NOTES

1. Teacher certification represents an interesting example of ambiguity between licensure and certification. States require certification for individuals teaching in public schools, but there is often no similar restriction for teaching outside the public system. This is similar to physician certification in the United Kingdom, where

physicians can practice without being a member of one of the Royal Colleges but cannot receive reimbursement from the National Health Service.

2. As with many issues related to licensure and certification, there are exceptions—or at least gray areas. For example, the USMLE comprises three steps. Successful completion of Steps 1 and 2 typically is required to enter residency training, and in some states individuals receive a formal training license. Because of this special use, these first two steps focus on what might be viewed as entry-level skills. A full unrestricted license is, however, only awarded after completing the third step in the examination process—the focus of that step is not constrained in the same way.
3. Work samples are another common item type in personnel assessments for certification.
4. In addition, it is important that decisions about feedback be made at the test development phase (i.e., as an intentional part of the overall testing process) rather than as an additional consideration after the test has been developed and/or administered.

Assessment of Social-Emotional, Soft, Character, Behavioral, and Intrapersonal and Interpersonal Skills

Patrick C. Kyllonen
ETS

Jiyun Zu

Intelligence plus character—that is the goal of true education.

Martin Luther King Jr.

We have long recognized that schools develop character along with mathematics and language skills. Students are taught, at least implicitly, to pay attention to the instructor, to put effort into their work, to show up and complete assignments on time, to be considerate of other students, to avoid arguing with the teacher and fighting with other students, to be honest and truthful, and to develop a love of learning. As a society, we believe that such behaviors and attitudes are important for the future success of students—success in education, in the workforce, and in life, generally. However, these beliefs have not typically translated into policy or practice in educational testing.

Testing reflects policy priorities and influences what is taught and learned (Frederiksen, 1984; Levin, 2012). Since 2001, federal and state policies have centered around evaluation of students' knowledge of subject areas, as seen in the Every Student Succeeds Act and its predecessor, the No Child Left Behind Act of 2001, as well as in our *Nation's Report Card* (National Assessment of Educational Progress). International assessments such as the Program for International Assessment (PISA), which began in 2000; Trends in International Math and Science Study (TIMSS), beginning in 1995; and Progress in International Reading Literacy Study (PIRLS), beginning in 2001, along with national accountability assessments in most countries of the Organisation for Economic Co-operation and Development (OECD) all focus on curricular content knowledge. We evaluate teachers with value-added models based entirely on student gains in academic achievement, as measured by curricular tests (McCaffrey et al., 2003).

Only recently has there been an explicit attempt to move beyond a general acknowledgment of the school's role in building character to embracing character development as part of the core school mission warranting its monitoring. In the United States, a subset of 10 California school districts (the California Office to Reform Education) received a waiver from the federal government to implement their own accountability assessment, which included social-emotional learning skills (West, 2016). The District of Columbia Public Schools is administering social and emotional learning (SEL) survey measures to assess readiness (District of Columbia Public Schools, 2017). Many states have by now published social-emotional learning standards paralleling mathematics, English language arts, and science standards (Collaborative for Academic, Social, and Emotional Learning [CASEL], 2020a). Chile's ministry of education is mandated to include social-emotional skills as part of its national accountability assessment (Ministerio de Educacio, 2016); other countries are following suit (Bravo-Senzana et al., 2023). The OECD recently launched its Study on Social and Emotional Skills parallel to PISA, but designed to monitor progress in student development of social-emotional skills, rather than cognitive skills (OECD, 2019a). Many organizations have issued position papers on the importance of SEL (Aspen Institute, 2018; Atwell & Bridgeland, 2019; OECD, 2015; Salzburg Global Seminar, 2018; Schanzenbach et al., 2016). Online resources are now available to find and evaluate

social-emotional learning assessments, including Rand's (Hamilton et al., 2018) Education Assessment Finder, CASEL's (2020b) SEL Assessment Guide, California's Guide to Social and Emotional Learning Resources (California Department of Education, 2018), and others. What has changed?

EVIDENCE FOR THE IMPORTANCE OF INTERPERSONAL AND INTRAPERSONAL SKILLS

Benefits-of-Education Studies

One important source for change was economists working from a human capital theory framework. Human capital theory (Becker, 1994) is the idea that individuals are rewarded for their productivity (e.g., measured as earnings, or labor market outcomes more generally, including employment and nonincarceration), which is driven by the set of skills, knowledge, and health individuals bring to the labor market. These attributes are affected by education, on-the-job training, medical care, and other factors. This framework enables quantifying the value of investments in education on economic productivity, the rate of return for a high school or college education (Card, 1999). A finding is that educational attainment is an important causal determinant of employment and earnings (private returns to education; Barrow & Rouse, 2005; Card, 1999) as well as national economic strength (social returns to education; Moretti, 2005), hence the public investment in education. However, the benefit of education on labor market outcomes is only partly due to the gains in cognitive skills associated with education, perhaps only about 20% (Bowles et al., 2001). Most of the benefit is due to factors other than the cognitive skills acquired, as measured with standardized tests, hence the attribution to noncognitive skills. Recent evidence shows that returns to cognitive ability have even gone down since the 1980s, with a 30% to 50% larger effect of wages in the 1980s compared to the 2000s (Castex & Dechter, 2014).

Another key demonstration of the benefits of education not accounted for by cognitive ability was Heckman and Rubenstein's (2001) finding that General Educational Development (GED) holders, individuals who failed to complete high school but scored comparably to high school degree holders on cognitive tests and therefore were similar in cognitive skills, experienced very different labor market outcomes. GED holders were far more likely to be unemployed and have trouble with the law (Heckman & Rubinstein, 2001; Heckman et al., 2014). The signaling value of a high school diploma is a potential alternative explanation for these findings—employers value degrees—but empirical studies support a human capital interpretation over a signaling interpretation (Clark & Martorell, 2014).

A third source of findings concerns the value of early childhood education. Although such programs were motivated with the goal of boosting cognitive ability for children living in impoverished environments, a common finding was that cognitive ability gains tended to fade out after a few years, as determined by comparison with control groups (Bailey et al., 2017). However, long-term treatment effects have consistently

been realized in many positive outcomes, including increased educational attainment and employment and less incarceration (Barnett, 1996).

The significance of all three of these study clusters is that they demonstrate the importance of noncognitive skills—skills associated with education that were not related to the cognitive gains education produces. However, aside from the cognitive versus noncognitive distinction, these studies tended not to identify the specific nature of the noncognitive factors associated with the education effect. A question is, What are these “noncognitive” benefits of education?—What is it that teachers teach and students learn, other than mathematics, reading, science, and other subject matters, that are of value in school, to employers, and in life?

Predictions-From-Measures Studies

Studies have been conducted by economists and psychologists examining the predictions of educational, workplace, and life outcomes from self- or other-report surveys. In higher education, a meta-analysis of psychosocial and study skill factors by Robbins et al. (2004) found the highest correlates of grades to be academic self-efficacy and achievement motivation and those of retention to be academic goals, academic self-efficacy, and academic-related skills. These factors were predictive after controlling for socioeconomic status, cognitive ability (test scores), and high school grades. Richardson et al. (2012) similarly found academic self-efficacy to be among the highest correlates of grades, along with effort regulation, need for cognition, and grade goal. In economics, Lindqvist and Vestman (2011) found that a composite measure based on ratings by a clinical psychologist of 18-year-old males predicted low earnings and chronic unemployment 20 years later. Segal (2013) found that misbehavior ratings of eighth-grade students by their teachers predicted earnings 20 years later after controlling for educational attainment and cognitive test scores.

These studies are suggestive of the importance of noncognitive factors but were also limited by the lack of a reliable strategy for categorizing noncognitive predictors. Beginning in the late 1980s and into the 1990s, the Big Five or five-factor model of personality arose in prominence (P. T. Costa & McCrae, 1992; Digman, 1990; Goldberg, 1993; John & Srivastava, 1999). We discuss this model further in the section “What Are the Key Skills?” but for our purposes here, it suffices to say that the model posits that individual personality descriptions are captured by five independent dimensions, Extroversion, Agreeableness, Conscientiousness, Neuroticism, and Openness. As in many realms, particularly measurement, standardization leads to progress (Cochrane, 1966), and the adoption of the five-factor model had a major impact on the value and frequency of prediction studies. Meta-analyses of workplace outcomes (Barrick & Mount, 1991; Dudley et al., 2006; Rothmann & Coetzer, 2003; Salgado, 1997; Tett et al., 1991), lifetime earnings outcomes (Gensowski, 2018), general life outcomes (B. W. Roberts et al., 2007), and educational outcomes (Noffle & Robins, 2007; Poropat, 2009; Salgado & Tauriz, 2014) have been conducted within the Big Five framework, leading to findings particularly of the importance of Conscientiousness (i.e.,

being organized, responsible, and achievement striving) on school, life, and workforce outcomes (Almlund et al., 2011; Levin, 2012; National Research Council, 2012; Ozer & Benet-Martinez, 2006).

Note on the Relative Importance of Cognitive Versus Noncognitive Skills

Cognitive ability is sometimes treated as a control variable to examine the incremental predictiveness of noncognitive variables (Nofle & Robins, 2007; Robbins et al., 2004; Segal, 2013). However, several studies have also compared the prediction given by cognitive versus noncognitive variables. Poropat (2009) and Richardson et al. (2012) found that some of the noncognitive factors have as strong a relationship with outcomes as cognitive abilities do. Poropat (2009) computed correlations of academic performance with intelligence, $\rho = .25$ (47 studies, all levels), and Conscientiousness, $\rho = .22$ (138 studies, all levels), findings in line with findings from the workforce (Levin, 1989; Salgado & Tauriz, 2014). Borghans et al. (2016) examined four large longitudinal data sets to show that personality, as expressed in grades and achievement scores, was more predictive of various life outcomes (e.g., wages, education, arrests, life satisfaction, civic participation) than IQ scores were. B. W. Roberts et al. (2007) found that the correlations between personality measures and a variety of life outcomes (mortality, divorce, occupational attainment) were of the same magnitude as the correlations between cognitive ability measures and socioeconomic status measures with those outcomes.

One complication in reporting simple correlations is correcting for range restriction—Levin (2012) pointed out that such corrections can distort findings. Selection on cognitive and noncognitive ability can operate differently—selecting on cognitive ability is often direct and affects the variance of cognitive test scores on the selected sample. Selecting on noncognitive factors is often indirect and often unmeasured. However, a persistent finding is that within a cohort, the correlation between noncognitive scores and outcomes is stronger for those in the lower half of the ability distribution (Lindqvist & Vestman, 2011; Segal, 2013). Noncognitive ability appears to be particularly important for students who leave school early and have difficulties maintaining employment.

A challenge in comparing the relative importance of cognitive and noncognitive skills is that measures of them call on both skills so their effects are difficult to disentangle (Borghans et al., 2011, 2016; Kyllonen & Kell, 2018). Being unmotivated temporarily or characteristically can produce low cognitive test scores and comprehension difficulties can affect responses on a personality survey.

Workplace-Demands Studies

Employer surveys ask employers what skills they look for in new graduates or how important various skills were for job performance. The findings from such surveys have been consistent. Casner-Lotto and Barrington (2006) found that what they called *applied skills* (e.g., critical thinking/problem-solving, oral and written communications, teamwork/collaboration, diversity, leadership, professionalism/work ethic) were

far more likely to be considered “very important” to success at work by employers compared to *basic knowledge/skills* (e.g., English language, reading comprehension, mathematics, science), particularly for high school and 2-year graduates. For these two groups, the two skills most likely to be rated as most important were professionalism/work ethic and teamwork/collaboration. Other surveys have found similar results, both domestically (Cengage, 2019; National Association of Colleges and Employers, 2018) and internationally (Barton et al., 2012).

A question is whether employer surveys provide a distorted picture of the skills sought. Employers might say *X* is important when asked in a survey, while looking for *Y* during recruiting. Rios et al. (2020) examined 142,000 job advertisements and found that 70% of job ads requested at least one of what they called “21st-century skills,” with the top skills being oral and written communication, collaboration, problem-solving, communication skills, social intelligence, and self-direction. These results are largely in line with results from the employer surveys, although terminology differences make them somewhat hard to compare. Employers routinely assess these skills using personality tests, structured interviews, situational judgment tests, game-based assessments, and reference checking (U.S. Office of Personnel Management, 2018b).

Another kind of workplace demand study has involved examining the actual activities workers engage in on the job. These studies typically have the theme of effects of technology on the nature of work. An influential early study by Autor et al. (2003) examined jobs (using the Dictionary of Occupational Titles database) in the years 1960 to 1998 and found that the effect of technology was to substitute for routine cognitive and manual tasks but complement activities involving nonroutine analytical and interpersonal tasks. This has led to a decline in manual tasks (routine and nonroutine) and a rise in nonroutine analytical and interpersonal tasks, thereby increasing the demand for the latter. The analysis was later extended to 2009, showing even clearer trends, but also showing a plateauing of nonroutine tasks (Autor & Price, 2013). Deming (2017) conducted a similar study covering the years 1980 to 2012 and showed that jobs requiring social interactions have grown considerably, showing a trend for an increasing “social skills” premium. Weinberger (2014) presented similar findings using Dictionary of Occupational Titles data showing a growth in employment and earnings for occupations requiring high levels of both cognitive and social skills compared to those requiring only one or the other. Burrus et al. (2013) applied a principal component analysis to O*NET ratings, identifying 15 competency components (mixtures of cognitive and noncognitive competencies), and showed that the most important competencies by both importance ratings and correlations with earnings were what they labeled problem-solving, fluid intelligence, teamwork, achievement/innovation, and communication skills.

