the effectiveness of this strategy is subject to the limitations discussed previously.

Much of the conceptual framework and methodologies within which psychometricians have approached issues of comparability (particularly of score distributions) was developed when consequential testing was done as PBA under generally strict standardization of administration conditions and testing formats. To be sure, testing conditions across PBA sessions varied in small, presumably inconsequential ways. The basic PBA administration infrastructure could be assumed to be stable, reasonably homogeneous, and familiar to the vast majority of current and future test takers. These assumptions of homogeneity and stability undergirded the argument that standardized test scores were fair, valid, and reliable and that results from such assessments could be confidently and meaningfully compared over time.

Early forays into consequential TBA (e.g., for military selection, licensure, graduate admissions) occurred largely with adults at test centers where the variability in equipment (desktop computers) was limited and under the control of the testing organizations. Given these conditions, it was also reasonable to assume that the TBA administration infrastructure was stable and homogeneous. Thus, similar claims for the fairness, validity, and comparability of TBA results could be made. Against this backdrop, historical approaches to evaluating comparability (particularly of score distributions) seemed appropriate. Unintended differences in difficulty due to mode, for example, could be identified and adjusted for *once*, much the way adjustments have been made to alternate forms of admissions tests like the SAT and ACT. That adjustment could then be applied to results produced by future forms of the TBA, rendering them comparable to past PBA results and to one another.

However, the technology landscape for TBA is different and far more variable, particularly in K–12, where laptop computers and tablets are used for instruction as well as testing. Differences in displays (size, resolution), input mechanisms (keyboards, mouse, touchscreen), and operating systems carry the potential to inadvertently introduce construct-irrelevant differences and impact psychometric properties, not only in comparison to PBA versions, but also among the “same” TBA taken on different devices.

NAEP provides a good example of the challenges that consequential testing programs face. To remain relevant, NAEP has already transitioned many of its assessments (reading, mathematics, U.S. history, civics, geography, and science). Up through 2024, NAEP’s operational approach has been to standardize by administering the assessment on the *same* device configuration brought into the participating schools by NAEP personnel. This approach is an attempt to provide, at any given time, a stable and consistent infrastructure capable of delivering the full range of NAEP assessment tasks and of producing comparable scores.

However, maintaining a stable delivery architecture *over time* is becoming untenable. Hardware, software, and interface design life cycles make change inevitable. New delivery devices, operating systems, and assessment software are periodically

introduced. Concomitantly, as NAEP gains experience with its digital delivery system, the program itself will want to make user interface and task design improvements. These changes will affect to varying degrees how the test taker interacts with the test, which could in turn materially change the meaning of results over time. This evolution will be continuous and inexorable.

Of course, when NAEP was a paper-and-pencil assessment, changes in assessment procedures and content were also periodically introduced. At these limited change points, *bridge studies* (using random-groups designs) were conducted to adjust for the potential impact of the changes on assessment results and to confirm the valid reporting of trend. For PBA administrations, results from the sequence of assessments occurring before and after the change could be safely assumed to be comparable since the basic underlying test delivery system (e.g., booklets, pencils) represented a constant delivery infrastructure. However, in the TBA era, conducting mode-comparability studies at major change points may not be practical, economically feasible, or enough to confirm valid trend reporting. Even with a relatively stable assessment in content and procedures, the constant evolution of the delivery infrastructure may be too great.

In contrast to NAEP, Smarter Balanced and PARCC have taken a different approach, electing to support TBA delivery across a wide range of digital devices. This strategy presents a different challenge: how to accumulate and present evidence of comparability across a potentially large number of different devices. As is true for mode effects, the research on device effects has generally used some version of the designs described earlier. Reviews by DePascale et al. (2016) and W. D. Way et al. (2016) summarized some of the key findings about the impact of such factors as screen size, input device, and item type, as well as how these factors interact with such things as content area. But given the continuing rapid evolution of TBA, a strategy of amassing comparability evidence (as historically done for PBA and TBA) would appear to be Sisyphean considering the plethora of existing TBA device configurations. And as noted, the COVID-19 pandemic brought the administration of some TBA programs to the home, where an even greater array of device configurations may be found.

Considering this reality, a more expansive approach to comparability is required. W. D. Way et al. (2016) argued that we have moved from an era of standardization to one of personalization. In that latter era, consequential testing is more accurately viewed as a collection of variations, many of which are intended to adapt the experience to the individual in a way that maximizes their access to assessment content (see also Bennett, 1999, regarding “generalized accommodation,” and Bennett, 2024). From this point of view, it will be necessary to supplement, if not entirely replace, studies documenting the comparability of results between variations with mixed methods interdisciplinary approaches. Such approaches should provide test, item, and interface design principles usable across a wide range of assessment situations. The knowledge obtained would inform the engineering of personalized testing conditions in a way that maximizes validity and fairness by increasing the likelihood that results can be treated as comparable across a range of devices.

As W. D. Way et al. (2016) so aptly put it,

What is clear is that the evolution of technology will only continue and that schools will continue to adopt different technologies in different time frames and will have little patience for a measurement field that is unprepared to accept these technologies for testing purposes. Establishing a framework and a process for evaluating new devices and new technologies is perhaps more important than understanding the impact to comparability of any specific device or technology. (p. 274)

D. Way and Strain-Seymour (2021) have taken a step in that direction by proposing a framework for device and interface features that might affect test performance and, thereby, perhaps offer a path to greater comparability through the personalization in the manner W. D. Way et al. (2016) suggested. That idea is consistent with an emerging alternative view of standardization in educational testing more generally. For example, Sireci (2020) argued for UNDERSTANDization, in which the first step is to appreciate the implications of diversity within the student population and then critically evaluate the ways in which traditional standardized procedures may lead to biased estimates for some individuals and groups. The third step involves adjusting those procedures to eliminate potential biases.

Some precedent for this view exists in the way in which testing programs now handle accessibility. For example, Smarter Balanced offers accessibility features in three categories: accommodations (available to those students with documented need through either an Individualized Education Program or a 504-accommodation plan), designated supports (available to any student for whom school officials have indicated the need), and universal tools (available to all students; Smarter Balanced, 2023). Universal tools include English glossary (i.e., pop-up definitions for selected construct-irrelevant words), highlighter, strikethrough, zoom, and notepad. Among the designated supports are masking, color contrast, text to speech (for all items except reading passages), glossary translation in 10 languages and several dialects, and translated test directions in 19 languages. Accommodations are provided through braille, closed captioning (for listening items), American Sign Language video presentation (for listening and math items), and text to speech (for reading passages in Grades 6 and above), among other mechanisms.

Smarter Balanced test administrations, thus, may vary considerably across students depending on the category of accessibility features for which they are eligible and the features utilized within that category. This variation is intended to follow the guiding principle that, when selectively metered, accessibility supports can contribute to more valid measurement because the assessment is more appropriately customized to student characteristics.

The beginnings of a scientific framework within which to conceptualize comparability for students with special needs may exist in the research on the so-called interaction hypothesis and on differential boost. The interaction hypothesis indicates that accommodated tests (e.g., the availability of text to speech) should result in students

with special needs achieving higher scores than they otherwise would, coupled with no difference for general education students taking the same accommodated test. In contrast, differential boost focuses on the expected increase in scores for students legitimately needing the accommodation, ignoring any effect (or lack thereof) on general education students. Sireci and O’Riordan (2020) provided a comprehensive review of issues related to accommodations and comparability, Sireci et al. (2005) gave a discussion of the interaction hypothesis among students with special needs, and Pennock-Roman and Rivera (2011) did the same for English learners.

Though comparability is emphasized in many consequential use cases, it is important to acknowledge that too large an emphasis may have the unintended negative consequence of inhibiting advances in measurement science and practice. Comparability of scores to previous versions of an assessment may be undesirable if it is obtained at the cost of innovation in test design and task types that provide the potential for improved measurement precision and tapping important constructs. Thus, as testing programs transition from PBA to TBA, they must carefully weigh the costs and benefits of maintaining comparability to past results.

When severing comparability to past results, new reporting scales are typically introduced, which can be extremely disruptive to test takers, test users, and other stakeholders. Testing programs that do so often provide concordance tables showing pairs of scores, new and old, having the same percentile rank in a particular population of test takers. Such statistical relationships can be helpful during the transition when stakeholders may be required to make consequential decisions about test takers, some of whom have scores on the prior reporting scale and others on the new scale. Concordances, however, carry their own risks of misuse and misinterpretation. The reported statistical relationship does not imply interchangeability of results and score meaning. In situations where the knowledge, skills, and abilities measured by the old and new version of the test are substantially different, the statistical relationships may not hold in populations different from those on which the concordance was established or in subgroups of the population. (See, for example, Dorans & Walker, 2007; Pommerich, 2007; and Sawyer, 2007, for a discussion of the uses and limitations of concordances.)

Strategies like instituting innovations incrementally to avoid disrupting comparability at a single time point represent a different approach to balancing the trade-offs. The strategy being used by NAEP for its assessments in reading, mathematics, and science appears to follow such an evolutionary approach. In its initial stages, the transition concentrated on moving the current paper assessment to digital delivery. Later stages introduced innovative item types like SBTs and simulation-enhanced performance tasks. Subsequent stages include a 2025 field test of web-based delivery on school-provided devices and possibly further explorations of adaptive testing.

Introducing such innovations in stages—and evaluating their impact on the comparability of results through careful experimental study and other empirical approaches (see, for example, Jewsbury et al., 2020)—will help NAEP develop validity evidence for supporting construct-based inferences from existing trend lines. If supported

by empirical study, changes in results from the original assessments to the newer innovative ones can be interpreted as due largely to construct-relevant factors, overall and for most or all subgroups of interest. The evidence supporting construct-based inferences is likely most sound for those assessments close to the transition points—and to the comparability studies—where the innovations were introduced. The validity of construct-based inferences may be less well supported for assessments farther apart in time, given the potential cumulative effect on score meaning of the multiple innovations and the absence of studies directly comparing the modified and original versions. Given the rapid changes in technology and the potential advances in assessment practice, increased ambiguity as to the meaning of changes in results over longer time spans may be the price paid for maintaining a relevant assessment system.

In other instances, where an evolutionary approach is not practical or desirable, breaking with the past may represent the wiser course. NAEP again provides an example where decisions to forego comparability with prior assessments were made. The most recent instance concerns the transition of the writing assessments at Grades 8 and 12 from paper to TBA in 2011 (U.S. Department of Education, 2012). The new NAEP writing assessment was based on a different framework than that used in prior years (1998, 2002, and 2007). The implementation of that framework required the assessment to reflect the reality that most writing in the second decade of the 21st century in educational and work settings was already done with the aid of technology. TBA delivery included the concomitant introduction of resources such as a thesaurus, as well as such common computer tools as spell check, cut, copy, and paste—all of which had no analogue in the NAEP PBA context. In addition, the new framework called for changes to the assessment tasks that required a purpose for writing and a specific audience to be addressed. NAEP decided that the changes reflected important social and educational developments and chose to begin new trend lines without empirical study of comparability. The loss of comparability to prior assessment results was seen as a necessary and desirable trade-off in return for maintaining the program's relevance and position as an innovation leader.

Response Processes

Whereas a loss or reduction in the comparability of results and score meaning to PBA might be viewed as a negative effect of the transition to TBA, a more positive outcome relates to the availability of data about the response process. The response process describes the cognition in which a test taker engages when encountering an item stimulus, formulating an answer, and entering that response (Wilson, 2005; Ercikan & Solano-Flores, this volume). For some constructs, the test taker's cognitive process is itself a relevant target of measurement, either instead of, or in addition to, the final product of that process (e.g., in medical patient management, scientific inquiry). This section discusses how technology enables the observation and analysis of evidence concerning response processes. Such evidence can be captured and analyzed from the data collected in any type of TBA, even ones that include only traditional

multiple-choice items. However, the potential value, as well as the challenges of such capture and analysis, increases with task complexity.

The simplest response processes might involve multiple-choice tests of declarative memory: The respondent is asked to recall a fact, find the matching response from a fixed list, and mark the appropriate option. The response process to an algebra item might be more complex, perhaps involving multiple steps of problem translation, integration, solution planning, and execution. A yet more complex response process is evoked when a student is asked to write a persuasive essay. This task might bring into play such aspects as choosing the thesis, outlining and planning the argument, drafting text, and editing and revising that text. A final type of response process is exemplified by a simulation-enabled science performance task. Here, selecting a hypothesis, choosing variables, designing and running an experiment, and interpreting the results would all be relevant.

Next we describe the diverse uses of response process data, after a short introduction to the types of data that TBAs can collect. These uses include validation, quality control, security, and new insights into group and individual performance.

Types of Response Process Data

TBAs can, in principle, provide a stream of process data to supplement the traditional scored response. Log files are commonly generated, recording key events in the response, as well as in the navigation of the assessment. Design of good log files is a new but important part of assessment development (Hao & Mislevy, 2018). On the one hand, whereas every keystroke, finger swipe, mouse action, and latency can be recorded, the resulting data will constitute a large, potentially uninterpretable, collection. Recording too little, on the other hand, may lose valuable information. In general, it is recommended to record as much information as possible because new analytic techniques are emerging for dealing with the data.

No matter the actual item format, TBAs can provide latency data for each student on each item. For example, when a student loads an item, when they select a response, and when they submit can be recorded. For reading comprehension items, timestamps can denote how long a test taker stayed on a single screen; for a writing task they can indicate how long the test taker paused before beginning to write and between characters, words, and sentences. The more interactive an item, the more timestamped events can be collected.

As the called-for interaction increases, more details of the process used to complete a task can be inferred from the log file. In writing tasks, for example, the recorded keystrokes can allow for a real-time recreation of exactly how an essay was composed. Mouse actions can also be recorded for items that involve more complex response formats. For highly interactive tasks, such as simulation-enabled performances, each step can be logged, providing a fine-grained record of the test taker's path to solution.

It is useful to consider the different levels of inference that might be made about a test taker's response process from log files. The lowest level is descriptive, based on the raw

data. These data might include each keystroke, cursor movement, and mouse action, along with assessment-generated events such as the running of a video clip. While data at this level are often more difficult to interpret, they may be used to create a playback, or description, of a student performance. Such playbacks can be used for quality assurance, validity studies, and performance ratings by humans and as a formative resource for instructors or test takers. This level of data is also objective. If the log records a mouse click on a specific button at a particular time, it is almost certain that the click occurred as recorded.

A next level of inference is the action or decision layer. At this more semantic level, mouse clicks or keystrokes may be interpreted as indications that the test taker decided to take an action within the task. Thus, a mouse click becomes “selecting response X” or, in the context of a science simulation, “running a new trial.” While these inferences are relatively low level, one cannot be sure that the test taker intended the interaction as it might be interpreted.

The highest semantic level identifies strategies, plans, and knowledge. This level requires the combination of multiple events into a meaningful pattern in the context of the task. For example, we might infer that a student implemented a “control-of-variables” strategy to test a particular hypothesis (LaMar et al., 2017) or that a student wrote an outline as a plan for their intended essay.

It is worth noting that timing data can strengthen or weaken inferences. For example, we might infer that a test taker did not take the time required to develop a strategy or even read the question prompt. This judgment would indicate that the events recorded in the log file were more likely associated with random noise than with planful actions and strategies.

Utility of Response Process Data

Because the test-taker response process is central to the integrity of educational measurement, process data have multiple uses throughout the assessment life cycle. Assessment designers have long employed student cognitive labs to test and refine items in development (e.g., see Connolly & Wantman, 1964, for an early example). Think-aloud protocols or retrospective interviews aim to make observable how the test taker works through questions so that item functioning can be improved.

With the help of automatically generated process data, far larger test-taker samples can be evaluated than are possible with these more labor-intensive methods. In the early stages of assessment design, such data can be used to identify usability problems with the computer interface and to select which tasks are most likely to evoke response processes involving the target construct. Items that allow for shortcut solutions or the use of construct-irrelevant skills can be identified and modified or dropped. Whereas gathering some types of validity evidence is a routine part of assessment design (e.g., item alignment, cognitive labs), most evidence is generally gathered from pilot, field test, and operational administrations because those events provide the sample sizes needed for psychometric analysis. Examining automatically gathered process data could

complement these analyses (Ercikan & Pellegrino, 2017). For example, Zhang, Deane, et al. (2019) compared the psychometric properties of a scenario-based English language arts assessment design to alternative structures and found that a single scenario functioned best with the essay appearing after (rather than before) a series of lead-in tasks. These psychometric analyses were complemented by process investigations that evaluated *how* students wrote their essays. Those investigations showed that the scenario-based design reduced the impact of general writing fluency processes on essay score, thereby presumably giving students with less keyboard facility or lower verbal fluency more opportunity to display their argumentation skills (Guo et al., 2020; Zhang et al., 2017). (See Padilla & Benitez, 2014, for a detailed discussion of theory, relationship to other evidence types, and methods in using processes for validation.)

Once an assessment is deployed, response process data can be a valuable tool for test security and data integrity (Qian et al., 2016). For example, item response times can be used to identify unusual patterns that may suggest cheating (Marianti et al., 2014). Test takers who use a hidden answer key or memorize answers from an illicit examination copy are likely to have a mismatch between their item completion times and the distribution of times from the test-taker population. Such a mismatch may occur in part because, by virtue of not having to engage item solution processes, the former group moves through items more quickly than do honest test takers. Similarly, a test taker who is copying from another test taker will show not only great similarity to that individual's responses, but also synchronicity in timing with those responses. The detection of any such events can allow the possibility of real-time alerts to examination proctors.

Process data can also be used as part of quality assurance to identify when something has gone wrong in administration or scoring. With the addition of technology, quality assurance must include digital delivery, user-interface functionality, data recording, automated scoring, and data transfer and storage. Increasingly, assessment developers look to the best practices of software engineering for proper quality assurance methodologies because the assessment is a software product. Similar to how software engineers create unit tests during development, assessment developers can specify constraints on the expected response patterns while they craft the items. Cognitive labs can also be used to generate estimates of those patterns. During both pilot testing and final deployment, large deviations from the expected patterns would then be flagged for investigation.

After the completion of a test administration, process data can be used to understand performance in greater detail than is possible through test scores alone. Such data can, for example, illuminate group differences in scores (e.g., Bennett et al., 2021; Guo et al., 2019; Zhang, Bennett et al., 2019). Greiff et al. (2015) used process data from PISA TBA items to uncover inquiry strategy use and differential strategy use by country. Such understanding might lead to adjustments to scoring practices (when it is found that scoring privileges one type of solution), teaching (when important solution approaches are not being taught), or instruction (when it is found that a population group is not benefiting sufficiently from existing teaching practices).

At the individual level, process data could be used for formative feedback to the teacher or test taker. Those data might be used to identify test takers who are likely to be guessing (Lee & Jia, 2014), as well as those who appear to hold particular misconceptions or procedural weaknesses. In a more open-ended problem space, the level of depth at which an individual is engaging might also be described. Such evidence might enable identification of not only those who need additional guidance, but also those who could benefit from further challenge.

Analysis and Scoring of Response Process Data

The simplest process data consist of response times augmenting the raw item response. Thus, for every item, the response, its score, and the total time taken are available for analysis. Models of test speededness (van der Linden, 2017) that account for student changes in strategy due to time constraints and models that predict guessing and cheating behaviors have been applied to such data (Guo et al., 2016; van der Linden & Lewis, 2015). The remainder of this section will deal with more complex-response interactions, leading to more data available for each item response.

The rich and varied information contained within complex-response process data presents a significant challenge for analysis. The log file contains an abundance of low-level events that do not readily translate into relevant inferences. Consequently, the statistical methodology used to make those inferences needs to be well understood and appropriately validated. Here, we discuss a few of the more common approaches, along with recommendations for analysis and modeling of process data from complex tasks.

Because of the scale and complexity of the data, psychometric methods traditionally used for the analysis of item responses and test scores are frequently inappropriate. Process data are irregular in that the recorded events not only vary in number and meaning across students but also are context dependent. Furthermore, the parameter space of models used in the analysis of such data is large and assumptions of conditional statistical independence are clearly violated. For these reasons, new methods from machine learning or computational statistics may be better suited to these data. Rather than relying on models that predefine the relationships among variables, in machine learning these relationships are derived from the data. This derivation, or “learning,” requires a large amount of data; depending on the complexity of the algorithm and the number of parameters, data requirements range from thousands to tens of thousands of records. These methods are extremely useful when there is a large quantity of factors (variables or parameters) or when the relationships between the factors are complex and ill-defined. In either case, predefining a full model is impractical.

Machine learning methods are either *supervised*, which means that a labeled data set is used to train the models, or *unsupervised*, in which patterns are identified within the data without prior labeling. Labeling presents a particular difficulty for educational applications. While unambiguous classification may be more typical of some traditional machine learning domains, such as computer vision (either the picture contains a cat or it does not), “ground truth” is less common in educational and psychological

assessment. Human raters are frequently used to label data, but allowances should be made for their known fallibility (e.g., see Ho & Kane, 2013, with respect to the rating of teaching processes). Performance replays can be constructed from the process data to aid in human labeling (R. Baker & de Carvalho, 2008), which may improve consistency. Unsupervised learning is used primarily in exploratory analyses as a method for identifying common patterns within a large data set, frequently involving clustering or dimensionality reduction. For assessment purposes, such analyses can be particularly helpful in discovering response processes that are different from the expected approaches.

Both types of machine learning expect input data in which each record is represented as a feature vector—that is, a list of variables having numeric values (see also Shermis et al., this volume). The mapping of raw data to feature vectors, known as feature engineering, is a critical step because anything not encoded into the feature vector will not be usable for classification or clustering. For example, the content of text documents is frequently modeled as a “bag of words” in which the feature vector is simply the count of each dictionary word used in the document. This representation does not include word order, encoding “house boat” identically to “boat house.” The representation vector could be expanded by adding bigrams (two-word sequences) or part-of-speech tags to enable such distinctions. For analyzing response process data, features can include the count of specific actions taken, the mean time between actions, or the most frequent action in a given time slice. Feature detectors can be crafted that identify significant patterns of action within the raw data, which can then be added to the feature vector. Once the feature vectors are constructed, machine learning uses a variety of statistical techniques to classify or cluster records.

For assessment, classification can be used to evaluate performance, with categories like “high,” “moderate,” and “low.” Classification can also be used to identify records that are likely the result of guessing or cheating behaviors. For generating formative information from a summative assessment, classification can be used to identify strategies or misconceptions. Machine learning methods applied to the classification of process data include support vector machines, *K*-means clustering, logistic regression, classification and regression trees, and deep neural networks (Baradwaj & Pal, 2011; Rivas et al., 2019).

Common to all machine learning is that few assumptions are imposed about the relationship between the features in the data and the final classifications. The statistical methods iterate to optimize a loss function (e.g., classification match with prior labels, or data fit), but may add and delete factors and relationships between factors or combine the results from multiple models in a weighted fashion. This methodology makes final classifications hard to defend because the logic behind the classification is not transparent.

An alternative, or complementary, approach is theory-driven modeling. In these methods, the relationships between the data and the inference are defined in advance. The models may contain parameters that will be tuned given the data, but the meaning

of the classifications or inferences are clear *ab initio*. Bayesian networks are an example of modeling complex data with a theory-driven approach. Relationships between the features (observable variables) and the targets of inference (unobservable variables, or latent nodes) are defined by the network structure, while the exact probabilistic relationships between nodes are learned from the data.

More commonly in educational assessment, a combination of the above two approaches is used. Data mining can identify clusters of common action patterns. Content experts then examine these patterns and infer, for example, the strategy that the test takers employed. Once a set of interesting strategies is identified, models can be built to classify records by strategy or score the performance based on the action patterns observed.

One of the more active areas of process data research has been in writing, particularly for essays composed as part of standardized assessment. Using a combination of theory-driven and bottom-up approaches, this research has found meaningful relationships between essay scores and such basic features as the types of pauses that characterize composition and the length of writing bursts (Almond et al., 2012; Guo et al., 2018; Zhang & Deane, 2015). Theoretically predictable differences in feature patterns among writing task types have also been detected (Deane et al., 2018). Studies have used unsupervised data reduction methods like exploratory factor analysis to select and aggregate low-level log file features into scales (Deane, 2014; Zhang & Deane, 2015) and profiles (Bennett et al., 2022). Meaningful differences among writing proficiency levels and among gender, socioeconomic status, and racial/ethnic groups have been discovered using such scales (Bennett et al., 2020, 2021; Guo et al., 2019; Zhang, Bennett, et al., 2019).