There also have been studies attempting to project skill demands for the workplace of the future. A workshop conducted by the National Research Council (2008) reinforced the findings of the growing importance of broad interpersonal and social skills, noting the same conclusion in the earlier SCANS Commission report (Kane

et al., 1990) and suggesting the addition of adaptability. A study by Frey and Osborne (2017) attempted to predict the probability of computerization for 702 occupations in the United States, based on O*NET data, concluding that close to half of U.S. employment was at risk. They showed that the most resistant occupations were ones involving perception (finger and manual dexterity), creativity (originality and fine arts), and social intelligence (social perceptiveness, negotiation, persuasion, and caring for others), particularly when in high-wage jobs requiring high levels of educational attainment. A study by McKinsey Global Institute (Manyika et al. (2017) concluded that future occupations will require more interactions and management, as well as more social-emotional, creative, and logical reasoning abilities. A recent edited volume by Oswald et al. (2019) explored educational implications for the future of work (Hilton, 2019).

These three clusters of studies—benefits of education, predictions from measures, and workplace demands—all point to a growing recognition of the importance of non-cognitive, character, or social-emotional skills. There also appears to be evidence that the importance of these skills is likely to increase in the future as a result of changes in the workforce related to technology. This highlights the importance of the topic for educational measurement.

A Note on Terminology

In the title of this chapter, we refer to interpersonal and intrapersonal skills and other names; in the chapter, we use various terms to refer to the same general set of attributes. Terminology in this field is a source of frustration and confusion (Duckworth & Yeager, 2015; Reeves & Venator, 2014). SEL or social-emotional competencies or skills is terminology that has taken hold in K–12 education circles (CASEL, 2020b). It perhaps supersedes character or character skills, although character education is still a prominent reference. For a long time, What Works Clearinghouse maintained a separate Character Education category (Institute of Educational Sciences, 2007), although that appears to now be replaced by a Behavior category (Institute of Educational Sciences, 2020). In higher education, interpersonal and intrapersonal skills are widely used because of the National Academies of Science's (2017) adoption of that terminology. Also used is “hard-to-measure” skills or competencies (Stecher & Hamilton, 2014) and 21st-century competencies (Soland et al., 2013). In the workforce, soft skills (Kyllonen, 2013) and behavioral competencies (Society for Human Resource Management, 2014) are widely used, as is emotional intelligence (Goleman, 1995) (Emotional intelligence also has a more technical meaning; J. D. Meyer et al., 2008.) Economists have historically referred to noncognitive skills, to contrast with the cognitive skills measured with IQ and standardized achievement tests (although Messick, 1978, used the term noncognitive, noting its problems, but blaming its necessity on Bloom's 1956 usurpation of cognitive to define a particular set of skills). Industrial-organizational psychology refers to “other factors” as seen in the acronym KSAO, for knowledge, skills, abilities, and other factors.

Skills are prominent in economic or human capital theory discussions as a shorthand for whatever is learned in school or in training that has value in the workforce. But measurement psychologists have historically distinguished knowledge, skills, and abilities and added attitudes, values, beliefs, and behaviors, as seen in *Buros Mental Measurements Yearbook* (Carlson et al., 2020). Twenty-first-century skills, skills for the new economy, and others appear in the literature to reflect the changing demands of school and the workplace as a result of changes in technology (Oswald et al., 2019). *Skill* itself as a term may be thought of as controversial to describe some attributes, but its evolving widespread acceptance is shown in a *New York Times* opinion piece by U.S. senator Jeff Flake (2017), titled “We Need Immigrants With Skills, But Working Hard Is a Skill.” Personality is also used. However, the concept of personality, like the concept of intelligence, is associated with heredity and permanence, and so educators have tended to shy away from this terminology, believing personality to be outside the control of teachers and the educational system. As discussed in the next section, the foundation for this belief may be chipping away.

MALLEABILITY OF PERSONALITY

A recurring problem in the field of the assessment of noncognitive skills in education is the widespread belief that personality or character traits are fixed, and therefore outside the realm of education. Personality traits have been defined as the “relatively enduring patterns of thoughts, feelings, and behaviors that reflect the tendency to respond in certain ways under certain circumstances” (B. W. Roberts, 2009). Numerous studies have shown that personality traits are rank-order stable over decades (Ferguson, 2010) and heritable (Vukasovic & Bratko, 2015). However, this is true of achievement as well (Rimfeld et al., 2018), and also of social cognitive constructs, such as interests, self-concept, and academic effort, popularly believed to be more malleable, but which have been found to be no more so than the Big Five personality traits (Rieger et al., 2017).

Damian et al. (2019) tracked personality change in 1,795 adolescents tested 50 years later, finding moderate stability of personality across that period ($r = .31$ corrected for measurement error). But they also found growth of about half a standard deviation for personality factors over the period, in the direction of maturity (over time, greater Emotional Stability, Conscientiousness, Agreeableness, Openness).¹ Specific activities, such as psychotherapy, can have relatively swift and substantial effects on personality change (B. W. Roberts et al. 2017). Social-emotional learning interventions in school have similar and lasting effects on students’ personality as well as academic and other outcomes (Durlak et al., 2010, 2011; Taylor et al., 2017). Together, these findings challenge beliefs about the permanence of noncognitive factors or their inaccessibility to education, whether they are called personality traits, social-emotional competencies, noncognitive skills, or something else. Like habits, personality can change; personality is relatively enduring but not fixed.

WHAT ARE THE KEY SKILLS?

Considerable evidence supports the importance of noncognitive skills in school, the workplace, and life. What are those skills? What noncognitive skills are most important, and what skills are the ones driving educational and workforce outcomes? What skills should be given attention in education, and what skills should be monitored for growth and development?

Two specific skills have received an enormous amount of attention in education circles. One is grit (Duckworth, 2016), and the other is growth mindset (Dweck, 2006). Since 2016, it seems to have been almost impossible to attend a meeting of educational practitioners or policy makers without the word *grit* being mentioned. Grit seems to play an outsized role, serving as a stand-in for all the skills that are missed by standardized cognitive tests. Growth mindset has played a similar role and has received a comparable number of mentions in practitioner and policy discussions. A solid scientific literature attests to the importance of the constructs of grit and growth mindset on outcomes. However, something else may be at play. Both constructs have simple but compelling narratives—for grit, work hard in a sustained way and you will succeed; for growth mindset, believe that your successes and failures are a result of the effort put in, rather than your intelligence or external factors, and by doing so you will respond more productively to successes and failures (“the power of yet”). The two constructs also have charismatic advocates with popular TED talks (Duckworth, 2013, 50 languages, over 19 million views; Dweck, 2014, 42 languages, over 10 million views) and best-selling books (Duckworth, 2016, 21 weeks on the *New York Times* bestseller list; Dweck, 2017).

There have been meta-analyses of the constructs. Credé et al. (2017) examined 584 effect sizes from 88 samples and 66,807 individuals and showed that Duckworth’s grit was uncorrelated with cognitive ability ($\rho = .05$)² and highly correlated with Conscientiousness from the Big Five ($\rho = .84$). Grit predicted grades, both in high school ($\rho = .16$) and in college ($\rho = .17$; the study did not report grit’s incremental prediction beyond general cognitive ability, but given the low correlation between grit and cognitive ability, the result likely would have been similar). Grit could be separated into two correlated constructs, perseverance and consistency (correlated $\rho = .66$), and perseverance was shown to be the stronger correlate of grades ($\rho = .26$ and $\rho = .10$, respectively). These findings are largely in line with Poropat’s (2009) findings and others reviewed in the previous section.

Several meta-analyses of the growth mindset work have been conducted. Sisk et al. (2018) examined $k = 273$ studies with over $N = 365,000$ students and showed that the correlation between growth mindset and achievement was $\rho = .12$, and only about 37% of the studies found a correlation greater than zero. They also found that this relationship was not moderated by academic risk, socioeconomic status, or test score versus grades outcomes. But it was moderated by age, such that the correlation was zero for adults. Sisk et al. (2018) also examined the effect size of mindset interventions, finding $k = 43$ studies ($N = 57,155$ participants) attempting to improve growth mindset. Of the 43 studies, 5 of them showed significant improvement, with an estimated effect size of

$d = .08$. Age, at-risk status, intervention type, and intervention length did not moderate effect size. But there were indications that lower socioeconomic groups benefited more and that reading-based interventions were more effective than computer programs. Yeager et al.'s (2019) randomized control trial ($N = 6,320$ relatively low-achieving students) found a similar estimate, $d = .11$, on grades. Lazowski and Hulleman (2016; $k = 92$, $N = 38,377$) estimated a much higher $d = .49$, although they included both randomized and quasi-experimental designs and a larger group of "motivation interventions." Other than the latter estimate, these effect sizes are "small" by Cohen's (1992) rules of thumb, although Yeager et al. (2019) argued that $d = .2$ should be considered a large effect and that their intervention attained a substantial proportion of that effect.

However, as can be seen from Hattie's (2009) review of effect sizes related to student achievement, there may be many more potentially important factors than grit and growth mindset. Of Hattie's 252 effect sizes, 225 of these showed $|d| > .11$ (Yeager et al.'s 2019 estimate is based on a randomized control trial, whereas Hattie's also included observational data).

At the time of this writing, the CASEL SEL Assessment Guide (2020b) listed 157 constructs from 26 assessments. An organizing framework is clearly needed. John and De Fruyt (2015) provided a way to organize all "21st-century constructs" identified in a review (Trilling & Fadel, 2009). Table 19.1 provides the results of a principal component analysis of self-ratings on these constructs by 350 University of California undergraduates. Five components were extracted that align with the Big Five, suggesting that the five-factor model is a robust characterization of human self-descriptions, regardless of the origins of those self-descriptions.

MOST IMPORTANT SKILLS TO ASSESS: FRAMEWORKS

Various proposals suggest how best to organize the large pool of noncognitive constructs and to highlight the most important ones. We review those that have the most impact on education discussions.

Collaborative for Academic, Social, and Emotional Learning (CASEL): Five-Dimension Framework

CASEL has influenced policy and practice related to social and emotional skills in schools in the United States, particularly in pre-K–12. The CASEL website states that "CASEL was formed in 1994 with the goal of establishing high-quality, evidence-based social and emotional learning (SEL) as an essential part of preschool through high school education." CASEL proposes (a) to conduct research on the efficacy of SEL, (b) to assist in practice and implementation, and (c) to promote legislation at the local, state, and federal levels.

CASEL worked with the Illinois State Board of Education to implement SEL student learning standards for three broad goals of (a) developing self-awareness and

Table 19.1 Principal Component Analysis of 21st-Century Skills and Big Five Alignment

Factor 1: Collaboration (A)	Factor 2: Task Performance (C)	Factor 3: Emotion Regulation (N)	Factor 4: Engagement With Others (E)	Factor 5: Open- mindedness (O)
Compassion	Self-discipline	Self-confidence	Social connection	Curiosity
Care	Focus	Self-esteem	Teamwork	Inquisitiveness
Cooperation	Perseverance	Decisiveness	Social awareness	Willingness to try new ideas
Kindness	Self-control, school	Tackling tough problems	Public speaking	Receptivity
Respect for others	Grit	Cheerfulness	Assertiveness	Innovation
Empathy	Organization	Happiness	Leadership	Vision
Tolerance	Diligence	Optimism	Courage	Insight
Fairness	Precision	Tranquility	Charisma	Tinkering (inventing)
Trust	Dependability	Balance	Speaking out/taking a stand	Learning from mistakes
Forgiveness	Reliability	Stability	Bravery	Excitement creating something new
Gratitude	Consistency	Equanimity	Enthusiasm	Appreciating beauty in the world
Appreciation of others	Trustworthiness	Self-compassion	Passion	Living in harmony with nature
Living in harmony with others	Goal orientation	Self-kindness	Zeal	Spirituality
Interconnectedness	Motivation		Inspiration	Mindfulness
Inclusiveness	Work ethic		Spunk	Existentiality
	Effort		Spontaneity	Awe
	Productivity		Playfulness	Wonder
			Humor	Reverence
				Self-reflection
				Self-awareness
				Consciousness
				Self-actualization
				Authenticity

Note. Column headings indicate aligning Big Five factor: A = Agreeableness, C = Conscientiousness, N = Neuroticism, E = Extraversion, O = Openness. Adapted from “Education and Social Progress: Framework for the Longitudinal Study of Social and Emotional Skills in Cities” (EDU-CERI-CD(2015)13.en), by O. P. John & F. De Fruyt, 2015. OECD Publishing.

self-management skills, (b) using social awareness and interpersonal skills to establish and maintain positive relationships, and (c) demonstrating decision-making skills and responsible behaviors in personal, school, and community contexts (Durlak et al., 2011). The components of these goals—self-awareness, self-management, social awareness, relationship skills, and responsible decision-making—have become the major constructs around which CASEL’s work is organized. The “CASEL 5” did not result from a scientific analysis of either SEL programs or individual differences, but instead informally emerged to characterize aspects and points of emphasis of various SEL programs, using language that policy makers found useful. SEL language has been adopted widely in government circles, such as in state and national standards, television programs, and other media.

CASEL maintains an extensive website with resources and links. CASEL focuses on SEL programs rather than assessments, but hosted an assessment work group for several years, resulting in several useful reports (Assessment Work Group, 2019) and resources, including the SEL Assessment Guide (CASEL, 2020b), along with a blog, a comparison of frameworks (Blyth et al., 2019), an alignment tool, webinars, and assessments emerging from several years of design challenges. CASEL has produced summaries and meta-analyses on the efficacy of SEL programs (Durlak et al., 2010, 2011; Mahoney et al., 2018; Taylor et al., 2017), a handbook on research and practice (Durlak et al., 2015); and position papers based on research findings and working with stakeholders on the CASEL website.