For an extended interactive performance, a different approach from modeling a set of extracted features is to model the behaviors of the individuals within the context of the problem that they are solving. Decision models calculate the probability of a person making a choice in a particular situation, given the person's goals and beliefs (C. L. Baker et al., 2011). One can think of this approach as if we were programming an autonomous agent to perform the task. Given a goal, the agent will need to select actions, monitor the results of those actions, and select next steps until the goal is met or it gives up. Partially observable Markov decision processes are one example that can be applied to such assessment performances (Bellman, 1957; Howard, 1960). This model calculates the probability of a person taking a given action in a particular state of the problem as a soft-max¹ over the expected total rewards for taking that action. Goals are encoded into the reward structure, which quantifies both the rewards for reaching different problem states (e.g., a solution to the problem) and the costs of taking specific actions. Beliefs are encoded into the model's transition functions and state space as subjective understanding of both the probabilistic effects of taking particular actions and what is possible. Inferences about the test taker's abilities, goals, and beliefs can be made by fitting the model to the response data produced by the test taker (LaMar, 2018).

Automatically Scoring Complex Constructed-Response Tasks

The preceding section centered on evaluating response processes, a method that could be applied to a wide range of test item types and used for a variety of purposes that do not necessarily factor into the scores reported on consequential tests. In the current section, we focus on scoring *per se* and on a select class of assessment tasks. In particular, the section addresses automatically scoring a variety of complex constructed-response tasks requiring judgment of product features, process features, or both. We describe the tasks to which such artificial intelligence (AI) approaches have been commonly applied, give a high-level description of how scoring works, and suggest the types of evidence that ought to be considered for validation (see also Shermis et al., this volume).

Bennett and Zhang (2016, p. 142) offered the following definition for automated scoring: “the machine grading of constructed responses that are generally not amenable to exact-matching approaches because the specific form(s) and/or content of the correct answer(s) are not known in advance.” As they noted, that definition is quite broad, encompassing grading approaches that differ considerably as a function of the constructed-response task being posed and the character of the answers expected from a given population of test takers.

As of this writing, automated scoring is used operationally by many testing programs, including for postsecondary admissions (GRE General Test Analytical Writing Assessment, TOEFL iBT, Pearson Test of English), occupational and professional licensure (USMLE), and school accountability (selected Smarter Balanced states). The primary motivations are to reduce the cost associated with human scoring and increase the speed of reporting.

The types of tasks to which automated scoring has been applied operationally include essay writing, speaking, architectural design, patient management, accounting, mathematical problem-solving, and relatively short text responses associated with reading a passage or justifying a mathematical problem solution (Williamson et al., 2012). One important dimension along which such tasks may vary is in being static versus dynamic. For instance, in the GRE General Test Analytical Writing Assessment, the product or outcome—that is, the submitted essay response—is the only aspect graded. In contrast, the USMLE includes a section containing 13 computer-based case simulations (USMLE, 2018). As mentioned, each simulation presents a patient management problem that changes as the test taker interacts with it (e.g., the test taker’s decision to run a diagnostic test produces a result that must be considered and acted on). Consequently, USMLE automated grading must account for the *process* used to manage the patient, as well as such outcomes as the final diagnosis and prescribed treatment.²

Irrespective of the task and AI approach, automated scoring generally includes three conceptually separable parts: feature extraction, feature evaluation, and evidence accumulation (Drasgow et al., 2006). In *feature extraction*, the scorable components of the response are computed (e.g., parsing and tagging words for essay scoring; identifying what actions were—and were not—taken in managing a patient). *Feature evaluation* entails judging the extracted components (e.g., the agreement of subjects and verbs;

the appropriateness and order of actions in patient management). Finally, *evidence accumulation* involves aggregating the feature evaluations to produce one or more scores. For essay evaluation, judgments about subject–verb agreement would be combined with those related to other aspects of essay quality (e.g., organization, development, content); for patient management, evaluations of the appropriateness and order of actions would be combined with those pertaining to the suitability of the diagnosis and treatment.

Within a task type, automated scoring systems can be differentiated along multiple dimensions. One important dimension is whether scores are created to predict human scores empirically or, alternatively, are generated from theoretical propositions or rules. Most approaches to automated essay scoring take the first path. That is, they employ feature weights empirically derived to predict human scores, for example, by linearly regressing those scores on the extracted features (e.g., Burstein et al., 2013). This focus on predicting human scores has been driven by a long tradition of human essay rating, whereby human scores have come to be accepted by many users as a “gold standard” (Powers et al., 2015). An alternative approach used in some scoring systems is to employ propositions or rules based on some theoretical decomposition of what constitutes a quality performance in that task domain. The decomposition is based on expert judgment and may involve having one committee develop the rules and another committee verify the rules and the scores those rules produce, without ever optimizing the automated algorithm to predict human scores per se. That approach was essentially followed in the automated scoring of architectural design problems (Bejar, 1991; Braun et al., 2006) and in medical patient management (Clauser et al., 2016). In such approaches, humans are used as experts in defining scoring features and aggregation rules, as well as for quality control when the scores are produced.

A second dimension along which scoring approaches for a given task type may differ is specific to those approaches that seek to maximize agreement with some criterion, like human scores. The dimension is the extent to which transparent versus black-box machine learning methods are utilized. For example, in some approaches, computable features are developed from a construct theory or from an existing scoring rubric. Once computed, those features are combined by weighting them empirically to produce a score (or other judgment such as a diagnostic categorization). Divulging the computable features and their relative weights permits users to make an evaluation of the extent to which those features cover the construct theory or rubric, aspects in which the features may fall short, and how the weighting comports with the intended construct. In contrast, other approaches to automated scoring extract large numbers of computable features without any prior construct or rubric mapping and algorithmically use whatever features best predict the chosen criterion (usually human scores).³ Recent uses of large language models (LLMs) for essay scoring would appear to work in this way, though there may be ways to reduce the black-box problem via combination with more interpretable measures (e.g., Mizumoto & Eguchi, 2023). In general, however,

such approaches will not be transparent to users and may not even be scrutable to the system's developers.

The most common approach to evaluating the quality of automated scoring has been to compare the generated scores to those produced by operational human raters under the supposition that machine–human agreement equal to or greater than human–human agreement constitutes validation. As multiple commentators have pointed out, machine–human agreement is best viewed as *one* piece of evidence in the validity argument for automated scores or, said another way, validation should be broadly based (Attali, 2007; Bennett & Zhang, 2016; ETS, 2021; Williamson et al., 2012).

A considerably more comprehensive validation conceptualization has been offered by Bennett and Zhang (2016), which considers multiple sources of evidence. Their conceptualization began with the validity argument for *human* scores. It is necessary to evaluate that argument if human scores are to be used as evidence for validating the automated scores (Bejar, 2012). With respect to human scores, they asked:

- Do the test-taker response processes align with the construct definition? For example, if the computer interface is an unfamiliar one, test-taker time and cognitive resources may be split between figuring out the interface and completing the task, thereby contaminating human scores with irrelevant variance.
- Does the human scoring rubric fully capture the construct definition? If the rubric unintentionally drives human raters toward a subset of that definition, then that subset will dominate scores.
- Are operational human raters using construct-relevant scoring processes? If raters are using shortcuts (e.g., avoiding the extremes of the score scale, using correlates such as response length), then their scores will be a less meaningful evaluation criterion.
- Do raters agree reasonably highly with one another? If not, their justification as a validation criterion will be undermined.
- Do raters treat unusual responses in appropriate ways (e.g., responses that may not fit the existing rubric but clearly indicate a high level of competency; ones that attempt to game their way into a higher score)?
- Do human ratings of one task predict ratings on other tasks from the same universe reasonably well? If not, the argument for an underlying construct will be called into question.
- Do the ratings relate in theoretically predictable ways to other measures of the same construct and to measures of different constructs?
- Do the above results hold to reasonably similar degrees across important population groups? If not, those differences may reflect unfairness in human scoring.

With respect to the validity argument for automated scores, Bennett and Zhang (2016) asked:

- Was the model trained and calibrated on an appropriate sample of artifacts from the target population? If not, it may encounter responses that it cannot properly evaluate.
- Are the model's features related to one another empirically in theoretically meaningful ways and do the features and their weighting fully capture the rubric and construct definition? This question centers on whether the resulting scores are a faithful measure of the intended construct rather than some subset of it or simply a measure of one of that construct's correlates.
- Do the automated scores agree with human ratings (in the best case, with the mean rating taken across multiple experts grading under ideal conditions who agree highly among themselves)? Machine agreement with a consensus among experts makes for a more reliable and arguably more valid criterion than agreement with a single rating generated under more rushed, operational conditions.
- How effectively does the automated scoring handle unusual responses?
- How well do the automated scores predict performance on other tasks from the universe?
- Do the scores relate to external criteria in the expected ways?
- Are the functional characteristics described above invariant across population groups?⁴
- What are the likely intended and unintended impacts of using automated scoring on the behavior of test takers and those who educate them? For example, do students indiscriminately use more low-frequency words and complex sentences (when simpler vocabulary and constructions might better serve given writing purposes) because they believe such use will increase their automated scores?
- How does automated scoring compare on each of these dimensions to human scoring? Notable differences in functioning between the methods should be investigated and explained because they are likely to point to sources of inaccuracy, irrelevant variance, or unfairness in one or the other method.

In closing this section, we offer several important points. The first point is that it is generally not the automated scoring engine being evaluated, but the scores it produces. Those scores depend on the nature of the examination questions posed and the population assessed. The validity of scores may vary to the extent that either questions or population characteristics change.

A second point is that, as noted, agreement with human ratings is questionable as the sole criterion for automated score validation. This statement especially holds if the validity argument for the human ratings themselves has not been firmly established. Rather, multiple sources of evidence should be sought to permit a more rigorous and complete evaluation of the validity argument for automated scores. To the extent that those evidentiary sources suggest the same positive conclusion, the argument will be strengthened.

Third, one of those sources of evidence should be an analysis of the features used in scoring, their weighting, and the alignment of these features and weights to the construct definition. In other words, it is difficult, if not impossible, to rigorously evaluate the validity of automated scores without a clear understanding of how those scores are generated and how that generation method comports with the intended construct. Such an understanding presumes transparency of the automated scoring system. The need for such transparency is being increasingly recognized in legal frameworks governing AI systems used more generally to make decisions that have significant impact on people's lives (G20, 2019; Madiega, 2019; OECD, 2019). That recognition is, in turn, fueling efforts to create explainable AI (Dwivedi et al., 2023; Futia & Vetro, 2019; Kuang, 2017; Maglieri & Comande, 2017; Turek, n. d.).

A final point is that our efforts to build a strong validity argument for constructed-response scoring, whether automated or human, should ramp up as the consequences associated with test results increase. This stipulation holds even when those constructed-response scores are not the major portion of the test. Such is the case because, when the decisions emanating from test results have significant and hard-to-reverse impact, it is the testing program's responsibility to ensure that, to the maximum extent practicable, all test components are meaningful and fair indicators of proficiency.

ASSESSMENTS USED TO SUPPORT INSTRUCTIONAL DECISION-MAKING

The section "Assessments Used to Support Consequential Purposes" dealt with consequential TBA, where decisions based on a single result may have a dramatic influence on an individual, group, or institution and may not be easily reversed. In the current section, we focus on TBA uses that generate more easily reversible decisions with less dramatic effect in any given instance. In particular, we discuss the current landscape for TBAs used to support instructional decision-making in real time at the individual student level. We will briefly trace some of the important milestones in the development of such embedded, technology-based formative assessment, noting relevant innovations in design, task type, scoring, and modeling.⁵ (See also Brookhart & DePascale, this volume, for a discussion of formative assessment.)

The use of technology-based assessment for instructional decision-making is premised on the principle that individualizing instruction, as would be done in one-to-one tutoring, is more effective than targeting instruction to the group. This principle was implemented through mechanical devices known as teaching machines, which used simple forms of assessment to direct instruction. One of the earliest such machines was created by Pressey (1926, 1927), whose initial purpose was to build a testing device for presenting and scoring responses to multiple-choice questions. Realizing its value for instruction, he incorporated such rudimentary mastery criteria as not eliminating a question until it had been answered twice correctly. Following publication of Skinner's (1958) seminal "Teaching Machines" article, the same basic ideas led to CAI, which

afforded more complex branching possibilities based on the student's prior response(s) (Suppes, 1972; Van Meer, 2003).