National Academy of Sciences/National Research Council

The National Research Council (2008, 2011, 2012) and its renamed successor, the National Academies of Sciences, Engineering, and Medicine (2017), conducted a series of workshops and consensus reports on interpersonal and intrapersonal skills. The 2012 consensus report reviewed several 21st-century skills frameworks and created a synthesized framework, organized around models from individual differences studies in abilities (Carroll, 1993) and personality (John & Srivastava, 1999). The taxonomy posited a set of cognitive (cognitive processes and strategies, knowledge, creativity), interpersonal (teamwork and collaboration, leadership), and intrapersonal (intellectual openness, work ethic, positive core self-evaluation) competency clusters. Each competency cluster (e.g., teamwork and collaboration) was in turn cross-walked to 21st-century terminology taken from the source documents (communication, collaboration, teamwork, cooperation, coordination, interpersonal skills, empathy, perspective taking, trust, service orientation, conflict resolution, negotiation), an O*NET descriptor or skill (Peterson et al., 1999; social skills), and a basic factor from the individual differences literature (e.g., Agreeableness). The value of organizing around existing models of abilities and personality is that such models provide an empirical foundation for categorizing constructs, in much the same way that John and De Fruyt’s (2015) analysis does (see Table 19.1). This is a way to address the problem of jingle (a single term to describe multiple constructs) and jangle (multiple terms to describe the same

construct; Reeves & Vanator, 2014). It also provides a way to categorize interventions, with an expectation that specific construct interventions will provide spillover effects on within-category constructs in accord with a transfer gradient.

The National Academies (2017, p. 2) also convened a group to

examine how to assess interpersonal and intrapersonal competencies (e.g., teamwork, communication skills, academic mindset, and grit) of undergraduate students for different purposes . . . to include identifying a range of competencies that may be related to postsecondary persistence and success, and that evidence indicates can be enhanced through intervention. (p. 2)

They identified eight competencies: (a) “behaviors related to conscientiousness . . . to self-control, hard work, persistence, and achievement orientation”; (b) “sense of belonging—a student’s sense that he or she belongs at a college, fits in well, and is socially integrated”; (c) “academic self-efficacy—a student’s belief that he or she can succeed in academic tasks”; (d) “growth mindset—a student’s belief that his or her own intelligence is not a fixed entity, but a malleable quality that can grow and improve”; (e) “utility goals and values—personal goals and values that a student perceives to be directly linked to the achievement of a future, desired end”; (f) “intrinsic goals and interest—personal goals that a student experiences as rewarding in and of themselves, linked to strong interest”; (g) “prosocial goals and values—the desire to promote the well-being or development of other people or of domains that transcend the self”; and (h) “positive future self—a positive image or personal narrative constructed by a student to represent what kind of person he or she will be in the future” (pp. 5–6). The report stated that “self-report methods, with their known limitations, predominated in the assessments of the eight competencies” (p. 8) and that “analysis of the quality of the assessments used in the intervention studies revealed spotty attention to reliability and almost no reported evidence of validity or fairness.” (p. 8).

OECD’s SSSES framework

OECD manages the PISA (OECD, 2019b) and the Program for the Assessment of Adult Competencies (PIAAC), among others. PISA and PIAAC are surveys measuring respondents’ cognitive proficiency and include background questionnaires. OECD recently launched the Study on Social and Emotional Skills, an international cross-sectional (ages 10 and 15) survey of students, teachers, and parents focusing on social and emotional skills, conducted in 12 city sites (Kankaraš, 2017; OECD, 2019a). The long-term goal is to monitor the growth of social-emotional skills from school to the labor force in a policy-relevant, feasible, valid, reliable, comparable, ethical, cost-effective, and sustainable way.

The project has published several framework documents (Chernyshenko et al., 2018; John & De Fruyt, 2015; Kankaraš & Suarez-Alvarez, 2019; OECD, 2015). OECD (2015) provided the justification for the study with a comprehensive literature review, concluding that social and emotional skills, as important as they are, were hard to measure, and consequently teachers, schools, and policy makers

do not know “if their efforts at developing these skills are paying off,” and that these skills “are seldom taken into account in school and university admissions decisions” (p. 13).

OECD (2019a) proposed the Big Five as an organizing framework because of positive research on the psychometric qualities of Big Five measures (reliability, predictions of outcomes) and a sound justification for five independent dimensions. Even with only five dimensions, the model is comprehensive, particularly when lower order correlated dimensions are added (Dudley et al., 2006; John & Srivastava, 1999; Paunonen & Ashton, 2001). Also, the Big Five has a scientific underpinning in the lexical hypothesis (Goldberg, 1993), that language evolves to accommodate the most important and salient differences between people in the form of descriptors. There are competitors to the Big Five, such as the six-dimension hypothesis (Lee & Ashton, 2004), but this is a relatively minor variation. Major alternative explanatory models are not readily available. Seeming alternatives, such as 21st-century skills, can easily be shown to be largely captured by the Big Five, as John and De Fruyt’s (2015) analysis showed (see Table 19.1).

The OECD (2019a) framework proposed five domains with several facets within each domain: task performance (achievement motivation, responsibility, persistence, self-control), emotional regulation (stress resistance, optimism, emotional control), collaboration (empathy, trust, cooperation), open-mindedness (tolerance, creativity, curiosity), and engaging with others (sociability, assertiveness, energy). These are the Big Five factors (Conscientiousness, Neuroticism, Agreeableness, Openness/Intellect, and Extraversion, respectively) with more palatable names. The framework adds a sixth dimension, compound skills, which includes critical thinking, metacognition, and self-efficacy. Unlike some of the frameworks reviewed here, this framework is not merely notional or a helpful organizing scheme, but a structural model and, with the assessments being administered, a measurement model, which can be evaluated with confirmatory factor analysis. A report on preliminary findings is available (OECD, 2021).

UC Consortium on Chicago School Research (UCCCSR)

UCCCSR conducted a comprehensive literature review to identify the noncognitive factors critical to children’s learning and development (Farrington et al., 2012). They sought to identify factors that were linked to academic achievement, at all ages and academic levels, that were simultaneously “not fixed traits,” but ones that could be shaped by the educational context. The nature–nurture distinction is fuzzy and often overblown, but a perception of fixed traits versus malleable competencies has influenced the research conducted in this area. UCCCSR’s literature review can be viewed as a framework for noncognitive factors. They proposed five categories of factors: (a) academic behaviors (going to class, doing homework, organizing materials, participating, and studying); (b) perseverance (grit, tenacity, delayed gratification, self-discipline, self-control); (c) mindsets (sense of belonging, growth mindset, self-efficacy, belief in the value of academic work); (d) learning strategies (study skills, metacognitive

strategies, self-regulated learning, goal setting); and (e) social skills (interpersonal skills, empathy, cooperation). There has been some empirical research evaluating this framework (Farruggia et al., 2016; Wanzer et al. 2019).

Other Frameworks

The range of noncognitive variables goes beyond the Big Five and the constructs identified thus far. Here, we discuss proposals that expand the list of potentially important constructs.

Social Attitudes

Saucier (2000, 2013) identified several social attitude dimensions (or belief system components: beliefs, attitudes, ideologies, worldviews) using a lexical approach. Respondents were given 389 descriptions of terms ending in “ism,” such as authoritarianism, liberalism, conservatism, and communism, sampled from the dictionary. They rated their agreement with the descriptions, and factor analyses resulted in four factors—(a) alpha (tradition-oriented religiousness, e.g., creationism); (b) beta (unmitigated self-interest, e.g., hedonism); (c) gamma (communal rationalism, e.g., utilitarianism); and (d) delta (subjective spirituality, e.g., reincarnationism). Saucier (2013) included additional items identifying a fifth factor, inequality-aversion (e.g., egalitarianism vs. elitism, jingoism). He found traditional religiousness correlated with Republican Party (within the United States) preference. Inequality aversion, subjective spirituality, and communal rationalism correlated with Democratic Party preference; and unmitigated self-interest correlated negatively with Openness/Intellect and Agreeableness.

Economic Preference Parameters

Almlund et al. (2011, Table 6), proposed a set of economic preference parameters—time, risk, and social preferences—based on the behavioral economics literature and argued that they overlap Big Five factors. Time preference (delay discounting) relates to one’s ability to delay gratification; risk preference refers to the amount of risk one is willing to assume; and social preferences have to do with leisure, altruism, trust, and positive and negative reciprocity. There are conceptual overlaps—risk-taking is a facet of Extraversion, time preference (punctuality vs. procrastination) is related to Conscientiousness, and trust is related to Agreeableness. A. Falk et al. (2015, 2016) administered measures of economic preferences along with the Big Five and found some overlaps; they also found correlations with national indicators such as educational attainment, savings rate, and risk behaviors (e.g., smoking).

Kyllonen (2016) proposed (but did not test) a taxonomy to summarize all these constructs. The major categories were the Big Five, generalized attitude dispositions, interests, personal beliefs, cultural and behavioral norms, social axioms, attitudes toward school, values, subjective well-being, economic preferences (time, risk, and social preferences), emotional intelligence, metacognition, creativity, collaboration, cognitive bias susceptibility, emotions, moods, and states of mind.

National Assessment of Educational Progress

Several other frameworks should be mentioned because of their importance in the field. One is for background (contextual) questionnaires for large-scale assessments, such as the National Assessment of Educational Progress (NAEP) (National Assessment Governing Board, 2013), PISA (OECD, 2017b), and other major assessments, such as TIMSS, PIRLS, and PIAAC. The National Assessment Governing Board (2013) identified priorities for NAEP contextual data collection, which were (a) NAEP reporting categories (socioeconomic status, gender, race/ethnicity, disability status, and English language status); (b) contextual factors with relationships to achievement; and (c) subject-specific information, with priority based on validity, reliability, universality (can be collected from all students), currency, respondent burden, logistic feasibility, cost-effectiveness, timeliness, nonintrusiveness, whether trends are important, and whether the information contained is valuable for understanding academic performance and how to improve it. NAEP is administered every year, and there are many different questionnaires (student, teacher, school), which are changed regularly. The student questionnaire is limited to 15 minutes. The National Center for Education Statistics (n.d.-b) provides details and the questionnaires themselves.

PISA

PISA measures reading, mathematics, and science every 3 years (since 2000; highlighting a different subject each cycle) to about half a million 15-year-olds in 70+ countries and includes a 30-minute student questionnaire. The PISA 2018 questionnaire framework (OECD, 2019b), highlighting reading, includes three construct categories: student background (e.g., out-of-school reading, socioeconomic status), schooling (teacher qualifications, instruction time, parental involvement), and noncognitive/metacognitive. This latter category includes attitudes motivation, strategies dispositional variables (achievement motives; incremental mindset; perseverance; subjective well-being; information and communications technology, motivation, and practices) school-focused variables (learning beliefs, attitudes toward school, achievement goals), and dispositions for global competence (included because global competence was assessed in the PISA 2018 survey). The latter includes communication and relationship management, knowledge of and interest in global developments, Openness and flexibility, and emotional strength and resilience. There are common themes and scales across the PISA cycles as well as changes (see OECD, 2013a, 2016, 2019b, for the past three questionnaire frameworks). There have been many analyses of the constructs together to determine the dimensionality and structure of these scales (J. Lee & Stankov, 2013; Marsh et al., 2006).

The California Office to Reform Education (CORE)

CORE is a coalition of eight California school districts serving over half a million students. It was the first U.S. jurisdiction to obtain a waiver from the U.S. Department of Education's No Child Left Behind legislation to administer a noncognitive assessment for the purposes of accountability. The questionnaire measured four constructs in

students—self-management, growth mindset, self-efficacy, and social awareness (West, 2016). There was not a systematic process for identifying these constructs, but they are some of the more popular in K–12 discussions. Two come from the CASEL five; growth mindset comes from Dweck (2017), but is related to locus of control and attribution theory, which have been a part of education discussions for decades (Graham, 1991; Rotter, 1966), as has self-efficacy (Bandura & Schunk, 1981; Schunk, 1989).

Mission Statements

Oswald et al. (2004) identified 12 critical skills for college by sorting statements coming from college mission statements. They clustered into intellectual (knowledge, continuous learning, and curiosity/artistic appreciation), interpersonal (multicultural tolerance, leadership, interpersonal, social responsibility), and intrapersonal (health, career orientation, adaptability, perseverance, ethics) behaviors. With a similar methodology, Stemler et al. (2011) identified cognitive, social, emotional, and civic as the most common themes in high school mission statements.

Competency Identification

Shultz and Zedeck (2011) conducted extensive interviews with practicing lawyers, asking questions such as, “If you were looking for a lawyer for an important matter for yourself, what qualities would you most look for?” They identified 26 effectiveness factors, divided into eight categories (cognitive, research and information gathering, communications, planning and organizing, conflict resolution, entrepreneurship, working with others, character). This approach has also been used in developing competency frameworks, which are widely used in business for promoting assessment and training needs. One example is SHL’s Great Eight (Bartram, 2005). These eight high-level competencies have been mapped to the Big Five (the letter in parentheses indicates the competency’s highest correlate (A = Agreeableness, E = Extraversion, O = Openness; N = Neuroticism; C = Conscientiousness; g = cognitive ability): learning and deciding (E); supporting and cooperating (A); interacting and presenting (E); analyzing and interpreting (g); creating and conceptualizing (O); organizing and executing (C); adapting and coping (–N); enterprising and performing (–A). Each of these is divided further into specific competencies. Leading and deciding is divided into deciding and initiating action and leading and supervising. Deciding and initiating action is further divided into six competencies, including making decisions, acting on own initiative, and taking calculated risks. Other competency frameworks are Clifton Strengths (Rath & Conchie, 2008) and Lominger’s 67 competencies (Lombardo & Eichinger, 2004), which include competencies such as dealing with ambiguity, creativity, motivating others, planning, and building effective teams. Competencies are typically identified based on factor analysis of responses to rating scale items written to represent a broad variety of attitudes, values, and behaviors relevant to workplace performance, providing an empirical foundation to this work. But there is less emphasis on finding commonalities across competency frameworks (because of market incentives) compared to the case with personality psychology.