The 1980s saw the advent of intelligent tutoring systems (Sleeman & Brown, 1982), today more commonly called adaptive learning or personalized learning systems. Whereas teaching machines, and the CAI implementations that succeeded them, were built on behaviorist conceptions of learning, intelligent tutors brought cognitive learning models to bear and combined them with AI approaches (Anderson et al., 1985). Those domain-specific cognitive models and AI methods were used to track a student's knowledge state dynamically as it evolved during an instructional sequence and progressively adjust instruction as a function of that changing knowledge state. This real-time assessment was initially deterministic, meaning that uncertainty was not factored into the evaluation of the student's state. These deterministic systems were followed by ones that incorporated probabilistic modeling, typically in the form of Bayesian networks, into their real-time assessment of student knowledge state (Corbett & Anderson, 1995; Mislevy & Gitomer, 1995; VanLehn & Martin, 1998).

Many of the intelligent tutors created over the past several decades did not go beyond the prototype development stage and, consequently, were not widely used in classroom settings (Shute & Zapata-Rivera, 2010). One tutor that has been widely used is Carnegie Learning's MATHia, a direct descendant of Anderson and colleagues' extensive, long-term research program at Carnegie Mellon University (Anderson et al., 1985, 1995; Pane et al., 2013; Ritter et al., 2007). A second widely used tutor is ALEKS (Assessment and Learning in Knowledge Spaces), based on the research of Falmagne and associates at the University of California, Irvine (Doignon & Falmagne, 1999; Falmagne et al., 1990). Both ALEKS, now a product of McGraw-Hill Education, and MATHia are used at the school level as well as in higher education. A third, more recently developed example is Woot Math, which helps students in Grades 3–8 learn core math concepts, starting with rational numbers (Milne et al., n.d.). Rather than the more elaborate cognitive-domain modeling approach taken in MATHia, Woot Math concentrates selectively on a small number of ideas and misconceptions identified as key by expert teachers and researchers. Of note is that, in addition to selecting tasks based in part on Rasch models, the system adaptively determines how fast each student should move along the instructional sequence, offers help based on Bayesian models of each student's understanding, presents additional instructional modules, and inserts new levels with review tasks.

A final example can be drawn from the class of tutors known as personalized learning apps, which can be accessed on mobile phones, tablets, or conventional computers. As an instance from this class, the Duolingo language learning app (<https://www.duolingo.com/>) offered as of this writing instruction in three dozen or so languages, with the more common language courses having on the order of 150–200 brief lessons. Lessons are organized around topics common to language learning (e.g., shopping, food, entertainment), into which new vocabulary and linguistic structures are progressively integrated. Each lesson is composed of an optional synopsis of the content to

be covered and exercises taking various forms (e.g., matching, selecting and arranging words to form a sentence, speaking a presented sentence). Adaptivity and such learning sciences' principles as spaced repetition are employed in exercise selection via probabilistic models (Protalinski, 2020; Settles & Meeder, 2016), although the particular models used operationally have not been identified.

Intelligent tutors, and their CAI and teaching machine predecessors, had in common that instruction was generally built around the presentation and solution of a series of discrete problems designed to evaluate student standing. In contrast, educational games and simulations often present a more thematically integrated problem-solving experience as a means of facilitating and monitoring learning. That experience may require more problem-solving steps, and the state of the game or simulation may change in response to student actions. Thus, educational software based on games, as well as on simulations, is often more performance oriented.

Like intelligent tutors, games and instructional simulations can, in principle, be built on cognitive-domain models, use AI, and incorporate probabilistic methods to estimate skill level. Estimation can be dynamic, allowing real-time modulation of the state of the problem situation in play or of the difficulty level of the problem situation to be presented next. As of this writing, we could locate no commercially available, widely used, and well-documented examples that possessed all these features. Several commercially available games and simulations, however, do possess one or more of these attributes.

As an example, Math Garden allows students to practice basic addition, subtraction, multiplication, and division skills (Klinkenberg et al., 2011). The game is in many ways quite traditional, presenting a series of drill-type math problems for which correct solutions add garden flowers and garner coins for buying virtual prizes. In addition, no cognitive domain model or AI is employed. Presentation is adapted at the item level using estimates of student competency that incorporate both speed and accuracy. Estimates are dynamically generated via the Elo (1978) rating system (originally developed for chess competitions).

An example from science is Inq-ITS (Gobert et al., 2018; <https://www.inqits.com/>). This system employs a collection of laboratory simulations that allows students to design and conduct experiments. Inq-ITS uses the Next Generation Science Standards as its cognitive-domain framework, coaching students through the NGSS practices of designing investigations, using evidence to make claims, and backing up those claims with evidence and reasoning. The system employs machine learning techniques to evaluate student responses, generate real-time alerts for teachers, and give students feedback on specific aspects of their inquiry practice. Bayesian knowledge tracing, described in the next section, is employed to estimate student skill levels (LaMar et al., 2017, pp. 143–145).

The formative assessment designs, tasks, scoring, and modeling methods used in intelligent tutors, games, and simulations can run from simple to complex. Common to most systems of interest are presenting a sequence of problems created to facilitate learning some set of domain competencies, scoring in real time, probabilistically

estimating knowledge state (or skill level) from that scored performance, and using that estimate to in some way modulate the current task or choice of the subsequent one. In the following paragraphs, we briefly discuss similarities and differences among these systems in the problems employed, presentation design, response requirements and evaluation, and feedback.

As noted, the problems that these systems present may be discrete or part of a thematically related sequence. Thematically related sequences are often introduced by a scenario intended to give a real-world context, motivate the student, and indicate a goal to be achieved. One or more problems typically follow. In an intelligent tutor, a problem statement, related stimuli, and any associated tools are available to the student. A game would add mechanics (i.e., rules and procedures for play) and such motivating elements as points for correct responding, graphics, and audio. In educational simulations, the student interacts with an invented milieu that is intended to represent the key features of some real-world environment, such that the invented environment mimics the real one. The simulated environment may include runnable models that process inputs and produce outputs like their real-world counterparts (e.g., behaving like a patient with a specific medical condition). Problems may also be presented outside the simulated environment, in which case the student responds to those problems based on his or her interactions with the simulation. Alternatively, or in addition, the students' interactions with the simulation may constitute evidence for evaluating knowledge state. Regardless, the simulated environment itself becomes part of the problem.

With respect to presentation, in intelligent tutors, presentation is typically adaptive. Games and simulations, however, may have linear, item-level adaptive, or multistage adaptive designs. In linear designs, all students encounter the same problems in the same order. Many educational games take this approach, allowing a student to progress to a higher level only when some criterion performance has been reached (e.g., a fixed number of problems answered correctly). In item-level adaptive designs, the difficulty of the next problem is determined at least in part by performance on earlier problems. Multistage designs differ from item-level adaptive ones primarily in the frequency of adaptation, adjusting the difficulty of tasks at the stage level, rather than at the item level.

As to response requirements and evaluation, in intelligent tutors, games, and simulations, such requirements may involve entering a number, clicking on a hot spot, moving objects on screen, writing text, or manipulating sliders, dials, or other components. Responses in all three types of systems can be evaluated in terms of the resulting product, the process used to generate that product, or both, depending on the underlying domain model. However, even when the domain model specifies that evidence of proficiency lies in the correctness of an outcome (e.g., a mathematical result), examining the process used to generate that outcome can be the basis for action. That action could take the form of feedback (e.g., providing hints, pointing out errors in process, showing a worked example), choosing new problems, or making other adjustments to instruction.

Feedback itself may be provided before or after responding. A response that is not given quickly enough may trigger some event to occur. That event could be visible, as in the provision of a hint, or invisible, as in updating the estimation of the student's knowledge state. Feedback may also immediately and visibly follow an action—for example, an English-language-learning game character might offer a puzzled look if a grammatically incorrect sentence is entered.

Probabilistic Models for Assessment Embedded in Instructional and Learning Systems

As indicated in the section immediately above, to provide feedback, as well as to adjust instruction, the formative assessment embedded in the learning and instructional systems of interest uses probabilistic models. In this section, we explore some of these models, their evaluation, and their validation.

Within tutoring systems, “student models” are used to track relevant parameters for various characteristics of interest including proficiency, engagement, and affective state (Johns & Woolf, 2006). These models are essential for enabling personalization of the tutoring experience, with the most basic model indexing where the student might be in relation to mastering the content being taught. In such models, proficiency is estimated dynamically from the student's performance to enable real-time adjustment to instruction. Estimation is done through some form of psychometric (or other probabilistic) model.

Although adaptive tests also dynamically estimate proficiency, they presume no change in proficiency over the course of the assessment. In contrast, proficiency should be expected to change because of interacting with a tutoring system. In addition, the system must be able to generate frequent formative feedback. Effective feedback requires specific, accurate, actionable observations about student performance (Hattie & Timperly, 2007; Shute, 2008). Thus, models need to be able to estimate specific strengths, weaknesses, and, in some domains, misconceptions.

For adaptive learning systems like intelligent tutors, the purpose of the student model extends beyond direct feedback to enabling the selection of appropriate next-instructional steps. These interventions might be in the form of hints, encouragement, explanatory text or video, a worked example, or selection of the next problem.

At a high level, the student model can be decomposed into the representation of the student's state and the method used for updating that representation. Approaches to representing student state vary considerably, but some common ones include overlay models, which characterize the student's knowledge as a subset of an expert's knowledge; perturbation (or buggy) models, which catalog both the student's correct and incorrect ideas or misconceptions; and stereotype models, which represent the student through membership in predefined classes (Chrysafiadi & Virvou, 2013; Desmarais & Baker, 2012). The methods for estimating and updating these models also vary widely, but frequently they involve a combination of a hidden Markov model (HMM) and a more traditional psychometric model.

The dynamic nature of updating estimates of student state makes the HMM a particularly suitable statistical tool. The HMM (see Figure 9.5) specifies how an unobserved latent variable, for example, mastery of skill K , might change over time based on observed variables, x_i , for example, answers given to problems within the learning system. The statistical relationship between the unobserved variable and the observed one is known as the emission probability, $p(x_i = 1 | K_i)$. For many student models, this emission probability takes the form of a psychometric model (e.g., IRT, cognitive diagnostic model, CDM; Rupp et al., 2010). The probability of the latent variable changing between student actions is known as the transition probability, $p(K_i = 1 | K_{i-1})$. Within adaptive learning systems, this probability is related to the learning rate. Additional parameters, frequently represented as ϵ , can include amount of time between occurrences and a quantification of the intervening instruction.

FIGURE 9.5
A Hidden Markov Model for Estimating Student State Over Time

Because the form and content of adaptive learning systems vary widely, the modeling approaches also vary. For learning systems that primarily present a series of problems for the student to work through (e.g., ASSISTments, Heffernan & Heffernan, 2014; Andes, vanLehn et al., 2005), the key inference at any given moment is whether the student has mastered a particular, narrowly defined skill. This inference allows the tutor to introduce a new skill once the current one has been mastered. Thus, an overlay model is frequently employed to represent the student, with a discrete set of Boolean variables tracking mastery of the skills or knowledge components of interest. The most common updating method for this purpose is Bayesian knowledge tracing (BKT; Corbett & Anderson, 1995), which takes the form of an HMM. In BKT, the probability of a student having mastered a skill L on their n th attempt is modeled as the sum of the probability they had previously mastered it at the $(n - 1)$ th attempt and the probability that they had not previously mastered it but now have mastered it (transitioned) on this attempt (T_n):

$$p(L_n) = p(L_{n-1} | X_{n-1}) + (1 - p(L_{n-1} | X_{n-1})) * p(T_n) \quad (1)$$

The emission probabilities in BKT usually take the form of a CDM (Rupp et al., 2010), which models correctness of response based on a set of skills represented as Booleans, either mastered or nonmastered. CDM models include slipping and guessing parameters to account for an incorrect response when the requisite skills are present (slipping) and a correct response when the requisite skills have not been mastered (guessing). Combinations of skills can be modeled either as conjunctive or as compensatory, allowing the flexibility to apply appropriate cognitive theory for the domain.

Another common approach to student modeling within adaptive learning systems is performance factor analysis (Pavlik et al., 2009). Such models characterize student knowledge in terms of continuous variables and make use of an updating mechanism that is a variation of IRT with a learning parameter (slope).

More recently, advances in recurrent neural networks have been applied to the problem of estimating and updating student proficiency variables in what is known as deep knowledge tracing (DKT; Piech et al., 2015). DKT uses the same inputs and outputs as BKT, but rather than computing probabilities of skill mastery and using them to estimate subsequent performance, the probabilities of success on future items are predicted directly with a recurrent neural network, usually using a long short-term memory layer to ensure that past performance has an extended impact on future predictions. At the time of this writing, several extensions to DKT have been developed that augment the input vectors with both item information (including difficulty and skill tapped) and additional performance information, such as the amount of time taken to solve the item (Ai et al., 2019). Structural improvements to the predictive models have also been proposed, including applying regularization to prevent large variance in the predictive output (Yeung & Yeung, 2018). While the recurrent neural networks approach requires a large training data set, the flexibility of these models to utilize complex inputs, incorporate domain-specific data transformations, and interface with other models makes it likely that DKT and other uses of deep neural networks will have a major impact on adaptive learning technology in the near future.

Models that are more deeply grounded in learning theory have also proven useful for interpreting behavior in solving complex tasks. In particular, the ACT-R cognitive architecture (Anderson et al., 1997) has been used to predict student actions in multistep problem-solving using a technique known as *model tracing* (Corbett et al., 1995). ACT-R models cognition at a fairly low level, including declarative memory, working memory, and procedural knowledge in the form of if-then production rules. These models predict not only keystroke-level student actions, but also the time between actions, providing additional predictions that can be used for model validation. Because there are so many parameters involved in an ACT-R model, individual parameter estimation is not attempted. Instead, student actions are compared to an ideal student, or expert, model. In some adaptive learning systems, this comparison is sufficient because any off-path action triggers tutoring until the student returns to the ideal path.

Bayesian models and estimation have been popular in adaptive learning systems, including the intelligent tutors built on ACT-R (Koedinger & Corbett, 2006). One

attraction is that Bayesian estimation can occur iteratively as each new data point updates the models' probability distributions. This real-time updating allows the system to act on an estimate as soon as it passes a set certainty threshold. In ACT-R tutors, this "knowledge-tracing" technique allows the system to select tasks that exercise knowledge components the student is not likely to have already mastered (Alevan et al., 2017).

One particular type of Bayesian model, the Bayesian network (Bayes nets), is frequently used to represent complex relationships between the evidence emerging from student performance and the latent variables that make up the student model (Chrysafiadi & Virvou, 2013). A Bayes net is a directed acyclic graph in which nodes represent variables and relationships between nodes are described with conditional probability distributions. In adaptive learning systems, the variables represented are almost always categorical, making these relationships conditional probability tables (CPT).

Figure 9.6 shows a simple Bayes net that might be part of a psychometric model (note that there are too few observable variables for this model to be identifiable given the number of latent variables). The observable variables (x_1, x_2, x_3) are indicators (behaviors) from a student performance, while K_1 and K_2 are latent variables that explain differences in performance. In this example, we include an intermediary latent node S_1 that could indicate a particular strategy students might implement. The observable behaviors x_1 and x_2 are indicators of use of this strategy and, as such, are not conditionally independent given K_1 , but are conditionally independent given S_1 . Observable x_3 has two parents (K_1, K_2) making this variable a within-observable multidimensional measurement model. The way in which K_1 and K_2 interact to produce the observable x_3 can be flexibly defined by the CPT of x_3 , allowing for compensatory, noncompensatory, and more complex relationships to be modeled.

FIGURE 9.6
A Simple Bayesian Network

Note. The gray nodes represent latent variables and the white nodes are observed variables.

A Bayes net can be updated when new observations are made, giving a running dynamic probability distribution for the latent variables. One of the most attractive properties of using Bayes nets for student models is that complex relationships between cognitive and affective latent variables can be modeled to explain specific behaviors. Thus, for learning systems that employ dynamic estimation from student interactions in a simulation, game, or other complex performance, the Bayes net is a natural choice. These models can also be found in formative assessments that include both complex evidence and student models (Almond et al., 2007, 2015).

Evaluation of Student Models in Instructional and Learning Systems

The overall functioning of adaptive learning systems has generally been evaluated based on the achievement gains produced as compared to a traditional curriculum (e.g., Pane et al., 2013). While such gains may suggest that the system is working properly, they do not necessarily confirm the validity of the student models. Similarly, the absence of learning gains does not necessarily imply a failure of the models. Because the function of the student model is to enable feedback or adaptation of tutoring, the model's value might best be judged with respect to how effectively it achieves these goals during the learning session. Experimentally contrasting a linear presentation of problems with one dictated by knowledge tracing, for example, can identify the student model's impact on achievement (Corbett et al., 2000, as cited in Aleven et al., 2017, p. 528).

Other evidence as to the quality of model functioning can be provided by how well the models predict the student's next action or the success of their next solution attempt. Because this prediction is seen as a classification task, researchers in the learning system and data-mining communities have frequently used a classifier accuracy metric known as area under the curve. Area under the curve is calculated by plotting the probability of a true positive by the probability of a false positive over the range of possible threshold values for the classifier. The area under the curve would thus be 1.0 for a perfect classifier and 0.5 for random selection.

COMBINING CONSEQUENTIAL DECISION-MAKING AND INSTRUCTIONAL SUPPORT: CAN TECHNOLOGY-BASED ASSESSMENT DO BOTH?

Earlier sections addressed assessments used to support consequential purposes and assessments used to support instructional decision-making. The affordances of technology make it easier to imagine the possibility of generating information from the same assessment that might simultaneously serve consequential decision-making and instructional-support purposes. Several approaches might be taken to satisfy this dual end, with the approaches differing in fundamental ways, especially in foregrounding one or the other purpose.

The least radical approach would entail generating formative information from consequential TBA. Here, the consequential purpose would be central and the formative purpose supplementary. As an example, a state English language arts accountability assessment will typically produce total scores, proficiency levels, and other scores. One or more of the other scores may come from a response to an essay task, including scores summarizing overall writing quality as well as ones characterizing such writing traits as content and conventions. To be sure, such trait information provides only a very minimal level of formative information. More valuable might be a description of *how* the student wrote the essay, generated by capturing and analyzing the keystrokes used to create it (Zhang, Bennett, et al., 2019). For instance, was there evidence of planning (e.g., the rudiments of an outline early in the writing session), verbal fluency (e.g., long bursts of text), word-level monitoring (e.g., correction of typos), or global monitoring (jumps from one cursor position to another followed by insertions and deletions)? Were there indications of difficulty in typing (signaled by consistently lengthy intervals between key presses) or of problems in word finding (e.g., long pauses between words)? Possibly more valuable for the teacher and student would be the ability to replay, in speeded-up time, the essay as it was written, thereby giving an opportunity for discussion and reflection on the writing process (Vandermeulen et al., 2020). A process description and replay could lead to the realization that typing practice was needed or that instruction in planning or in how to edit should be provided.

The above approach clearly foregrounds consequential assessment by building into it secondary mechanisms for more effectively supporting instructional decisions. Those mechanisms will be far from ideal. Such feedback will occur late in the school year, be limited to that which can be either wrung from the existing assessment or designed into it without compromising its primary purpose or practicality, and be divorced from the context of classroom instruction. Along with other reasons, these limitations have motivated third-generation proposals that attempt to better balance the two assessment purposes. That is, these proposals move toward foregrounding instructional support decisions, with information for consequential decisions coming as a by-product. Periodic, or through-year, assessment offers one version of this idea (Bennett, 2010b; Bennett & Gitomer, 2009; Northwest Evaluation Association, 2019).

In through-year assessment, measures are repeated at various time points. A key benefit of this model is that consequential decisions (e.g., school accountability) would no longer be based on a single measure taken at one time point, but rather on some aggregation of the through-year observations. Also, more frequent feedback would be provided from each of the through-year events.

Many features of this idea could in principle be varied, including the number of TBAs administered, what content they cover, when they are given, the extent to which districts and schools can choose the ordering, and how results are accumulated into a performance index. The greater the variation in these features across schools or districts, the lower will be the comparability of the results (Bennett, 2020). The highest level of comparability would generally result from administering a fixed number of assessments

created from the same content specifications at selected time points to each student under the same conditions and scored with the same aggregation rules. Administering different forms of a comprehensive interim assessment during 1-week windows in fall, winter, and spring would be a simple example, though the extent to which it would foreground instructional support decisions might be arguable (Shepard et al., 2011). More attuned to instructional support decisions would be a regimen in which each assessment focused on a different critical competency associated with grade-level standards. Such a design would either require all schools to follow the same instructional sequence or allow them to choose the order of administration, complicating comparability and test security. (See Georgia Department of Education, 2018, pp. 80–82, for a description of such an assessment piloted under the federal Every Student Succeeds Act Innovative Assessment Demonstration Authority.)

In through-year models, many rules for aggregating results are possible, each derived from a different conception of achievement (Wise, 2011). Weighting the results as a composite with the greatest emphasis given to the most recent assessment would reflect a view of achievement as competency accumulation. A different weighting could mimic the way grades are averaged over quizzes, midterms, and final exams, with this more even weighting suggesting a view of achievement as a collection of accomplishments. A third possibility is to aggregate results based on test information, which would emphasize precision in measuring the dimension common to the several assessments. Finally, taking some function of the difference between the first and last result conceptualizes achievement as the extent of growth. Psychometric models related to these different types of aggregation have been explored by Mislevy and Zwick (2012), Fu and colleagues (Fu & Feng, 2018; Fu et al., 2012, 2013), and Rijmen (2009).

Perhaps the most radical proposal for foregrounding instructional support decisions while generating information for consequential decisions as a by-product is to use a record of daily learning interactions, potentially removing the need for separate assessments entirely (Bennett, 1998, pp. 11–14; Gee & Shaffer, 2010; Pellegrino et al., 2001, pp. 283–287; Tucker, 2012).⁶ There are many attractions to this third-generation idea, including the sociocognitive one that the contexts for learning and assessment become identical. That is, both activities draw on the very same content, knowledge representations, and tools (Bennett, 2015), increasing the value of the derived information for adjusting instruction. An example of how this idea might work instructionally can be found among adaptive learning systems like MATHia (Ritter et al., 2007). As noted, these intelligent tutors estimate from real-time learning interactions what a student knows and can do with respect to a content domain and then base moment-to-moment adjustments on that dynamically computed estimate.

Using this type of data for consequential decision-making, however, would be very challenging (Bennett, 2015). One obvious concern is that the assessment model is essentially an extreme case of through-year assessment—that is, one without constraints. The reality is that, within a state and even within many districts, students in the same grade use *many* different electronic learning applications. These applications

vary in their content coverage, emphases, and order; knowledge representations and tools; rigor and quality of problems posed; and scoring criteria and methods, among other things. Further, some environments are likely to be employed more frequently with certain demographic groups, thereby confounding group and measure. A related, but broader concern is that the evaluation instrument is no longer independent of the school or district, leading to the perception that these entities are appraising themselves. Also possibly problematic is the continuous recording of behavior for use in consequential decision-making, which raises both privacy concerns and such educational ones as the potential for discouraging experimentation in teaching and learning. Discouraging experimentation would be unfortunate because such behavior serves a critical function in learning (Kapur, 2010).

Several possibilities exist for reconciling more effectively the goals of consequential assessment with those of assessment for instructional support. These possibilities revolve around systems of assessment—that is, TBAs designed to function synergistically in their pursuit of different goals because trying to fashion a single method for achieving competing goals leads to a suboptimal solution for each goal. One such proposal follows the competitive sports model (Bennett, 2015), a variation of through-year assessment. During instruction, students utilize whatever electronic and other learning environments their schools employ, with learning interactions recorded and used for guiding (and occasionally describing) instruction but never for consequential purposes (as in the practice periods before, and often interspersed within, a sports competition). Students and teachers are informed when an assessment for consequential purposes is to occur (i.e., the actual competition). That assessment is common in design, content specifications, administration window, and scoring across all schools and districts. For state policy makers, such a system could provide the data needed to evaluate how well individual schools were performing in educating all groups of students (from some aggregation of the common assessments' results), along with descriptive data about what students in each school were doing (from sampling the recordings of learning behavior). The latter data might allow instruction to be described at an unprecedented level of detail, greatly enhancing our understanding of learning activity, content, and rigor differences occurring across teachers, classes, schools, districts, and demographic groups.

SUMMARY AND CONCLUSION

This chapter considered three broad classes of TBA: ones used to support consequential purposes, ones used to support real-time instructional decision-making, and third-generation ones that attempt to combine both purposes.