Personality Testing Frameworks: The Big Five and Facets

Personality assessments are built around frameworks. The Big Five is an important framework. However, the most popular personality assessments typically provide many more than 5 dimensions. Analyses of items from the International Personality Item Pool (Goldberg et al., 2006), a repository of over 3,000 personality items aligned with over 400 commercial instrument scales, reveal over 25 factors (Condon, 2018). Major commercial instruments measure more than 5 dimensions: SHL's OPQ (32 dimensions); Gallup's StrengthsFinder 2.0 (Rath, 2007) (34 dimensions, called themes), and Lominger (Lombardo & Eichinger, 2004) (67 competencies). A. Costa and Kallick (2008) proposed 16 habits of mind, essential characteristics for success, including persisting, managing impulsivity, and thinking independently. C. Peterson and Seligman (2004) proposed 26 character strengths rolled up into 6 classes of virtues. A consistent finding is that the 5-factor model (or the 6-factor HEXACO model, Lee & Ashton, 2004) is the highest order of a hierarchical model (John & Srivastava, 1999; Drasgow et al., 2012). Although facets (lower order components) tend to be less stable across samples and languages than the Big Five, the 5- (or 6-) factor model is the best model we have of the major independent dimensions of human descriptions of personality, with additional structure of maybe 20 or 30 reliable factors beneath the Big Five.

Comparison of Frameworks

The frameworks reviewed only scratch the surface—Berg et al. (2017) identified 136 frameworks in the K–12 area alone! And there are higher education frameworks, such as ACT's holistic framework (Camara et al., 2015). A question is, How can such frameworks be evaluated or compared? A report from the CASEL assessment work group (Blyth et al., 2019) proposed 10 criteria. Five concerned conceptual clarity: specificity (defines competencies), balance (includes interpersonal, intrapersonal, and cognitive competencies), developmental (specifies how development occurs), culturally sensitive (accommodates cultural differences), and empirically grounded (reflects findings of associations between competencies and school, work, and life success). Five concerned implemental support: intended for practice, resources for practitioners, resources for use by children and youth, resources for measurement and data use, and empirically tested. The criteria were developed with practitioners in mind—school staff seeking a framework for implementation in response to district, state, or federal policies or mandates. Related CASEL efforts include a white paper on what frameworks are and why they are useful (Blyth et al., 2018) and tools for selecting and cross-walking frameworks (Jones et al., 2019).

The Big Five personality model has been influential in framework development. OECD's Study on Social and Emotional Skills program has adopted it, and workforce testing has embraced it. Long-standing workforce tests are issuing five-factor model conversions and score reports, and new assessments are specifically tailored around the Big Five. Why is that? The five-factor model likely has more research—reliability, prediction studies, and, increasingly, personality change studies—than any other model of individual differences in social and emotional dimensions. The Big Five has become a

standard and therefore a means to align findings and advance the field quickly. CASEL language is more popular, certainly within K–12 education, and it is highly represented in policy statements and in state social-emotional learning standards (SEL itself is a CASEL coinage). The Big Five’s power is that it emerged from an empirical finding regarding the words we use to describe ourselves and others (Goldberg, 1993). For these reasons, the Big Five model and CASEL’s five competencies are the dominant frameworks today. Few, if any, frameworks can satisfy all the requirements laid out by Blyth et al. (2019). It is likely that for the foreseeable future no one framework will be adopted universally for diverse uses. As frameworks are implemented, for various purposes, and results are analyzed, we may see more consolidation based on what kinds of frameworks prove most useful.

METHODS

Separating methods and constructs is difficult. The construct of personality is almost completely confounded with the rating scale method for measuring it. In the research literature and in policy discussions, mention of personality is invariably linked with rating scale measurement. We suspect that resistance to implementing personality assessment in schools has to do with the limitations of rating scale methodology. Despite widespread agreement on construct importance, there may be doubt about the adequacy of ratings scales for measuring them. Imagine a world in which, instead of mathematics tests, we administered self-ratings of mathematics knowledge and ability. Significant decisions would not likely be based on such data.

Disentangling method and construct is useful conceptually and for the field to advance, which has been acknowledged for over half a century (Campbell & Fiske, 1959). There may be methods other than rating scales for measuring personality. *Persistence* can be measured variously:

- Self-rating: “How often do you work on a task until you are finished: Rarely/sometimes/often/always or almost always?”
- Teacher rating: “X completes their assignments on time: True/Not true?”
- School administrative record: Missed assignments____; tardiness____
- Performance test: Length of time spent adding columns of numbers before requesting a break
- Situational judgment test: “You have a test the next day and don’t feel fully prepared. You are very tired and you are not thinking clearly. What do you do?”
- Behavioral interview: “Tell me about a time when you had to persist on a task despite many barriers in your way.”

Here, we review the main methods used to measure intra- and interpersonal skills. We review the main issues in the design, development, and scaling of assessments and the key evidence and challenges with respect to reliability, validity, and fairness (for additional information on these three concepts, see Lee & Harris; Lane & Marion; Zwick; and Rodriguez & Thurlow, all in this volume).

Self-Report Ratings

Self-report ratings are rating scale measures, known as Likert-scale measures (Likert, 1932). They refer to a statement or a question a respondent is asked to express agreement or other judgment about (e.g., behavior frequency). An example is, “How much do you agree with the statement, I am a hard worker? Strongly agree/agree/neither agree nor disagree/disagree/strongly disagree,” or “How often do you come to class prepared? Never or almost never/seldom/sometimes/often/always or almost always.” The research we have reviewed to this point is based on this method. The contextual questionnaires in NAEP, PISA, PIAAC, World Health Organization’s Health Behavior in School-Aged Children survey (Inchley et al., 2018), and most assessments in RAND’s Education Assessment Finder (Hamilton et al., 2018) and CASEL’s (2020b) SEL Assessment Guide are based on this method, as are the assessments used in the CORE Districts and the items in ETS’s SuccessNavigator. The Big Five personality model is based on self-report ratings.

There are general rules for item writing (Alreck & Settle, 1994; Fowler, 2006; National Assessment Governing Board, 2002). Items should be precise (e.g., regarding who the question refers to, the time frame), concise (e.g., ask one question, one topic; avoid “double-barreled” questions; do not use more words than necessary), neutral (e.g., avoid leading the respondent to a preferred answer), and simple (avoid esoteric vocabulary or complex sentence constructions). An easier rule of thumb is the headline rule. Imagine a *New York Times* headline that summarizes findings from the survey based on one item. “40% of New York 4th graders agree that what they learn in school is important for their future” is fairly interpretable. “30% of New York 4th graders *often believe* that what they learn is irrelevant” is probably not—what does “often believe” mean?

The NAEP contextual questionnaire group (Bertling, 2015) developed a format taxonomy for rating scale questions, applicable to questionnaire assessments broadly. Their 12-scale taxonomy specified *frequency* (“how often”) versus *amount/extent* (“how much”); frequency scales were abstract or quantified, with abstract being *absolute* (without reference point) or *relative* (with a reference point). Two types of quantified scales are absolute (i.e., counts) and *average quantified frequencies* (average counts within a time period). There are eight amount/extent scale types: time, emphasis, possibility to change, similarity to self (“like me”), agreement, confidence, likelihood, and importance. Each is associated with specific recommended response categories. An absolute abstract frequency scale uses the categories “never or hardly ever,” “once in a while,” “sometimes,” “often,” and “always or almost always.” An average quantified frequency scale uses the categories “never,” “about once or twice a year,” “about once or twice a month,” “about once or twice a week,” “every day or almost every day,” and “several times a day.” An agreement scale uses the labels described in the previous paragraph; a similarity-to-self scale uses “not at all like me,” “a little bit like me,” “somewhat like me,” “quite a bit like me,” and “exactly like me.” This was implemented in PISA 2022 (OECD, 2023).

Research issues include how many response categories to use (e.g., 2, “true of me” versus “not true of me” to 11 or more, such as a continuous graphic scale) (Revilla et al., 2014,

suggested 5 for agreement scales) and whether to include a neutral middle point (e.g., “neither agree nor disagree”) (Moors, 2008, suggested probably not). There have been studies on the interpretation of frequency quantifiers, such as seldom and often (Bocklisch et al., 2012; Newstead & Collis, 1987), which may be useful in making response category labels by spreading out the categories (selecting category labels corresponding to a spread of specific percentages that might be informative). But determining the most effective approach for a particular context is difficult. An alternative is analyzing response data after data collection to determine category frequencies and to explore the relationship between item responses and the underlying trait level using nonparametric methods, such as nonparametric option characteristic curves (Ramsay, 1991), or item response theory (IRT) methods, such as the nominal response model (Bock, 1972). R. H. Meyer et al. (2018) provided examples with the California CORE data.

Reliability

Two general approaches to analyzing and scoring rating scale data are classical test theory (CTT) and item-response theory (IRT). The CTT approach models test (or scale) scores (with exceptions; Legree et al., 2021). It assumes an observed test score is the sum of a true score and a random error. Ratings are assumed to be on an interval (continuous) response scale. A rule of thumb is that more than six ordered response category responses can be treated as continuous (Millsap, 2011, p. 121), but with fewer, they should be treated as categorical (Lubke & Muthen, 2004). Nevertheless, treating rating scale data as continuous is still the most common approach. The method involves transforming category responses (e.g., “strongly agree,” “agree,” “disagree,” “strongly disagree”) to numbers, usually 1 to k (sometimes, 0 to $k - 1$), where k is the number of categories, and then computing descriptive statistics (mean, standard deviation, skewness), and reliability (usually Cronbach’s alpha) from the continuous variable. West et al. (2020) used a CTT approach when analyzing the CORE Districts data. A self-management scale (e.g., “I came to class prepared”) used a five-category response scale (“almost never,” “once in a while,” “sometimes,” “often,” and “almost all the time”). The scale metric was transformed from the five scale categories, yielding a mean of 4.05 (presumably, the nine self-management items mean), a standard deviation of .69 and an alpha of .85 was reported (their Table 2). All four construct scales (self-management, growth mindset, self-efficacy, and social awareness) had five response scales, and although they had different labels (“not at all true” to “completely true” for growth mindset; “not at all confident” to “completely confident” for self-efficacy; “not carefully at all” to “extremely carefully” for social awareness), this allowed some degree of comparability across scales.

CLASSICAL TEST THEORY RELIABILITY In CTT, reliability is the proportion of true score to observed score variance, $r_{xx'} = \sigma_t^2 / \sigma_x^2$. Reliability is a function of both the average interitem correlation (or covariance) and the number of items in the scale, as can be seen from a formula for alpha, $r_{xx'} = \frac{n\bar{c}}{\bar{v} + (n-1)\bar{c}}$ where n is the number of items

in the scale, $\bar{c}$ is the mean interitem covariance, and $\bar{v}$ is the average item variance.³

One implication of this is that scales can be made more reliable simply by adding more items. This is shown in the Spearman–Brown prophecy formula, $r_{xx'}^* = \frac{kr_{xx'}}{1 + (k-1)r_{xx'}}$, where $r_{xx'}^*$ is the expected new reliability resulting from changing the test length by a factor of k ($k = 2$ to double the number of items or $k = .5$ to halve the number).

Reliability is important when correcting correlations with external variables and when determining effects of changes in reliability on changes in correlations with external variables. Disattenuated correlations between a scale, x , and an external variable, y , that is, correlations corrected for unreliability in both x and y , are computed as $r_{xy}^* = r_{xy} / \sqrt{r_{xx'} r_{yy'}}$. This can also be used for estimating changes in correlation with external variables, from r_{xy} to r_{xy2} based on changes in reliability, from $r_{xx'}$ to $r_{xx'2}$ is $r_{xy2} = r_{xy} \sqrt{r_{xx'2} / r_{xx'}}$; that is, the new predictive correlation is increased by a factor of the ratio of the square roots of the new to old reliabilities (Nunnally & Bernstein, 1994, eq. 7-1, p. 257).

IRT SCORING AND RELIABILITY IRT can be used to analyze and score data from rating scales. IRT treats the ratings as categorical variables and models the probability of choosing each rating category as a function of item parameters and person latent trait. There are many IRT models—van der Linden (2016) comprises 33 chapters, each dedicated to an IRT model (or class of models).⁴

There are ways to taxonomize IRT models to focus on the ones most important for the analysis of rating scales. First, distinguish continuous from categorical latent variables. Categorical latent variable models include mixture models and latent class models. These are relatively rare in analyses of rating scale data, although there are some applications for detecting response styles and faking (Eid & Zickar, 2007).

The most common IRT models assume a continuous latent variable underlying the ordered categorical responses. What is being modeled is the probability of selecting one of the k categories, such as “agree” or “strongly agree.” A set of “divide-by-total” polytomous IRT models (Thissen & Steinberg, 1986) that share common parameterization but with decreasing degree of constraints includes rating scale models (RSM; Andrich, 2016), partial credit models (PCM; Masters, 2016), generalized partial credit models (GPCM; Muraki & Muraki, 2016), and nominal response models (NRM; Bock, 1972). Item parameters for these models include item/category slope and category intercept parameters, which, respectively, represent the discrimination of the item/category as a function of the latent trait and the relative endorsement of a category.

The RSM (Andrich, 2016) assumes all item slopes are the same, and the differences of category intercepts between adjacent categories (e.g., disagree and agree, agree and strongly agree) are the same across items. The PCM assumes equal item slopes, but relaxes the constraints on category intercepts. The GPCM further relaxes the assumption of equal item slopes for all items in the scale, an assumption that characterizes

both the RSM and the PCM. However, discrimination is common across all categories. The NRM even further allows different categories to have different slopes. These are IRT models ordered by flexibility. Fitting these models to the same data can be used to test out different model assumptions (Preston et al., 2011). A cost for flexibility is the requirement for larger sample sizes. De Ayala (2009) recommended minimum sample sizes of 250, 250, 500, and 600 for the RSM, PCM, GPCM, and NRM, respectively. Once an IRT model has been determined, an individual can be scored as the estimate of the latent trait in the given IRT model.