For consequential testing programs, the rationale for moving to TBA is tripartite: align the testing medium with that of learning and of the information economy workplace, conduct assessment processes more efficiently, and measure what previously could not be measured as well or at all. In the United States, a first-generation

infrastructure exists for achieving these goals. Many state assessments, national and international group-score assessments (NAEP, PISA, Programme for the International Assessment of Adult Competencies [PIACC]), graduate and professional admissions measures (GRE General Test, TOEFL iBT), and occupational and professional assessments (USMLE, Architect Registration Examination, Praxis) are routinely delivered by computer in educational institutions or in dedicated centers. Other assessments, most prominently college entrance examinations, are beginning to be delivered in that mode as well.

As a result of the COVID-19 pandemic, some consequential programs have moved to include delivery via remote human and AI proctoring to test takers' homes and offices. Such administration had been used successfully on a small scale in a few niches for several years (e.g., competency-based education at the university level and, more recently, English language assessment via the Duolingo English Test). The COVID-19 pandemic, however, greatly accelerated testing at test-taker locations. In 2020, the GRE General Test, TOEFL iBT, Praxis, HiSet (a high school equivalency examination), the Law School Admission Test, and the International English Language Testing System added home options. Whereas there has been relatively little published research on the technical quality of assessments so delivered, we expect this evolution to continue as need drives use, with research catching up.

The successful deployment of a robust first-generation delivery infrastructure for consequential testing has offered a foundation for innovations in assessment design. Those innovations generally aim to increase construct fidelity by evoking more complex cognitive processes and allowing responses to be observed in finer detail. Four kinds of innovative assessment design were distinguished: TEIs, extended-interaction items, scenario-based tasks, and simulation-based performance tasks. Gathering validity evidence regarding the functioning of these types is critical to asserting that the evoked processes are in fact the intended ones, that the innovations do not introduce unfairness for groups or individuals, and that the Person $\times$ Task interaction associated with scenario-based and simulated-based performance tasks is appropriately accounted for.

The changes to practice that TBA entails inevitably raise challenges for score comparability. These challenges occur because many programs offer tests in both paper and technology modes, other programs wish to maintain TBA score continuity with past paper versions, and still other programs want to ensure constancy of score meaning when the digital test is offered on multiple technology platforms. Different degrees of comparability may be appropriate for different use cases and achievable through different methods. Comparability may be studied, and the data needed to make score adjustments gathered, via various designs. However, technology is changing rapidly, forcing assessment programs to change as well. That rapid evolution may make it impractical to study and adjust continuously for the effects of new assessment implementations. Thus, it may be necessary to replace an empirically focused approach with one grounded in design principles directed at maximizing validity and fairness for individuals and groups. Empirically based methods like those traditionally used for linking may still play a role

as one of the investigative methods used to derive assessment design principles or to document the degree to which device-agnostic results were obtained. However, empirical approaches cannot be relied on as the primary mechanism for ensuring and maintaining comparability. Moreover, the desire to maintain comparability over time needs to be balanced against giving testing programs license to incorporate the innovation required to remain relevant in a rapidly changing world.

One of the as-yet underutilized benefits of TBA is certainly its ability to capture evidence of response processes. Such evidence can contribute to the validity argument for an item or task, help in the identification of guessing or cheating, and indicate strategy use or the presence of misconceptions. Response process data may include actions, resulting events, and latencies. Those data may index relatively basic cognitive processes like fluency or higher level strategies, plans, and knowledge. Because of their complexity and scale, process data are often analyzed and modeled using relatively opaque, bottom-up methods like machine learning, as well as ones from computational statistics that allow for the instantiation of theoretical propositions (e.g., Bayesian networks). Combining bottom-up and theory-driven approaches holds promise in that machine learning can be employed to help build the theory to be implemented in, for example, a Bayesian network.

In contrast to response process data, the automated scoring of complex constructed responses is used operationally in many consequential testing programs. This use is driven by the need to cut costs and increase reporting speed. Such scoring usually focuses on an end product, such as an essay or an architectural design, although process data are also included in some instances (e.g., medical patient management). Multiple approaches can be used to score a given task type. Important distinctions among methods relate to whether the automated scores are created to predict human scores empirically or generated from theoretical propositions or rules. A second distinction specific to approaches that seek to maximize agreement with a criterion like human scores is the extent to which transparent versus black-box methods are employed. Whereas validation of scoring has usually focused on agreement with human scores, such agreement is best viewed as one piece of evidence in a more comprehensive validity argument. That more comprehensive argument may, among other things, need to include an evaluation of the validity of using the human scores as a criterion. Additionally, how automated scores are produced, and the alignment of that method with the intended construct, should be a consideration. Because of concerns over the use of AI in society generally, we should expect significant work on explainable, transparent scoring methods.

The chapter's second major section dealt with assessments used to support instructional decision-making. Such assessment is incorporated into intelligent tutoring (or adaptive/personalized learning) systems, educational games, and simulations. Intelligent tutors typically deliver instruction built around discrete problems, which may be similar to the TEIs and extended-interaction items found in consequential tests, whereas games and simulations often present a more thematically integrated problem-solving experience utilizing performance tasks. Tutors, games, and simulations

may employ some combination of cognitive domain model, AI, and probabilistic method to estimate competency dynamically and, thereby, modulate the current problem or choice of the subsequent one. Competency is tracked through a student model that includes a representation of the student's knowledge state (referenced to the larger cognitive domain model) and a method for updating that representation. Probabilistic methods employed in that updating have included BKT and Bayesian networks. MATHia, ALEKS, and the Duolingo language-learning apps are examples of such tutors in widespread use. Examples of games or simulations that appear to personalize learning via such methods include Math Garden and Inq-ITS.

In tutors, games, and simulations, response evaluation can focus on the product (e.g., answer to a math problem), the process used to generate it, or both, depending on the underlying cognitive domain model. However, even when the model specifies that evidence of proficiency lies in the correctness of a product, analyzing the process can suggest appropriate next steps in the form of feedback, selecting new problems, or making other instructional adjustments.

Used in some commercial instructional applications are automated scoring technologies, most commonly for writing or speaking, that share methodology with those employed for consequential assessment. Examples in composition include MyLab Writing and Criterion. These systems evolved separately from intelligent tutors. As a result, the former systems do not generally use cognitive domain models or probabilistic methods to estimate and represent student competency or to personalize instruction, instead only rating and giving feedback on each response in isolation. We should expect to see systems that use automated scoring to support instruction converge with intelligent tutors because the two approaches offer complementary capabilities.

The last section in this chapter described third-generation approaches that combine instructional support with consequential purposes. Approaches differ in the extent to which instructional support decisions or consequential decisions are foregrounded. Included were generating formative information from consequential TBA, through-year assessment, and generating consequential information from ongoing learning interactions. The last approach, while seemingly attractive, raises questions of comparability, privacy, and the potential for negative educational consequences. An approach based on the competitive sports model was proposed as a path that might offer the desired benefits while mitigating the issues raised by more radical models.

What might be productive directions for research? There are many possibilities and here we suggest but a few. One important direction for both consequential testing and instructional support purposes might be to build the foundation for operationalizing the use of process data. For example, research should be directed at identifying whether diagnostic profiles can be identified suggestive of differential instructional action. Placement in a profile could be part of the formative output from a consequential test (e.g., a writing assessment) or as part of personalized instruction. Questions concern

whether meaningful, distinct classes of behavior can be identified (e.g., dysfluent writer vs. fluent writer), whether placement of individuals in such classes is stable across tasks from the same domain, whether the addition of product information adds value, and whether instruction based on such placement results in more learning than a profile-agnostic alternative.

An associated direction concerns how best to report process data, whether in conjunction with a profile or not. If the reporting goal is to encourage reflection as to how one went about problem-solving, then performance replay should be studied. Key questions include identifying the replay formats that best facilitate reflection, learner action, and change in competency.

A third direction relates to the impact of simultaneously incorporating cognitive domain models, AI, and probabilistic methods into games and simulations. These capabilities are not yet commonly found together in commercial products. Experiments could be conducted to estimate the incremental effect of using such additions to increase personalization. A similar direction could be taken with respect to the insertion of cognitive domain models and probabilistic methods in learning systems that use automated scoring.

A fourth direction is associated with the implications of LLMs for validity, modeling, and analysis. The potential uses of LLMs are wide ranging, including item generation, constructed-response scoring, feedback, and reporting, among other possibilities (Bulut et al., 2024; Hao et al., 2024). This direction is notable because of the great interest evident in the field and the potential for improvements in efficiency and quality it seems to portend. Although this direction may pose new issues, because LLMs are a subcategory of AI, many of the challenges LLMs bring are the same ones as already noted in, for example, the section on Automatically Scoring Complex Constructed Response Tasks (e.g., bias, explainability, the need for validation criteria to be broadly based), as well as in other publications (e.g., Bejar, 2012; Bennett & Zhang, 2016).

Finally, calls to merge the purposes of consequential tests and instructional support are likely to grow as learning activity increasingly occurs online. Research should focus on studying the technical quality and instructional utility of approaches that attempt to account in principled ways for the challenges inherent in combining these divergent purposes. The competitive sports model is one example. Research should attempt to determine whether it can produce meaningful consequential results at the same time as it describes and guides instruction.

ACKNOWLEDGMENTS

We wish to acknowledge Steve Ferrara, Ryan Baker, and Denny Way for their helpful reviews on earlier drafts of the manuscript. Steve's reviews were as he was in life: constructive, gentle, modest, optimistic, and wise. This chapter is dedicated to his memory.

NOTES

1. Soft-max is an extension of the logistic function to multiple-category variables, for example, $p(x_i) = \frac{\exp x_i}{\sum_j x_j}$.
2. That USMLE uses both analysis of product and response process in computing scores raises the question of how automated scoring differs from response process analysis in the consequential testing context. As suggested in the section introduction, automated scoring is generally used to produce one or more quantities for input into computing a test score. Response process analysis, in contrast, has been more often directed at such purposes as providing validity evidence, identifying possible guessing or cheating behavior, describing how groups differ in their approaches to problem-solving, and suggesting how instruction might be redirected. Automated scoring is widely used in operational consequential assessment. Response process analysis is far less prominent.
3. The methods used here are like the machine learning methods described for the evaluation of response processes in the prior section.
4. Relatively few studies have looked at this issue, but those that have been conducted suggest the presence of substantively important differences in how algorithms operate across at least some demographic groups (Bridgeman et al., 2012; Ramineni & Williamson, 2018).

5. There are many examples of current assessments taking a more traditional mastery test form that are used to support instruction but are not of the type described here. Measures like the Smarter Balanced interim assessment blocks are linear tests constructed to measure mastery of a narrow competency (or set of related narrow competencies) (Smarter Balanced, 2019). Results are linked to instructional resources in the Smarter Balanced Tools for Teachers.
6. Note that the focus here is on learning interactions only. In contrast, some schools record virtually every student online interaction for purposes of identifying safety threats (Haskins, 2019).

Modeling Data From Educational Assessments

Michael C. Edwards

Arizona State University

Data from educational assessments can take on a variety of forms and be collected for a variety of purposes. The models and modeling required to infer meaning from assessment data are also varied. To treat this topic in breadth and to give proper respect to the diversity and volume of past research in this area, we take the perspective that modelers of educational assessment data are generalist statisticians who are not driven by a particular preconceived model or epistemology of measurement (see Tal, 2020, and the extensive references therein) and are not married to a single philosophy about statistical modeling or theory of inference (as in Rubin, 1984). As empirical researchers, we remain flexible and pragmatic in the usage of our statistical tools, with the chief goals of advancing our collective understanding about educational processes and empowering the users of educational assessments with information that they need to pursue improvement in educational outcomes.

In many ways, this more expanded view on statistical modeling is a point of departure from what is arguably one of the closest conceptual relatives to this chapter in the fourth edition of *Educational Measurement*. Yen and Fitzpatrick's (2006) foundational piece goes into depth on many aspects of item response theory (IRT) that are useful for practitioners and researchers, but it is narrower in scope. We view IRT models as an extremely important subset of the series of models that we will consider in this chapter.

Given the development of large-scale predictive modeling arising out of data-intensive computer science (see Breiman, 2001, for a discussion of the two cultures of statistical modeling), recent critiques of quantitative research and the psychometric tradition (e.g., Dixon-Román & Gergen, 2013), and the juxtaposition of imperfect theories in the social sciences with simplifying assumptions often made in statistical modeling under resource constraints, we must stress that the word “model” should be understood in the information-theoretic sense—that is, a model is a mathematical encoding that binds together data and theory (see Bonifay & Cai, 2017; Fanelli, 2019; Grünwald, 2007). A modeler's success should be judged by the extent to which the model's parameters and outputs enable researchers to understand contexts, processes, and outcomes more clearly. While considering how well the model accounts for the observed data (model fit), one must also consider modeling principles such as parsimony and interpretability. Therefore, our technical approach is decidedly more traditional than the data-intensive algorithmic modeling that takes the form of statistical machine learning.