In IRT, test information and measurement error vary with the latent trait. To get overall reliability averaging across the latent trait, Green et al. (1984) suggested marginal reliability. Following the CTT reliability definition of variance of true scores over variance of observed scores, the IRT marginal reliability is calculated as $(\sigma_{\theta}^2 - \bar{\sigma}_e^2) / \sigma_{\theta}^2$, where σ_{θ}^2 is the variance of latent trait and $\bar{\sigma}_e^2$ is the average error variance across the latent trait distribution.

CTT VERSUS IRT FOR RATING SCALE METHODS Most personality research and non-cognitive assessment research more generally employs CTT methods. CTT methods are convenient; well known; easy to apply with a wide variety of software, including spreadsheet software; and familiar to researchers and stakeholders; they can also be appropriately applied in small samples. IRT models are more complex, less well known, require specialized software, and generally require larger samples. But there are significant advantages to IRT methods. IRT overcomes the fundamental item–person confounding problem in CTT, separating item and person effects (van der Linden, 2016). This separation leads to many advantages: IRT can be used to provide better item diagnostics, scoring of test takers based on response patterns, form assembly, equating and linking of forms, assessment of change, and examination of measurement invariance across test-taking subgroups. These advantages are routinely discussed in IRT textbooks (Reise & Revicki, 2015), and the field of educational measurement has embraced IRT approaches. Because educational measurement increasingly includes personality and noncognitive assessment, a similar adoption of IRT methods in this realm can be expected.

Validity

EVIDENCE BASED ON CONTENT Rating scale items are simply statements about which a respondent expresses agreement (or frequency, amount, or extent). So, if respondents indicate that they “strongly agree” that “I am a hard worker,” this can be taken at face value as an indication of Conscientiousness, by the definition of Conscientiousness. Messick (1995) referred to this as content relevance. This *prima facie* case is bolstered by additional evidence that ratings on other indicators of Conscientiousness (e.g., “I am thorough in my work,” “I complete tasks in an efficient manner”) tend to intercorrelate. The literature on item intercorrelations based on the five-factor model attests to the nature of those relationships (John & Srivastava, 1999).

This interpretation can be challenged based on *calibration* and *faking* (or social desirability responding). The calibration challenge is that interpreting Respondent A's "strongly agree" that "I am a hard worker" as an indication of a higher level of Conscientiousness than Respondent B's "agree" that "I am a hard worker" (aside from the mapping of "hard worker" to "Conscientiousness," discussed in the previous paragraph) assumes that the two respondents have similar understandings of both the stem and the categories (Böckenholt, 2004). An example of miscalibration can be found in the meta-analytic correlation between self-estimates of cognitive ability and cognitive ability measured by tests: they are only correlated around $r = .33$ (Freund & Kasten, 2012).

The faking challenge has to do with respondents presenting themselves in a too-favorable light (self-presentation); social-desirability bias (Paulhus, 2002). Niessen et al. (2017) demonstrated self-presentation with university applicants who completed a set of ratings and then repeated the ratings after being selected into the program (reduced self-presentation). Scores were higher and outcome predictions were lower with self-presentation. West et al. (2018) minimized self-presentation by assuring anonymity, attaching no stakes to the assessment, and having the proctor (teacher) stay in the back of the room rather than roam the aisles looking over students' shoulders. Still, self-presentation presents a challenge, particularly in a high-stakes context.

EVIDENCE BASED ON CORRELATIONS WITH OTHER MEASURES The other key source of validity evidence for rating scale measures is in their correlations with external measures. Meta-analyses have shown moderate correlations between personality self-ratings and grades in higher education (McAbee & Oswald, 2013; Nofle & Robins, 2007; Poropat, 2009; Richardson et al., 2012; Robbins et al., 2004, 2009; Vedel, 2014). Conscientiousness is the highest correlate, typically in the mid .20s range. These studies, as well as the ones cited next, are typically conducted in low-stakes research settings, giving respondents little incentive to fake self-ratings.

West et al. (2018) found moderate correlations within grade between the four CORE Districts scales (self-management, growth mindset, self-efficacy, and social awareness) and grade point average (GPA; $r = .18$ to $.44$) and math ($r = .14$ to $.37$) and English language arts test scores ($r = .15$ to $.34$) (N s ranged from 7,893 to 127,134). This aligns with expectations based on our review and supports a test score interpretation that the four constructs are associated with educational success.

There are two key challenges to this interpretation, independent of the challenges associated with the calibration and faking issues discussed previously. The four scores are correlated quite highly, relative to their reliability. At the school level, correlations range from $r = .36$ to $r = .97$, with a median $r = .91$ (Hough et al., 2017). This suggests that there might not be four unique pieces of information in the four scale scores, which would challenge an interpretation based on the scale content (e.g., self-efficacy, growth mindset), perhaps toward an alternate interpretation based on the common elements across the scales (e.g., social desirability). The fact that West (2016) showed that the highest correlate of English language arts grades was the composite of all four measures,

rather than any individual measure, supports this idea. A subscore analysis, as suggested by Haberman (2008), would be informative to establish scale independence.

Second, interpreting results across grades is challenging. Figure 19.1 shows the cross sectional comparisons of CORE District students' SEL scores from Grades 4 to 12 and, for comparison purposes, the math and English language arts achievement test scores. Achievement test scores, which are vertically scaled and therefore comparable, are monotone, almost linear increasing. The SEL scores are from identical questions (i.e., the same questions were asked in the 3rd through 12th grades), scaled to a common metric. They sometimes go up, sometimes down, without a clear pattern. At the least, this challenges the interpretation of test scores as indicating an association of the four constructs with achievement. Fourth graders' social awareness is considerably higher than that of high schoolers, yet their achievement is considerably lower. Within a grade, the correlation is higher. The cross-grade pattern is difficult to interpret. Generally, age, period, and cohort effects all might influence findings like these (Ion et al., 2022).

Fairness

Fairness in assessments as well as communications about those assessments, in various standards documents (American Educational Research Association [AERA] et al., 2014; ETS, 2014, 2022), refers to the requirement that construct-irrelevant personal characteristics of test takers have no appreciable effect on test results or their interpretation. Fairness reviews conducted prior to pilot testing consider representation of the groups to be studied, accommodations, presentation and response formats, the potential effect of timing (e.g., time limits), language (e.g., English language learning status), experience with the technology, and prohibition of inappropriate language, among other factors. Noncognitive and cognitive assessments are not different in these regards. Generally, the goal is to avoid materials that are not fair because they include the wrong content and skills or they fail to include a good sample of the right content and skills (ETS, 2022).

MEASUREMENT INVARIANCE Measurement invariance analyses is conducted to ensure comparability of interpretation across groups (e.g., race/ethnicity, gender, age, language) or over time. With continuous data there are well-documented approaches to establishing measurement invariance through a sequence of tests for configural, metric, and scalar invariance. Tests for configural invariance establish that the factor structure is the same across groups; metric invariance establishes that item loadings are the same; scalar invariance establishes that the item intercepts and loadings are the same. Establishing metric invariance allows one to interpret the correlations between scale scores and external variables as comparable for the different groups; establishing scalar invariance allows one to interpret the mean scale (factor) differences between groups. Failure to establish measurement invariance at any point makes comparisons between groups problematic. It is not appropriate to claim a mean "Conscientiousness" difference between males and females if scalar invariance is not established. If a Conscientiousness item was "I enjoy assembling and disassembling car engines" and the mean difference on

**FIGURE 19.1**

Cross-Sectional Comparisons of CORE District Students Scale Scores Across Social-Emotional Learning (SEL) Scales (Top Four Panels) and Achievement Test Scores (Bottom Two Panels)

Note. Achievement test scores are vertically scaled and monotone increasing. SEL scale scores are from identical questions across years scaled to a common metric. They are not monotone increasing. From *Trends in Student Social-Emotional Learning: Evidence from the CORE Districts* (Working Paper), by M. R. West, L. Pier, H. Fricke, H. Hough, S. Loeb, R. H. Meyer, and A. B. Rice, 2018, PACE: Policy Analysis for California Education, CORE-PACE Research Partnership. Reprinted with permission.

a Conscientiousness scale that included the item showed a higher mean for males, one might be reluctant to conclude that males were more conscientious than females (Ployhart & Oswald, 2004).

With categorical data, as typically found on rating scales, the configural–metric–scalar series of tests is not appropriate, unless those data are treated as continuous. But if they are treated as categorical, an alternative sequence of first testing for configural invariance, then for threshold invariance, then for loadings and intercept invariance is recommended (Svetina et al., 2020; Wu & Estabrook, 2016). There are several reasons for conducting measurement invariance analyses. One is to determine the appropriateness of comparing groups. Another is to explore reasons for misfit, which can provide additional insight into group differences (Putnick & Bornstein, 2016). Typically, when conducting measurement invariance tests, steps are taken to identify misfitting items and delete them or relax certain assumptions about them (e.g., thresholds). This process can provide insights on possible reasons for misfit and allow for comparison of scale scores between groups. The practical importance of lack of invariance should also be considered (Nye & Drasgow, 2011; Schmitt & Ali, 2015).

Response Style

For rating scale items, response style is potentially a source of construct-irrelevant variance. Response style is a major factor in international assessments involving different languages, but it also can also differentiate subgroups within a language group (e.g., gender, race/ethnicity, immigrant status). There are well-documented differences between cultural groups in using the response scale, independent of the construct being measured. These include extreme response style (tendency to choose scale extremes, such as “strongly disagree” or “strongly agree”), modest or midpoint response style (tendency to choose the scale midpoint, such as “neutral” or “neither agree nor disagree”), and yeah-saying or acquiescence response style (ARS; tendency to agree). Response style effects can be adjusted for statistically. Khorramdel and von Davier (2014) identified extreme response style and modest or midpoint response style using a multinomial processing tree approach, showing the generalizability of response styles across response scales. He and van de Vijver (2015), using Teaching and Learning International Survey data, interpreted a general response style factor with positive loadings from extreme response style and socially desirable responding and negative loadings from modest or midpoint response style as response amplification versus moderation. Primi et al. (2019) identified positive and negative key item pairs (close to opposite) within a scale and presented both classical and IRT corrections to bias (typically positive bias, such as responding “strongly agree” to one of the pair and “neutral” or “disagree” to its opposite). C. F. Falk and Cai (2016) provided a general approach to modeling response styles. A special issue of the *British Journal of Mathematical and Statistical Psychology* (Khorramdel et al., 2019) assembled eight different approaches for correcting rating scale data for response style, including multidimensional IRT, IRTree, and clustering approaches. Some of these methods should routinely be applied to rating scale questionnaires.

Although rating scale approaches, particularly self-ratings, are by far the most common in the assessment of interpersonal and intrapersonal skills, there are significant challenges in their interpretation as construct measures. Also, while self-rating scales can be used in low-stakes assessments, they are problematic for high-stakes use (Niessen & Meijer, 2017).

Others' Report Ratings

Others' (informant) ratings refers to evaluations by others—peers, supervisors, professors, or others who are in position to evaluate the target. Unstandardized evaluations, such as letters of recommendation, are common, particularly in higher education and the workforce (personnel selection, promotions), but little research exists on them. Despite that, letters of recommendation and associated ratings are considered quite important in education admissions (Kuncel et al, 2014) and in the workforce (Judge & Higgins, 1998). Perhaps the reason for their popularity is that they protect against the faking and potential deception that can characterize self-reports. Personal statements are commonly required in admissions and scholarship competitions, despite little evidence for their value (Murphy et al., 2009). The reader of a recommendation letter can be at least somewhat assured that a relatively disinterested party is endorsing a candidate.

Research on letters of recommendation is based on post hoc numerical summaries of letter contents (Baxter et al., 1981; Kuncel et al., 2014). Such summaries correlate with outcome measures in higher education, GPA, and degree attainment and provide small, but incremental prediction beyond other measures in predicting attainment (Kuncel et al., 2014). But a quantitative summary of letter contents is not routinely available and is not how letters are typically used, which is more anecdotal. The future may bring natural language processing analyses of letters, as with essays and constructed response tasks (Madnani & Cahill, 2018), but little of that has appeared so far.

Many formats exist for others' ratings besides open-ended letters of recommendation. They range from a standardized letter of recommendation used for graduate admissions, such as ETS's Personal Potential Index (Kyllonen, 2006), to a clinical psychologist's rating of candidates' psychological fitness for military duty based on a 30-minute interview (Lindqvist & Vestman, 2011), a teacher's checklist of classroom misbehavior and a parent questionnaire used in the National Educational Longitudinal Study of 1988; National Center for Education Statistics, n.d.-a), and teacher and parent rating forms for students found in RAND's Education Assessment Finder (Hamilton et al., 2018) and CASEL's (2020b) SEL Assessment Guide, as well as for large-scale assessments such as the PISA Parent Questionnaire (OECD, 2017b), and the CORE Districts Teacher Questionnaire (West et al., 2018).

It is useful to consider the constructs and measures used. ETS's Personal Potential Index comprised six scales with a text box for each scale, which allowed evaluators to justify or elaborate on the ratings. The six scales were knowledge and creativity, communication skills, teamwork, resilience, planning and organization, and ethics and integrity.

Each scale comprised four items. For planning and organization, the items were sets realistic goals, organizes work and time effectively, meets deadlines, and makes plans and sticks to them. The rating scale included six categories: “below average,” “average,” “above average,” “outstanding (top 5%),” “truly exceptional (top 1%),” and “do not have sufficient information to evaluate.”

The Swedish military interview (Lindqvist & Vestman, 2011) was based on a clinical psychologist’s analysis of several attributes, combined to form a single composite score. The positive attributes were willingness to assume responsibility, independence, outgoing character, persistence, emotional stability, initiative, and social skills. Also considered was ability to adjust to the specific requirements of life in the armed forces (loss of personal freedom). Specific traits screened out were difficulty accepting authority, violent or aggressive behavior, psychopathology, and antisocial tendencies.

The CORE Districts teacher ratings were only for the self-management and social awareness scales, presumably because self-efficacy and growth mindset are largely unobservable. There were nine self-management questions and eight social awareness questions. The teacher questions were in some cases nearly identical to the self-assessment versions (student self-assessment: “I remembered and followed directions” versus teacher rating: “remembered and followed directions”), but in some cases there were small discrepancies (student self-assessment: “I was polite to adults and peers” versus teacher rating: “got along with others”). The response categories for the two scales were the same and were the same for teachers and students (“almost never,” “once in a while,” “sometimes,” “often,” “almost all the time”).

Others’ ratings have several conceptual advantages over self-ratings. An external other can place an observed target (a student) in a distribution of other observed targets (other students), whereas a self-rating is subject to biases discussed in the previous section (e.g., social desirability). Also, two or more independent raters can rate a target, whereas only one self exists (there can be different imagined selves, as in faking experiments).

Analysis, Scoring, Scaling, and Reliability

Almost all analysis, scoring, and scaling of ratings that appear in the literature is based on simple sum scoring across raters (R_1 , R_2) and classical test theory for evaluating ratings. Often, a statistic to measure rater agreement is computed, such as percent agreement, or Cohen’s (1960) kappa, which adjusts for agreement due to chance. This can be generalized to the situation with multiple categories (as with Likert scales), where closeness is credited using the weighted kappa statistic (Cohen, 1968), and with multiple raters (Conger, 1980). Although these methods remain popular, Gwet’s (2014) AC1 and AC2 statistics may be useful alternatives in some cases (Keener, 2020).

Generalizability theory (Brennan, 2001; Cronbach et al., 1972; see also Lee & Harris, this volume) can be used for analysis of ratings data. Generalizability theory is an extension of classical test theory in which measurement error is not unitary but is partitioned into sources such as multiple items, occasions, raters, or other factors. A generalizability theory analysis was conducted on the Personal Potential Index by McCaffrey et al.

(2018). They found high correlations among the six scales ($r = .67$ to $r = .90$), consistent with a halo effect (Thorndike, 1920). They found a large rater effect, larger than the effect for persons being rated. This is consistent with research (Baxter et al., 1981) finding more similarity between two ratees rated by the same rater than between two rated by different raters. Consequently, McCaffrey et al. (2018) estimated that 10 raters or possibly more might be needed to obtain a score that had the same level of reliability as commonly used admissions assessments. The authors also point out that there can be response style effects operating on evaluators, as there are on self-raters, including severity and leniency tendencies. These factors (halo, lack of rater agreement, rater response biases) likely operate in all rating situations but are only apparent when ratings are quantified.

IRT approaches can evaluate raters, most notably with the Rasch-based Facets software (Linacre & Wright, 2002), which has similar purposes as a generalizability theory analysis. Facets is designed to analyze data from multiple items and raters and estimates rater leniency-severity effects. To our knowledge, Facets has primarily been applied to ratings of cognitive tasks (e.g., writing), rather than to Likert-style ratings of noncognitive competencies.

Validity

EVIDENCE BASED ON CONTENT The content analysis case for ratings by others is essentially the same as that for self-ratings—ratings are straightforward statements expressing the rater's belief about the target based on observations. Others' ratings better predict outcomes than self-ratings with traits high in evaluativeness, such as intellect (Vazire, 2010). The key challenges to self-ratings, calibration and faking, are generally less applicable to observer ratings. An observer can compare the target to others without self-serving bias, increasing calibration, and the observer typically has minimal incentives to fake (there may be special circumstances where this is not true, such as the professor who takes pride in their students' accomplishments). Leniency severity and halo bias exist. Also, calibration is not guaranteed (McCaffrey et al., 2018). Some not-easily-observable traits are known only by the self (Vazire, 2010).

EVIDENCE BASED ON CORRELATIONS WITH EXTERNAL VARIABLES Several meta-analyses have evaluated others' ratings for predicting school (Connelly & Ones, 2010; Poropat, 2014) and workforce outcomes (Connelly & Ones, 2010; Oh et al., 2011). All have shown that ratings by others have higher correlations with outcomes than do self-ratings. Poropat (2014) examined Big Five factors' prediction of GPA. Targets ranged in age, but were mostly college students. The Big Five was measured by various instruments under various design conditions (one versus multiple raters; teacher vs. peer vs. spouse ratings). The main finding was that the correlations with performance given by others' ratings were higher than those given by self-reports for all of the Big Five factors (other rating $\rho = .38, .28, .18, .10, .05$ versus self-rating $\rho = .22, .09, .00, .06, -.02$ for Conscientiousness, Openness, Emotional Stability, Agreeableness, and Extraversion, respectively; Openness correlations go down substantially

when cognitive ability is controlled, but the others do not change). Poropat (2014) claimed that the magnitude of these correlations puts them among the largest effect sizes in education considering Hattie's (2009) meta-analysis of effect sizes in education. Feng et al. (2022) similarly found that teacher reports were more reliable than children's self-reports and more predictive than self-reports of school outcomes controlling for cognitive ability. These studies are generally low-stakes applications, in which ratings, by teacher, guardian, or self, are for school monitoring or program evaluation. McAbee and Connelly (2016) provided a framework for understanding discrepancies between rating sources.

Connelley and Ones (2010) also included school outcomes in their meta-analysis of mostly workplace outcomes. They found that simple correlations between self- and others' ratings of outcomes were similar, but others' ratings were substantially greater than and incremental to self-ratings in predicting outcomes when unreliability was corrected for. In addition, they conducted a meta-analysis on interrater agreement and found, like McCaffrey et al. (2018), that many raters, up to 10, would be needed to get reasonable interrater reliability; at the very least, they recommended having more than 1 rater.

Oh et al.'s (2011) meta-analysis focused on workplace outcomes. They found predictions comparable to the other meta-analyses. The true-score correlations between predictors and outcomes with other reports were $\rho = .37, .26, .21, .31, .27$, and for self-reports they were $\rho = .22, .05, .14, .10, .09$, for Conscientiousness, Openness, Emotional Stability, Agreeableness, and Extraversion, respectively. Other report correlations were like Poropat's (2014) estimates, except for the latter two (Agreeableness and Extraversion), which were higher in Oh et al. (2011) (studies did not overlap because Poropat, 2014, used educational outcomes, whereas Oh et al., 2012, used workforce outcomes). Oh et al. (2012) showed that multiple raters improved prediction (e.g., for Conscientiousness, $\rho = .32$ and $.41$ for one and three raters, respectively); however, even correlations with outcomes based on single raters were substantially higher than those based on self-ratings. Oh et al. (2012) also conducted regression analyses to show that others' ratings added incremental R^2 prediction to self-ratings (on average, $\Delta R^2 = .048$) but that the reverse was not true (on average, $\Delta R^2 = .005$). An earlier meta-analysis (Harris & Schaubroeck, 1988) estimated correlations of performance ratings between self-supervisor ($\rho = .35$), self-peer ($\rho = .36$), and peer-supervisor ($\rho = .62$), indicating the self is the outlier.

Two other studies from the economics literature similarly reported high correlations with outcomes based on others' ratings. The Swedish enlistment study (Lindqvist & Vestman, 2011) examined earnings, employment, and chronic unemployment 20 years after an overall noncognitive rating by one clinical psychologist was collected from 18-year-old males (the rating factors are discussed in a previous section). They found that the psychologist's noncognitive rating was a stronger predictor of outcomes than cognitive ability, particularly for the outcome of chronic unemployment, where it was a stronger predictor than cognitive scores by a factor of 5.

The National Educational Longitudinal Study of 1988 teacher ratings study (Segal, 2013) examined earnings 20 years after two eighth-grade teachers' ratings of student misbehavior (dummy variable: 1 if either teacher rated "yes" to any of the items: *rarely completes homework, is frequently absent, is frequently tardy, is consistently inattentive in class, and is frequently disruptive*; 0 otherwise). She found that after controlling for test scores, eighth-grade misbehavior predicted earnings, and after controlling for educational attainment, it predicted earnings at all educational levels, whereas achievement predicted earnings only for males with postsecondary degrees.

A question is, How much do others' ratings correlate with self-ratings? West et al. (2018) presented correlations between teacher and student self-ratings of $r = .41, .38$, and $.47$ for elementary, middle, and high school students, respectively, for self-management and $r = .22, .21$, and $.26$ for social awareness (teacher ratings were averaged when there was more than one teacher). However, correlations between teacher ratings on the two scales were considerably higher, $r = .85, .82, .85$, for elementary, middle, and high school teachers, indicating a considerable halo effect! Connelly and Ones (2011) also found that self-other agreement was at least moderately high. The mean observed self-other correlations were $\bar{r} = .37, .34, .34, .29$, and $.41$, for Conscientiousness, Openness, Emotional Stability, Agreeableness, and Extraversion, respectively, boosted substantially when correcting for unreliability. West et al.'s (2018) self-management and social awareness are similar to Connelly and Ones's (2011) Conscientiousness and Agreeableness, respectively, and then the correspondence in findings is much clearer. Also, Connelly and Ones (2011) found that the most accurate others' ratings came from friends and family (they did not examine teachers as a separate category); but there were some traits, such as Extraversion, for which strangers' ratings were as accurate as ratings from those who had known the target longer.

Fairness

The use of differential item functioning and measurement invariance approaches for analyzing ratings data is extremely rare, partly reflecting the rarity of ratings data for noncognitive characteristics generally. Also, response style effects and social desirability could undoubtedly be found in ratings data, but they have not been systematically investigated. Two other rating biases have been examined. One is the halo effect (Thorndike, 1920), the lack of differentiation in ratings across constructs. A halo effect was observed in the results of West et al. (2018), as the extremely high intercorrelations among ratings on the four CORE Districts variables (all $r > .80$). Similarly, McCaffrey et al. (2018) showed very high correlations among the six Personal Potential Index ratings (median $r = .81$). The other bias is rater leniency versus severity, which is like acquiescence response style in self-ratings. We are not aware of a body of literature that has examined this phenomenon in noncognitive ratings, although it is well studied and documented in ratings of cognitive test performance (Linacre & Wright, 2002).

In summary, others' ratings likely overcome some problems with self-ratings, most notably the reduction in social desirability, faking, response style, and calibration

biases. This may be what is responsible for findings of increased prediction of outcomes compared to self-ratings, which was found in several meta-analyses of both school and workforce outcomes. However, others' ratings introduce some additional problems, particularly halo, which results in a lack of differentiation between constructs, and the low level of agreement between raters. A common recommendation is to include others' ratings where possible, particularly more than one rater, with an awareness of their limitations.

Anchoring Methods

Anchoring methods refer to a set of techniques for increasing rating scale comparability across targets using scale anchors. These methods are intended not to mitigate or adjust for faking, but to increase interpretability of responses, particularly in low-stakes assessments. A scale anchor is a concrete behavioral descriptor or vignette, which may be more resistant to response biases than response category labels like "agree" or "often." Examples of anchoring methods are anchoring vignettes (AVs; King & Wand, 2007), behaviorally anchored rating scales (BARS; Kell et al., 2017; Klieger et al., 2018), behavioral summary scales (BSS; Borman, 1979), Rasch/Guttman scenario scales (Ludlow et al., 2020), and perhaps single-item measures of personality, bipolar single-item scales with richer descriptors (Woods & Hampson, 2005), which could have been included here, but we do not discuss them in detail. In principle, all of these can be used as self or other ratings, although AVs and single-item measures of personality are typically used as self-ratings and BARS, BSS, and Rasch/Guttman scenario scales are typically others' ratings.

Anchoring Vignettes

AVs supplement self-rating scale measures with additional vignettes that describe one or more hypothetical persons—the respondent's task is to rate vignettes the same way they rate themselves (on the same rating scale, with the same stem). With more than one vignette, the vignettes are designed to be at different locations on the scale (e.g., a high and low location). Assuming vignettes are interpreted the same way by all respondents (vignette equivalency assumption) and that the rating standards for self and vignettes are the same (response consistency assumption), self-ratings can be interpreted in relation to the vignette ratings to create a new anchored self-rating scale. Consider a case with one vignette ($J = 1$) describing a hypothetical person, X:

X sometimes arrives late to class; usually, but not always completes their homework; and sometimes procrastinates on assignments. How much do you agree that X is hardworking? (strongly disagree, disagree, agree, strongly agree).

The respondent is also asked to rate themselves on the same item:

How much do you agree that you are hardworking? (strongly disagree, disagree, agree, strongly agree).

The two responses enable transforming the Likert self-rating to a new relative (to the vignette) rating called C_i , for each respondent i . Given an item and the self- and vignette rating on that item, the respondent might rate themselves higher, lower, or at the same level as they rated the vignette; thus, the new scale C_i is a three-category scale. With two vignettes ($J = 2$), there are more possibilities (rate self higher, the same, or lower than the high-location vignette and higher, the same, or lower than the low-location vignette), and with three vignettes, still more (the number of categories in C is $2J + 1$). Response ties (rating the vignettes the same) and misorderings (rating the lower of two vignettes higher than the higher vignette) reduce the number of transformed categories (e.g., higher than both, lower than both, or neither), but do not entirely invalidate the nonparametric transformation rule logic.