We begin the chapter with a broad discussion of the various sources and types of data derived from educational assessments to help illustrate the need for the statistical modeler to pay attention to the purpose of statistical inference, to represent salient features of research design in the model, and to guard against overcomplication. This is followed by a discussion of various mathematical and probabilistic tools that have found success in applied statistics, including in educational assessment. We then introduce a general framework for modeling. The fact that most general constructs covered by educational assessments are, by their very nature, not directly observable necessitates our reliance

on, and a review of, relevant latent variable modeling techniques. While we will not shy away from technical discussions, our general orientation is theory and design driven, as opposed to purely data driven.

As to the empirical examples, we will introduce and report our analyses of two recent assessment and evaluation studies. First, we take a deep dive into a data set collected from a randomized, controlled, multisite trial of a math intervention with pre and post measures. This study illustrates modeling issues in a realistically complex scenario that combines key elements of contemporary psychometric analysis (e.g., item analysis, dimensionality evaluation, measurement invariance) with those of educational statistics in support of sound research design (e.g., representations of initial status, growth, unit of treatment assignment, nested or crossed relationships). Second, in the context of a project that aims to develop a new assessment program for English learners with severe cognitive disabilities, we highlight the need for advanced statistical modeling in a highly constrained space, as defined by legal requirements and practical considerations. We conclude by suggesting possible trends that the reader should be aware of in the modeling of educational assessment data.

VARIED PURPOSES AND SOURCES OF DATA

As other chapters in this volume indicate, educational assessments with different purposes can yield distinct types of educational assessment data. In practice, one assessment program may serve multiple purposes, and those purposes may also change over time (Ho, 2014). Therefore, we do not intend to create an exhaustive or mutually exclusive list in this section. Our hope is that by enumerating data sources explicitly, we may point out different features of these data and consequently different methods of statistical analysis and modeling that may be required.

Different Sources

Educational assessment data could be generated by the individuals being assessed or by others (e.g., raters or computer algorithms) and concern the knowledge, proficiencies, practices, or processes that would be desirable (or sometimes mandatory) for the educator, education researcher, or policy maker to understand and, if applicable, to quantify. These data may involve different types of variables (from discrete to continuous), and various kinds of nesting or cross-classification relationships among units may be present in the data set.

Classroom Assessments

We highlight classroom assessments first because they exemplify the need for educational assessments to serve the goal of student learning (see Brookhart & DePascale, this volume). These assessments are ideally brief, initiated by and from instruction, and scored rapidly—with or without technology—to provide feedback

to the learning process. Their purposes may range from practicing to progress checking to the diagnosis of misunderstanding or misconceptions. The data coming from these assessment instruments are also typically not as standardized as some of the other sources we will discuss. However, with the increasing awareness of formative assessment and instructional practices—and with the proliferation of educational technology products that can aid the teacher's timely use and scoring of curriculum-informed assessments—classroom assessments can yield an important source of data that are among the most authentic indicators of student learning and achievement that the educational assessment researchers and users have not yet been able to fully harness. On the one hand, when the consequences of lack of comparability in the results are few and minor, the statistical treatment of classroom assessment data may only require simple statistical tools, such as a box plot and sample descriptive statistics. On the other hand, when serving research or policy purposes, the classroom assessment data may need to be aggregated and analyzed for comparative purposes. In such cases, more advanced treatment—perhaps using latent variable models that are based on the item response or diagnostic classification traditions—might be necessary.

Summative Assessments

In contrast with classroom assessments, summative assessments are almost always developed and administered under far more strict requirements of standardization and comparability. In the U.S. context, statewide summative assessments are federally mandated and are typically developed to measure a set of content standards that are adopted by a state and should be broadly implemented in the state's public schools, though the latter may not always be the case. The summative assessments aim to take a snapshot of the students' achievement toward the end of the school year against the backdrop of a set of achievement standards expected of the students. When aggregated up to the level of schools and districts and disaggregated by important student background characteristics, these assessment programs provide important accountability data for policy makers and for the public (see Ho & Polikoff, this volume). The modeling of summative assessment data typically requires modern psychometric models and statistical analysis approaches such as IRT to aid the validation process and to ensure technical quality of the assessment with respect to dimensionality, calibration, linking and equating, item and test bias, setting of standards, evaluation of classification accuracy, etc. Increasingly, summative assessments are delivered with educational technology. Computerized adaptive administration methods have become increasingly common, requiring more advanced analytic techniques for development and maintenance (see Shermis et al., this volume). The particular psychometric approaches taken by the analyst may also depend on whether the assessment (or parts of the assessment) is being developed and field tested or is being maintained and evaluated on an ongoing operational basis.

Large-Scale Sampled Surveys

Large-scale sampled education surveys play important roles in education policy and research. National and international assessment programs that resemble the National Assessment of Educational Progress (NAEP) have proliferated since at least the beginning of the 21st century (see Ho & Polikoff, this volume). Other longitudinal data collection programs, such as the Early Childhood Longitudinal Study, have provided major sources of data for researchers and policy analysts. They combine features of typical educational assessments delivered under standardized conditions, with scientific and representative sampling of students, schools, and education agencies. Unlike standardized assessments for summative evaluation purposes, NAEP-like assessments often include measures of both student achievement and development, along with a host of background measures that can help policy makers and researchers understand the relationship and interactions among input variables and student outcomes (see also Braun & Kirsch, this volume, for a discussion of international large-scale survey assessments). To the individual student participants, these large-scale sampled surveys are of low stakes. But because they help provide broad gauges of the performance of education systems, their design and analysis often involve highly complex combinations of IRT modeling, latent regression analysis, and design-based inference (e.g., complex survey design adjustments).

Evaluation Studies

Evaluation studies, including randomized controlled trials and quasi-experimental evaluation studies of the effectiveness of programs and interventions, have become routine in education sciences. The emergence of notable outlets such as the *Journal of Research on Educational Effectiveness* is a testament to the change in landscape. Researcher-developed assessments are often used to measure outcomes of an intervention, as well as important correlates, mediators, and moderators. For instance, a randomized multisite trial of a math intervention might involve an assessment of student learning in the targeted domain(s) as the outcome(s) of interest. The fidelity of program implementation might be measured at the site (school) level to help understand treatment effect variation, using observational rubrics and protocols that result in quantifiable assessment items. The teachers' professional development related to the intervention may also be measured using survey items, to help understand their mediating effects. These assessment tools are routinely validated using a combination of classical and modern psychometric techniques, and the resulting scores may be modeled separately using multilevel/hierarchical regression. More recently, joint modeling and estimation methods have been developed that combine the data from these assessments with important design characteristics (e.g., treatment assignment indicator) to yield more informative inference about intervention effect (see Cai, Choi, et al., 2016).

Technology-Based Assessments

Since the beginning of the 21st century, interactive educational technology has been increasingly involved in the design and delivery of educational assessments. This technology not only offers researchers with a far richer set of templates to conceptualize what constitutes an assessment item, including game-like environments or simulations, but also brings the potential of a deeper coupling of assessment with instruction that can be scaled up with a high degree of quality not achievable via traditional means. Importantly, technology allows for the collection of what is known as *process data*, through embedding software code into the assessment delivery platform itself (see Bennett et al. and Ercikan & Solano-Flores, this volume). The process data provide insights well beyond the traditional right/wrong answers; they reveal the process of problem solution and can suggest feedback to the learner or the teacher that has greater diagnostic value. They also tend to be intensively longitudinal in nature. A relatively simple kind of process data, response time, has already received a considerable amount of attention in the literature. Models for other types of process data have also been studied, with general latent variable models with sequential dependencies proving particularly interesting in this context (see Bergner & von Davier, 2019).

Different Purposes and Modeling Choices

The eminent statistician John W. Tukey once said, “The best thing about being a statistician is that you get to play in everyone’s backyard” (Brillinger, 2014). This one-liner epitomizes the role statistical modelers can play in research—statistical modeling supports the full educational assessment development life cycle. We believe that the thorough participation of and input from statistical modelers in assessment design, validation, and use leads to better results than treating statistical analysis as merely one isolated step in the process. Conversely, we note that competent statistical modeling in support of educational assessment development requires a broad understanding of research design and its substantive objectives. Some tasks may require more complex models, but some—either because of resource or timing constraints—may require simpler alternatives. Ideally, the analyst should be equipped with an adequately general and flexible framework—one that can also be constrained and specialized to accommodate the specific situation at hand.

To this end, we provide Table 10.1 to help guide the reader, in a similar manner as Bartholomew et al. (2011) did in their introductory chapter or akin to Thissen and Steinberg’s (1986) taxonomy. In Table 10.1, we attempt to synthesize a number of widely used and “named” models in educational assessment research, as well as ones that have not yet been named. For example, on the one hand, with a single-level data collection design, all observed variables being categorical in nature, and the assumed underlying latent variable(s) being continuous, an appropriate model may

Table 10.1 An Overview of More Specialized Models in the General Framework

Latent Variables	Predictors Present	Data Structure							
		Single Level		Nested Multilevel		Cross-Classified		Observed Variables	
		Observed Variables		Observed Variables					
		Categorical	Continuous	Categorical	Continuous	Categorical	Continuous		
Continuous only	No	IRT model	Factor model	Multilevel IRT / hierarchical / two-tier item factor model	Multilevel factor model / bifactor model	Cross-classified IRT model	G theory model		
	Yes	Latent regression model	MIMIC model	Generalized and nonlinear random effects model	Hierarchical linear model / linear mixed model	Explanatory IRT model	Cross-classified linear mixed model		
Categorical only	No	DCM	Latent class model	Multilevel DCM	Multilevel latent class model				
	Yes								
Categorical and continuous	No	Mixture item factor model	Factor mixture model	Multilevel mixture IRT model	Multilevel factor mixture model				
	Yes								

Note. DCM = diagnostic classification model; G theory = generalizability theory; IRT = item response theory; MIMIC = multiple indicators and multiple causes. Gray cells = generalized latent variable models.

be an IRT model. On the other hand, if the design implies a cross-classified data structure (e.g., items are regarded as random samples and predictors are present for one or more of the random item effects in the model), an explanatory IRT model (de Boeck & Wilson, 2004) may be applicable. The reader should note that large swaths of the table are grayed out. This fact merely implies that while appropriate and potentially useful generalized latent variable models may be specified, they are not yet so widely used.

CORE STATISTICAL MODELING CONCEPTS

In this section, we introduce some core concepts that are fundamental to the modeling of complex multivariate data that are characteristic of educational measurement. These include latent variables, conditional independence, likelihood, prior, posterior, information, and model fit evaluation. It is helpful to keep in mind that we discuss these concepts to equip us with the knowledge to accomplish the major tasks of modeling data in educational assessment:

- model building, which is about the choices that one makes to create a model to reflect the design and the desired inference from the assessment data;
- estimation and inference, which is about systematically optimizing the parameters in a proposed model, given the data at hand and the choice of optimality; and
- quantification of error and uncertainty, which deals with the tolerance for error and uncertainty with respect to inference (primarily) and model fit (to the extent that the quality of inference is affected).

We assume that the reader has some knowledge in elementary probability and statistics and will elaborate on technical developments when possible.

The Ubiquity of Latent Variables

A latent variable is a random variable that is not observed but is, nevertheless, specified in a statistical model. As part of model formulation, latent variables are often posited in the analysis of educational assessment data because the constructs involved (e.g., proficiency in math or reading) are not as discernable as markers such as height or the amount of cholesterol per unit of blood. Latent variable models may include either continuous or discrete random variables or a mixture of both kinds in one model. The use of latent variables is so pervasive that statisticians often overlook their many incarnations. However superficially dissimilar, latent variables may appear as common factors in factor analysis and structural equation modeling, latent traits in IRT (which are also common factors), latent attributes in diagnostic classification models, incomplete/missing data in both survey nonresponse and statistical computation, and random effects in multilevel modeling. In all these cases, a distribution of the latent variable is assumed. This could be one of the “named” distributions

(e.g., normal or multivariate normal) or a discrete distribution with point probability masses on particular values (e.g., 0–1). In some cases, the distribution can be semiparametric or seminonparametric in nature (e.g., Woods & Thissen, 2006). We would like to mention that the latent variables we introduce in this chapter follow the *reflective indicators* mindset prevalent in psychometrics. For a recent discussion on reflective versus formative indicators, the reader is referred to Bollen and Diamantopoulos (2017).