SCORING AVs can be scored in two ways. A nonparametric approach transforms self-ratings to a new relative-to-anchor scale, as described in the previous paragraph. Some self-rating responses cannot be treated in a straightforward way because of ties or misorderings. Vignettes are written to be at a particular location (e.g., high and low), but they can be moved after the fact based on empirical findings as long as they are ordered the same for all respondents. Self-rating responses under these conditions can be treated as missing or by various assignment rules, which can be specified (Wand et al., 2016).

Parametric AV scoring uses ancillary variables such as country, gender, and race/ethnicity in addition to self- and vignette ratings to estimate scores on the latent factor, the unobserved perceived level. The parametric approach has several advantages over the nonparametric approach: Not all respondents have to rate all the vignettes, and misorderings are assumed to result from random error. The R package (R Core Team) “anchors” (Wand et al., 2011) handles both nonparametric and parametric scoring and includes many options and diagnostics.

RELIABILITY Internal consistency reliability estimation with AVs is not straightforward. Von Davier et al. (2018) showed that Cronbach’s alpha is not an appropriate measure of internal consistency for AVs, particularly when ties and misorderings occur, and that scale intercorrelations will increase when corrected by the same set of vignettes. However, test–retest correlations would still be useful (with the same or different sets of vignettes), as would a generalizability theory (variance component) analysis using vignettes as a random factor (e.g., using two sets of vignettes for the same construct; on one or multiple occasions). To our knowledge, such research has not yet been reported.

VALIDITY AND FAIRNESS The justification for AVs is that they adjust responses for response style biases and reference group effects with information from responses to the vignettes. This assertion depends on the vignette equivalency (different respondents see the vignettes the same way) and response consistency (respondents apply the same standards in rating themselves and the vignettes) assumptions. These can be vio-

lated (Kapteyn et al., 2011), and methods for evaluating these assumptions are needed. Despite this, a major finding with AVs is that they have been found to address the “attitude–achievement paradox” and increase country comparability on certain noncognitive scales (Kyllonen & Bertling, 2014). The attitude–achievement paradox is the common finding of a positive attitude–achievement correlation within country (e.g., between a personality factor and achievement), with a simultaneous negative correlation at the country level (e.g., the countries with high average personality scores will have low average achievement scores). This is a recurring finding in large-scale international assessments for many (but not all) scales, particularly ones that are more abstract, such as personality scales. Kyllonen and Bertling (2014) and He et al. (2017) showed on PISA 2012 that AV-adjusted scores on two scales (teacher support and classroom management) had higher correlations with mathematics achievement than unadjusted scores. He et al. (2017) also found that Asian cultures topped the ranking on teacher support after adjustment, a finding more in line with the literature. AV approaches have now been tried in numerous studies, with mixed results (Möttus et al., 2012; Primi et al., 2016). It is a complex method and there are many issues to consider in vignette and study design, but the findings from PISA 2012 seem promising and worth pursuing.

Rasch/Guttman Scenario Scales

Rasch/Guttman Scenario Scales is a method developed by Ludlow and colleagues (Ludlow et al., 2019, 2020), which also use vignettes, called scenarios. The respondent is presented a series of scenarios and asked to rate themselves (on a five-category scale going from strongly higher to strongly lower) relative to the character described in the scenarios; the scenarios describe people at different locations on the construct. Scenarios are developed using Guttman’s facet theory and mapping sentence approach (Guttman & Levy, 1982). This differs from AVs in that with AVs, the respondent rates self and vignette independently. Here, one compares oneself directly with the vignette (scenario). Constructs are defined hierarchically, so goal orientation might be a higher order construct, with clarity, effort, and frequency as lower order facets (analogous to the facets–factor relationship in the five-factor model; John & Srivastava, 1999). The Sentence Map contains sentences with location fillers representing different construct levels. Ludlow et al. (2020; Table 1b) provided an example:

clarity: “<name> has a {not at all clear| somewhat clear| extremely clear} vision of how to make goals a reality”

effort: “he/she places {almost no effort |some effort |a tremendous amount of effort} toward making long term aims a reality”

frequency: “he/she {almost never |sometimes |almost all the time} spends time in the day engaged in activities that bring him/her closer to his/her goals”

Because there are three mapping sentences with three locations each, there are m^n (m levels, n sentences) possible sentence combinations (e.g., LLL to HHH), but only enough need to be written (Ludlow et al., 2020, wrote 7 of the 27) to ensure spread

across construct levels. The sentences are transformed to scenarios through editing for flow and naturalness; some facets might be combined in a single sentence. Ludlow et al. (2020) (Study 2) presents six goal orientation scenarios: the highest (HHH) is “Bill knows how to make his goals a reality and constantly exerts tremendous effort toward accomplishing them”; the next highest (HHM) is “Jill is sure she knows how to achieve her goals. She is actively engaged in efforts to make her goals a reality and wishes she could be even more engaged.” The second to lowest level scenario (LML) is “Jim is unclear on how to make his plans a reality. Although he is rarely engaged in activities that move him closer to his goals, he does put some effort into working toward them.” Pilot testing can result in rewriting or swapping out scenarios (e.g., an LLH for an LHL).

SCORING AND RELIABILITY Ludlow et al. (2019, 2020) used the Rasch rating scale model for scaling and scoring. The analysis provides item and person locations on the variable maps, which can be examined to ensure good coverage on the construct continuum; revisions to items or to the selection of items can be made to ensure good coverage, as Ludlow et al. (2020) demonstrated. They also showed good model fit for their measure.

VALIDITY AND FAIRNESS The justification for using this assessment to draw inferences about an individual’s trait level follows the basic logic of other self-ratings measures—an individual is making claims about themselves. The claim is bolstered compared to simple self-ratings in that the self-description is in relation to a hypothetical other, although here, the claim is perhaps more direct than AVs; respondents are not rating themselves, then a vignette; respondents rate themselves directly compared to the vignette. This would seem to make the response consistency assumption more likely to be satisfied. A finding of good model fit supports the justification for its use. Poor model fit would indicate potential inconsistencies in the judgments being made by the respondent. Like AVs, scenario scales should reduce response style biases and reference group effects, although in Ludlow et al.’s (2019, 2020) application the rating scale (strongly higher to strongly lower) could allow response style effects.

The method is relatively recent, and little work has been done thus far on group differences or measurement invariance. However, measurement invariance approaches for Rasch measurement are available (Millsap, 2011; Wu & Estabrook, 2016).

BARS/BSS

BARS (Kell et al., 2017; Klieger et al., 2018; Oswald et al., 2004; Shultz & Zedeck, 2011) are discrete category rating scales (e.g., 0 to 5) with behavioral descriptions based on critical incidents appearing at various points along the rating scale continuum. BSS are similar, but represent composites of several incidents, resulting in more abstract behavioral descriptions. The behavioral descriptions, or anchors, help raters calibrate their ratings. The rater can locate the target relative to the anchors by essentially doing mental paired comparisons (e.g., “*x* is higher than Anchor 1,

but not as high as Anchor 2). Computer-adaptive versions of BARS, called CARS, have also been developed and evaluated with some success (Darr et al., 2017). A related alternative, the relative percentile method (Goffin et al., 2009), asks raters to rate employees against other employees, so that employees themselves serve as scale anchors.

BARS are developed through the initial collection of critical incidents, settings in which the construct is expressed through behavior. For example, Klieger et al. (2018) asked subject matter experts to recall examples of “highly ineffective, just good enough, and highly effective behavior” on job domains such as initiative/work ethic and flexibility/resilience. Subject matter experts are asked to describe the situation, the behavior, and the outcome associated with the critical incident and sometimes an interpretation (Hall et al., 1995). Incidents are sorted by dimensions or themes and then edited into behavioral statements such as “prior to transitioning to a new department, reaches out to relevant coworkers to inquire about strategies for a new position” (Klieger et al., 2018). Incidents are then rated on a six-point effectiveness scale resulting in a BARS. This general method was applied to lawyering (24 job domains; Shultz & Zedeck, 2011).

Scoring and Reliability

The fielded BARS provide ordered categorical data, typically treated in classical fashion, using sum scores and classical reliability theory. The method naturally lends itself to a generalizability theory analysis, with raters, items, settings, and occasions potentially serving as design facets over which to evaluate generalizability (Medvedev et al., 2019; Ohland et al., 2012). To our knowledge, except for Darr et al. (2017), few efforts have developed IRT models for the BARS development or application cycle.

Validity and Fairness

As an outcome measure, BARS do not have the correlational evidence that typically comes with predictor measures. Instead, for BARS, like licensure tests, validity evidence tends to be associated with the process by which the assessment is developed and based on content matches between the assessment items and the intended constructs (i.e., evidence based on test content). The BARS development process (Kell et al., 2017; Klieger et al., 2018)—the identification of the construct(s) based on job analyses, the collection of critical incidents, effectiveness evaluations, and content evaluations of items—is rigorous and designed to ensure validity evidence. Debnath et al. (2015) argued that BARS remain popular appraisal instruments because of their advantages over instruments that focus on traits (because traits are relatively immutable and subject to halo effects), results (because hard criteria are unavailable for many jobs), and behavior (such as checklists; they are too rigid and leave out evaluator judgment).

Neither differential item functioning nor measurement invariance analyses tends to be performed on BARS. However, self–other similarity bias exists for ratings. Supervisor–subordinate racial differences are associated with lower ratings for both Black and

White subordinates (Elvira & Town, 2002) and sometimes gender similarity effects are found, although not universally (Stone et al., 2016).

Forced-Choice and Ranking Methods

Forced-choice and ranking methods refer to tasks in which respondents are asked to choose from, rank, or express preferences between two or more statements. Ranking is an alternative response format to ratings. A forced-choice example would be, “Choose the statement more like you: ‘I enjoy working with others,’ or ‘I am a hard worker.’” A ranking example would be, “Rank the following 1 to 4 for how they describe you (1 = *most like you*; 4 = *least like you*): ‘I enjoy working with others,’ ‘I am a hard worker,’ ‘I am calm even in stressful situations,’ ‘I enjoy speculating about the origins of the universe.’”

Design Issues

UNIDIMENSIONAL VERSUS MULTIDIMENSIONAL FORCED CHOICE Forced-choice items may be unidimensional or multidimensional. Forced-choice statements on a unidimensional item are drawn from the same dimension but vary in their location: “I am a hard worker” versus “I do enough to get by.” The Myers–Briggs Type Indicator (Form M) uses 93 *unidimensional* forced-choice items (statement pairs), each asking individuals whether they are better described by positive or negative pole descriptors for the four bipolar factors they measure (extravert–introvert, sensing–intuition, thinking–feeling, judging–perceiving; roughly 23 pairs per factor). SHL’s Operational Personality Questionnaire (OPQ32r; SHL Group, 1999; Brown & Bartram, 2009) uses *multi-dimensional* forced-choice items (three-statement triads) to measure 32 dimensions, with items such as “Please choose one MOST true and one LEAST true statement: ‘I enjoy the companionship of others,’ ‘I try out new activities,’ ‘I look to the future.’”

BLOCK SIZE Block size refers to the number of statements ranked, typically either two, three, or four, with exceptions (Dueber et al., 2019, used 12). SHL’s two OPQ versions differ by having either three (104 triads; OPQ32r) or four (104 tetrads) statements (OPQ32i) per block (Brown & Bartram, 2013; the OPQ32r’s triads are the same as the OPQ32i tetrads with one statement removed per block). ETS’s FACETS (12 to 15 dimensions, 104–120 pairs; Naemi et al., 2014), DoD’s TAPAS (22 dimensions; Drasgow et al., 2012), and the Myers–Briggs Type Indicator Form M all use pairs.

RESPONSE FORMAT Common response formats are PICK (choose the option “most like me”), MOLE (choose the option most like me and the one least like me), and RANK (rank options 1 to n) (Hontangas et al., 2015). Some formats allow a graded preference, such as strongly prefer i , slightly prefer i , prefer neither i nor k , slightly prefer k , or strongly prefer k (Gallup’s Clifton StrengthsFinder 2.0, Asplund et al., 2014; 177 pairs to measure 34 dimensions), which can be modeled using IRT (Brown & Maydeu-Olivares, 2018). Another format is compositional (Aicheson, 1982; Brown,

2016), in which respondents express choices by dividing (say) 100 points across a set of four descriptors, such as assigning 50 to dependable, 20 to curious, 20 to modest, and 10 to calm; or selecting 10 descriptors from a pool of 30.

RESPONSE PROCESS (DOMINANCE VERSUS UNFOLDING) For a dominance response process, the higher a respondent is on a trait, the more likely they will endorse the trait (e.g., respond “strongly agree” or “almost all the time”). This is the typical assumption in personality assessments; it enables data to be fit by CTT models and the same IRT models used in cognitive testing, where the higher the ability, the more likely one is to get the item correct. An unfolding response process involves an ideal point in which a respondent is most likely to endorse an item whose location is the same as the respondent’s latent trait position and increasingly less likely to endorse an item farther away from their trait location, allowing rejection “from above” or “from below” (Chernyshenko, 2003; J. S. Roberts et al., 2000). An introvert would reject the item “I enjoy talking to a friend in a quiet cafeteria,” preferring no social interaction, and an extravert might reject the same item, preferring a more intense social experience. Not common in personality, ideal point models are common in attitude measurement, allowing disagreement with a middle-of-the-road policy from the ideological left or right. The appropriateness of unfolding for personality measurement is open to debate (Drasgow et al., 2010; Oswald & Schell, 2010). Nevertheless, using simulated and real data, Fu et al. (2022) found support for the theoretical claim but found mixed evidence with real data. They recommended fitting different models to different statements.

DATA TYPE Data yielded by forced-choice assessments can be either ipsative, quasi-ipsative, or normative (Salgado et al., 2015). Ipsative data produced by a forced-choice measure refers to a measurement scale within a single person, not comparable to other people (Cattell, 1944). Clemans (1966), Hicks (1970), and Gleser (1972) documented the qualities and limitations of this kind of data type, such as constraints on the average correlation among scales ($\bar{r}$ is bounded by $-1/(d-1)$ and $(d-4)/d$, where d is the number of dimensions) and average correlation of scales with outcome ($\bar{r}_{xy} = 0$), and its consequent unsuitability for factor analysis and internal consistency reliability computation. Normative data refer to a measurement comparable across people, as produced by a Likert scale (or right/wrong data from a cognitive test). Such data are amenable to factor analysis and internal consistency reliability measurement. Quasi-ipsative data refer to data produced by a forced-choice procedure, but with properties not as limited as ipsative data and closer to normative data-like qualities. In the literature there are several approaches for generating quasi-ipsative data. One is using forced-choice methods scoring only a subset of the dimensions. As d increases, the limitations of ipsative data are less restrictive. A variant is the use of forced-choice methods with phantom dimensions, where the phantom (unscored) dimension is represented by a set of items that are not related to the targeted (scored) dimensions (Horn, 1971; Salgado & Lado, 2018). Another approach is the IRT methods developed to overcome the limitations of ipsative data (Brown & Maydeu-Olivares, 2013; Stark et al., 2005).

Modeling, Scoring, and Scaling

UNIDIMENSIONAL APPROACH Unidimensional pairwise preference task data are normative data and can be analyzed by classical test theory and sum score approaches and by IRT models for binary and polytomous data (Rasch [von Davier, 2016], Rasch rating scale [Andrich, 2016], Rasch partial credit [Masters, 2016], two-parameter logistic, 2PL [Birnbaum, 1968], generalized partial credit [Muraki & Muraki, 2016], and the graded response models [Samejima, 2016]). Multidimensional items with unscored dimensions (phantom dimensions) can also be analyzed using unidimensional methods if targeted dimension statements are only paired with unscored dimension statements (Horn, 1971; Salgado & Lado, 2018). Such assessments yield binary or polytomous data that reflect preference (or degree of preference) for the target dimension only (i.e., not also for the unscored dimension). These methods are easy to implement, although not as efficient, perhaps, as multidimensional methods.

UNFOLDING APPROACH The unfolding approach proposed by Stark et al. (2005) involves two steps, a pretesting calibration step with Likert rating responses, followed by the test administration with pairs. The data from the Likert rating pretesting are calibrated based on the generalized graded unfolding model (GGUM; J. S. Roberts et al., 2000). Pairs are assembled so that the two statements are from different dimensions (mostly) and are matched on social desirability. Social desirability can be based simply on the Likert statement mean or principal component score after negative keyed items are reflected (Bäckströmm & Björklund, 2013; Kuncel & Tellegen, 2009) or from a separate data collection with “fake good” instructions (Pavlov et al., 2021). Test administration provides binary data on the pairs (i.e., selecting statement i over k or not). The binary choice data is analyzed with the multi-unidimensional pairwise preference (MUPP) model. Stark et al. (2005) argued that separating the Likert rating calibration step from the analysis of pairs has advantages in simplifying computation and in having a calibrated statement pool that can be used to create adaptive tests.

However, the Stark et al. (2005) method relies on the assumption that the GGUM calibrations are invariant across the Likert and forced-choice format, even though the two administrations would typically involve different samples in different contexts perhaps even years apart; and the Likert statement stands by itself, whereas the forced-choice statement has a context of other statements in the item block. Also, Stark et al.’s approach does not lend itself to item analysis based on the blocks. So, P. Lee et al. (2019) proposed GGUM-RANK to estimate statement parameters and person parameters directly from the test administration of multidimensional forced-choice blocks without pretesting. It uses a generalization of the GGUM model proposed by Hontangas et al. (2015) in which ordering (e.g., $A > B > C$) is seen as a sequence of steps, selecting A versus B and C, then selecting B versus C. This enables the use of

triads rather than pairs (as in Stark et al., 2005). Hontangas et al. (2015) also showed that ranking methods were superior to other approaches and demonstrated how true scores, expected a posteriori (EAP) estimates, and traditional scores could be obtained and compared. P. Lee et al. (2019) demonstrated their approach in both simulations and with empirical data using Markov chain Monte Carlo (MCMC) estimation with a Metropolis–Hastings within Gibbs (Tierney) algorithm. They seem to have found that the triad format was more efficient than pairs, that statement discrimination within blocks was critical for estimation accuracy, and, most important, that the method performed well in providing convergent and discriminant validity evidence with external measures.

Thurstonian IRT and Other Dominance Approaches

Brown and Maydeu-Olivares (2011) and Maydeu-Olivares and Brown (2010) proposed Thurstonian IRT as a dominance alternative to the unfolding approach, basing it on Thurstone's (1927) law of comparative judgment. The method does not require pretesting and can be applied to forced-choice or ranking data of any size blocks. Response data are converted to $n(n - 1)/2$ binary pairwise preferences for the n statements in a block and analyzed. Brown and Maydeu-Olivares (2012) provided a tutorial on how to estimate the model using a confirmatory factor analysis approach with Mplus (Muthén & Muthén, 2001).

The basic concept is that each statement i elicits a latent utility, t_i (i.e., a degree of *desiredness* or *endorsement-worthiness* to respondents), and statement i is preferred over statement j if $t_i \geq t_j$. Utilities are modeled as $t_i = \mu_i + \lambda_i \eta_a + \varepsilon_i$, where μ_i is the latent utility mean, λ_i is the factor loading of item i on the latent trait η_a , and ε_i is a normally distributed error with mean 0 and variance ψ_i^2 . The latent response variable (i.e., difference in utilities) is modeled as $y_{ij}^* = t_i - t_j = \mu_i - \mu_j + \lambda_i \eta_a - \lambda_j \eta_b + \varepsilon_i - \varepsilon_j$, which involves two latent traits (η_a, η_b), location parameters ($\mu_i - \mu_j$), factor loadings ($\lambda_i - \lambda_j$), and uniqueness parameter ($\psi_i^2 + \psi_j^2$). All these are specified as constraints in fitting a confirmatory factor analysis model in Mplus. Because of the complex error structure and often large number of latent traits, Thurstonian IRT models are typically estimated using limited-information methods.

Variations have been proposed. Wang et al. (2017) argued for the advantages of a one-parameter Rasch ipsative model (the Thurstonian IRT model is a two-parameter $[\mu, \lambda]$ model): It yields a single utility value for each statement, allows for between- and within-individual differentiation, and does not rely on statement blocks requiring mixed location (positive, negative) statements as Thurstonian IRT models do. This is an important issue because it can be a limitation of Thurstonian IRT models for high-stakes use (Bürkner et al., 2019). Morillo et al.'s (2016; Hontangas et al., 2016) MUPP-2PL model uses the MUPP choice model, but the 2PL instead of GGUM for calibration, making it a dominance model. Bunji and Okada's (2019) D-diffusion Thurstonian IRT model incorporates

response time information in the forced-choice item responses to improve model fit and increase the outcomes predictions. Response time information can inform response models (van der Linden, 2007); in personality, the assumption is that fast selection indicates easier option choices, such as stating “agree” to a binary Likert question (Ranger, 2013) or selecting an option in a forced-choice application (Bunji & Okada, 2019).

Reliability

Estimating reliability for unidimensional forced-choice models is straightforward, whether using CTT (e.g., alpha) or IRT (marginal reliability) approaches. Estimating reliability for the Stark et al. (2005) model is not straightforward. Hontangas et al. (2015) used a simulation study with known true scores and correlated them with EAP and traditional scores to show that EAP scores were more reliable. However, they did not address how reliability could be computed without knowing true scores. Seybert and Becker (2019) computed test–retest reliabilities, finding them to be only moderate and slightly lower than Likert scale versions of items. However, with rating scale test–retest reliability approaches, what is being measured is a mix of trait stability and stability of construct-irrelevant factors such as response style. Forced-choice methods are intended to reduce the proportion of response style variance and therefore should have lower test–retest factor correlations.

Estimating reliability with multidimensional forced-choice measures is discussed by Brown and Croudace (2015). They introduce the marginal reliability concept which can be estimated as theoretical or empirical reliability. Theoretical reliability involves averaging the model-based squared standard error for all trait values in the theoretical distribution, which requires multidimensional integration. Empirical reliability is preferred with many dimensions. This involves averaging squared standard errors of estimated trait scores in the sample, depending on the estimator used. For EAP, this is the posterior likelihood variance; for Maximum Likelihood (ML), the Fisher information inverse; for maximum a posteriori (MAP), the posterior information inverse. Brown and Maydeu-Olivares (2018) provided the solution for computing reliability from matrices produced by Mplus and provide R code for computing item information, standard errors, and reliability in the online supplement to that article. Mplus beginning in version 8.1 provides standard errors for MAP scores for IRT models of any dimensionality, which can be used to compute empirical reliability.

Validity and Fairness

The purpose of forced-choice and ranking approaches is to minimize the effects of response distortion but without altering the construct score. There are two situations in which this is important: high-stakes assessment, in which socially desirable responding or faking occurs; and for comparing individuals or groups with different response styles.

Faking effects can be examined experimentally: A treated group is asked to “fake good” to increase prospects for getting the job. Score inflation, the difference between scores

for the control and fake good groups, is less with forced choice compared to Likert-style measures (Cao, 2016; Cao & Drasgow, 2019), particularly when statements within a block are balanced in social desirability and normative approaches (e.g., IRT as discussed here) used for scoring. Bartram's (2007) meta-analysis showed that correlations with external measures (manager competency ratings) were higher with a forced-choice ($r = .38$) compared to a rating scale format ($r = .25$), in a study where managers used both. (With $N = 1,460$ and $r = .50$ across formats, this is a significant difference.)

A meta-analysis by Salgado and Tauriz (2014) showed that the multidimensional forced-choice format had substantially higher correlations with job performance and academic outcomes than the unidimensional forced-choice format. For Conscientiousness, rho (correlation between the predictor and outcomes corrected for predictor and criterion reliability and indirect range restriction in the predictor) was .40 for quasi-ipsative measurement (which includes both IRT and non-IRT multidimensional forced-choice assessments) but only .16 for normative forced choice (i.e., unidimensional). And this value, .40, is larger than any other meta-analyses of these variables, which tend to be dominated by Likert-scale measures.

A caveat to these positive findings is that cognitive ability may moderate these relationships such that brighter individuals may be more able to fake (Christiansen et al., 2005). However, Kyllonen et al. (2020) demonstrated incremental prediction beyond the GMAT/GRE and undergraduate GPA in predicting graduate business school grades and leadership activity for a forced-choice assessment administered during the admissions process. The increment in adjusted R -square was approximately .04 to .07 (depending on analysis details).

Forced-choice methods have advantages for evaluating culture/language group differences. Bartram (2013) found that at the individual level forced-choice and rating scale measures agreed moderately, but at the country level, correlations with external economic variables (the United Nation's Human Development Index, the Global Competitive Index) were more sensible with forced-choice measurement: Forced-choice Conscientiousness showed positive correlations with the economic variables, while rating scale Conscientiousness showed negative correlations. Country-level correlations do not have to follow individual-level correlations (ecological fallacy), but the forced-choice finding is in line with expectation and the rating scale finding is puzzling. In PISA 2012, two forced-choice scales (subject matter preference and learning style preference) were administered in a rating scale format in 2003 (same statement content). The rating scale format led to high correlations between dimensions and near-zero correlations with achievement. The forced-choice format led to expected negative correlations with each other (as an ipsative measure), but math preference had a high correlation with math achievement, as one would expect.

The studies cited here support the conclusion that forced choice improves the quality of information elicited with a survey instrument, at least when steps are taken to address the problems created by ipsative measurement. Designing and scoring forced-choice assessments is challenging—these are complex models relying on many assumptions.

And there are many questions remaining on how to improve the methodology. There are also user experience challenges. Respondents often complain about having to choose between two equally attractive (or unattractive) choices, even if test-taker motivation is unaffected (Sass et al., 2020). Still, forced-choice measurement is a promising methodology that ought to be included routinely in survey assessments of noncognitive skills, either as a supplement to or as a replacement for rating scale measures, particularly for high-stakes and cross-cultural assessments.

Situational Judgment Tests

Situational judgment tests (SJTs; also practical intelligence measures; McDaniel & Whetzel, 2005) have been popular assessment methods for organizational recruitment and selection (U.S. Office of Personnel Management, 2018a). This may be because of their high face validity (compared to standardized tests), low administrative costs (compared to interviews), relatively moderate subgroup differences (compared to standardized tests; Oostrom et al., 2015), lower susceptibility to faking (compared to personality tests; Kasten et al., 2018), and incremental outcome prediction beyond cognitive ability and personality (Clevenger et al., 2001; McDaniel et al., 2007). SJTs are also being considered in education for undergraduate (Oswald et al., 2004), business school (Hedlund et al., 2006), medical school (Patterson et al., 2016), and dental school admissions (Buyse & Lievens, 2011). SJTs can in principle be used to measure various skills but are mostly designed to measure interpersonal skills (Christian et al., 2010). The American Association of Medical Colleges is pilot testing SJTs for medical school admissions to measure eight primarily interpersonal competencies including service orientation, social skills, cultural competence, teamwork, and ethical responsibility (Ellison et al., 2024). SJTs are often ideally suited for education, training, and development purposes as well. Cox et al. (2017) presented evidence for advantages of SJTs over traditional training.

There are many kinds of SJTs, varying by intended construct (Chan & Schmitt, 2005; Christian et al., 2010; McDaniel & Whetzel, 2005), length (Crook et al., 2011), textual versus video items (Chan & Schmitt, 1997), instructions (Ployhart & Ehrhart, 2003), and other features (see reviews by