The latent variables are connected to the observations through a conditional distribution. This conditional distribution specifies the probability of the observed assessment data, given a particular value of the latent variables. In educational measurement, this conditional distribution can be understood as the measurement model. Technically, one can view the unknown parameters in the measurement model as latent variables as well. This is especially helpful in a fully Bayesian approach to estimation and inference, such as in data-augmented Markov chain Monte Carlo algorithms (e.g., Albert, 1992). Most of the time, it is helpful to keep the distinction between parameters of a structural nature and those of an incidental nature (Neyman & Scott, 1948) and to index these separately. In the next few sections, several examples are used to help illustrate the structural/incidental distinction. Specifically, characteristics of assessment items are regarded as structural, but individual-specific differences (e.g., standing of test takers with respect to the latent variable or variables) are treated as incidental. We also discuss the idea of measurement models as conditional probability distributions on latent variables.

Factor Analysis as Regression With Unobserved Predictors

Our first example is a classical one. In both Thurstone's (1935) common factor model and subsequent developments of confirmatory factor analysis and structural equation modeling (Jöreskog, 1969), observed variables are assumed to be a linear combination of continuous latent variables. Let y_i denote a generic (continuous) observed variable i and let us consider the case of p common factors indexed $\theta_1, \dots, \theta_p$; Equation 1 indicates that y_i depends on the common factors θ and the unique factor e_i ,

$$y_i = \lambda_{i1}\theta_1 + \lambda_{i2}\theta_2 + \dots + \lambda_{ip}\theta_p + e_i. \quad (1)$$

The weights λ of the linear combination are known as factor loadings, already familiar to education researchers. We consider them to be structural parameters. The common factors are the latent predictors in this regression model. Typically, the θ 's are assumed to have zero mean and unit variance, and the unique factor variance (say σ_i^2) is determined by the model as a residual variance component, representing variance in the outcome variable that is not accounted for by the predictors. Just as in linear regression modeling, the unique factor is often assumed to have a normal distribution with mean zero, effectively

becoming a disturbance term. This should make it immediately clear that the conditional distribution of y_i given values of θ is univariate normal, that is,

$$y_i | \theta \sim N(\lambda_i' \theta, \sigma_i^2), \quad (2)$$

where $\theta = (\theta_1, \dots, \theta_p)$ is a $1 \times p$ vector of random variables, $\lambda_i' = (\lambda_{i1}, \dots, \lambda_{ip})$ is a $p \times 1$ vector of factor-loading parameters, and $\lambda_i' \theta = \lambda_{i1}\theta_1 + \lambda_{i2}\theta_2 + \dots + \lambda_{ip}\theta_p$ is the vector “inner” product between λ_i and θ .

Item Factor Analysis and Multidimensional IRT

The second example builds on the linear model in Equation 1 and retells the story contained in Bock et al. (1988), Takane and de Leeuw (1987), and Bock and Aitkin (1981). In this example, the observed variable is discrete or categorical instead of continuous. To begin, let us consider the following regression model with the underlying continuous unobserved response process variate y_i^* as the outcome and θ 's as the predictors. As before, we assume that the θ 's are a set of uncorrelated standard normal variates, and the regression equation is

$$y_i^* = \lambda_{i1}\theta_1 + \lambda_{i2}\theta_2 + \dots + \lambda_{ip}\theta_p + e_i^* = \lambda_i' \theta + e_i^*. \quad (3)$$

For convenience, we shall let the error term e_i^* be normally distributed with mean zero and unique variance $\sigma_i^2 = 1 - \lambda_i' \lambda_i$. As is customary, we also assume that e_i^* is uncorrelated with the θ 's, such that y_i^* is conveniently scaled to have unit variance. The foregoing assumptions imply that conditional on θ , y_i^* is normally distributed with conditional variance $\sigma_i^2 = 1 - \lambda_i' \lambda_i$ and conditional mean $\lambda_i' \theta$.

Let us further assume that there is a threshold τ_i , and that the observed response y_i becomes positive/correct/endorsed ($y_i = 1$) if and only if $y_i^* > \tau_i$. We now see that the probability of a response of 1 from a subject with latent variable θ is equal to the following normal integral:

$$P(y_i = 1 | \theta) = \frac{1}{\sqrt{2\pi\sigma_i^2}} \int_{\tau_i}^{\infty} \exp\left(-\frac{(y_i^* - \lambda_i' \theta)^2}{2\sigma_i^2}\right) dy_i^*. \quad (4)$$

We can now make a change of variable for the integral by defining $z = (y_i^* - \lambda_i' \theta) / \sigma_i$, and that leads us to denote the probability of a response of 1 as

$$P(y_i = 1 | \theta) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\eta_i} \exp\left(-\frac{z^2}{2}\right) dz, \quad (5)$$

where

$$\eta_i = \frac{-\tau_i + \lambda_i' \theta}{\sigma_i}$$

is often known as the *linear predictor* in the generalized linear modeling literature (McCullagh & Nelder, 1989). But the right-hand side of Equation 5 is simply the standard normal cumulative distribution function with argument η_i , that is,

$$P(y_i = 1 | \boldsymbol{\theta}) = \Phi(\eta_i) = \Phi(\alpha_i + \boldsymbol{\beta}_i' \boldsymbol{\theta}),$$

for unstandardized item location or intercept parameter

$$\alpha_i = -\frac{\tau_i}{\sigma_i},$$

and unstandardized vector of item discrimination or slope parameters

$\boldsymbol{\beta}_i = \sigma_i^{-1} \boldsymbol{\lambda}_i = (\beta_{i1}, \beta_{i2}, \dots, \beta_{ip})$, with $\beta_{ip} = \frac{\lambda_{ip}}{\sigma_i}$. Using terminology from generalized linear models (McCullagh & Nelder, 1989), we would say that the model in Equation 5 uses a probit link function. Jöreskog and Moustaki (2001) provided an extensive discussion of this underlying normal approach, as well as the associated estimation methods.

We can approximate the model in Equation 5 with Birnbaum's (1968) logistic substitution, leading to a multidimensional IRT (MIRT) model that is widely familiar in educational measurement (Reckase, 2009),

$$P(y_i = 1 | \boldsymbol{\theta}) = \frac{1}{1 + \exp[-1.702(\alpha_i + \boldsymbol{\beta}_i' \boldsymbol{\theta})]}, \quad (6)$$

where the constant of 1.702 rescales the logistic parameters approximately to the probit/normal metric (see Camilli, 1994, for a recount of the history behind the approximation). Recall that we have assumed the $\boldsymbol{\theta}$'s to be uncorrelated. If we choose to estimate the more natural unstandardized item location and slope parameters, the standardized parameters in threshold and loading form can be recovered by these simple transformations (see Wirth & Edwards, 2007 or Cai, 2010a):

$$\tau_i = -\frac{\alpha_i}{\sqrt{1 + \boldsymbol{\beta}_i' \boldsymbol{\beta}_i}}, \quad \lambda_{ip} = \frac{\beta_{ip}}{\sqrt{1 + \boldsymbol{\beta}_i' \boldsymbol{\beta}_i}}.$$

If there is only a single latent variable, Equation 6 reduces to the familiar two-parameter logistic (2PL) model:

$$P(y_i = 1 | \theta) = \frac{1}{1 + \exp[-(\alpha_i + \beta_i \theta)]}. \quad (7)$$

In this case, the classical item difficulty parameter is equal to $-\alpha_i / \beta_i$, which corresponds to the value of θ at which the probability of the response of 1 is exactly 0.5.

Notice that as we complete the transition from the logistic as an approximation to the normal (from Equation 5 to Equation 6), we dropped the scaling factor of 1.702. The logistic model and its parameters form an entirely appropriate metric on which one can express item analysis results, and the scaling factor can and generally should be omitted in new educational assessment development projects to avoid misunderstanding or error. Obvious exceptions would include cases such as the maintenance of legacy banks of items calibrated under the normal ogive model.

Two-Tier and Item Bifactor Analysis

We now see that MIRT and item factor models are indeed deeply connected. In a certain sense, the distinction between MIRT and factor analysis is an artificial one largely resulting from historically separate software implementations. Realizing the underlying connection is of practical importance. In the development of educational assessments, it is imperative that the structural properties of the measurement instruments be examined. Usually this examination is treated as a part of dimensionality analysis, separate from considerations relating to item analysis, scaling, and test scoring. Unidimensional IRT modeling has become the default option for the latter, while factor analytic models dominate in dimensionality analysis. However, recent advances in item factor analytic methods and statistical computation have enabled the simultaneous modeling of item properties within a multidimensional measurement model.

As an example, consider Cai's (2010a) two-tier item factor model, which may be understood as a superset of the popular item bifactor model (Cai et al., 2011; Gibbons & Hedeker, 1992; Reise, 2012). In this model, the β_i 's form a particular pattern. Each item may load on two kinds of factors: the primary (Tier 1) factors, of which there can be any number, and a single group/specific (Tier 2) factor. When organized into a matrix, the item slopes may appear as the following for a six-item test:

$$\left(\begin{array}{cc|cc} \beta_{11} & & \beta_{13} & \\ \beta_{21} & & \beta_{23} & \\ \beta_{31} & & & \beta_{34} \\ \beta_{41} & \beta_{42} & & \beta_{44} \\ & \beta_{52} & & \beta_{55} \\ & \beta_{62} & & \beta_{65} \end{array} \right). \quad (8)$$

To the left of the vertical line, the primary factors form a familiar independent cluster pattern, perhaps representing two major domains or subjects, save for the fourth item, which cross-loads on both primary factors. To the right, there are three group/specific factors that influence three distinct item doublets, representing additional shared variation above and beyond the primary factors. A bifactor model has a single

primary factor. Wainer et al.'s (2007) testlet response theory model is a constrained version of the bifactor model, with equality (or proportionality) constraints on the slope parameters within each item and freely estimated variance components for each group/specific factor.

The parameters of item factor models such as those above may be estimated directly from educational assessment data, such as when field testing new items. When assessment developers are equipped with the knowledge that these methods exist and can support operational educational assessments at scale, new assessment programs may benefit directly by selecting models that appropriately reflect and correspond to the assessment design. The results of item factor analysis inform both item analysis and dimensionality analysis.

Generalized Partial Credit and Three-Parameter Logistic Models

Some educational assessments involve multiple categorical response data, rather than (or in addition to) dichotomously scored items. Examples include ordinal ratings of constructed responses, such as essays or short answers. Polytomous IRT models such as the generalized partial credit (GPC) model (Muraki, 1992) may be used in these cases. Suppose item i has C_i categories, with observed response $c \in \{0, \dots, C_i - 1\}$. A version of the GPC model may be written as

$$P(y_i = c | \theta) = \frac{\exp(c\beta_i\theta + \alpha_{ic})}{\sum_{m=0}^{C_i-1} \exp(m\beta_i\theta + \alpha_{im})}, \quad (9)$$

where the item slope β_i serves the same role as the discrimination parameter of a 2PL model. Since the category-specific intercept α_{ic} parameters are not identified without further constraints, the first intercept is typically fixed to 0 ($\alpha_{i0} = 0$). More broadly, the GPC model is one of many models in the nominal categories model family (Thissen & Steinberg, 1986). For further details, the reader is referred to Thissen et al.'s (2010) exposition.

For multiple-choice items that are dichotomously scored, the three-parameter logistic model (3PL; Birnbaum, 1968) can be used to account for the effect of guessing. The parameter γ_i is introduced to serve as a lower asymptote of the traceline:

$$P(y_i = 1 | \theta) = \gamma_i + \frac{1 - \gamma_i}{1 + \exp[-(\alpha_i + \beta_i\theta)]}. \quad (10)$$

When the lower asymptote is zero, Equation 10 becomes the familiar 2PL IRT model.

For an item with multiple categorical responses $c \in \{0, \dots, C_i - 1\}$, the conditional probability of observing response y_i is a multinomial with trial size 1 in C_i categories, that is,

$$f(y_i | \theta) = \prod_{c=0}^{C_i-1} P(y_i = c | \theta)^{x_c(y_i)}, \quad (11)$$

where the indicator function $\chi_c(y_i)$ takes a value of 1 if and only if $y_i = c$ and it is zero otherwise. This result parallels Equation 2.

Diagnostic Classification Models
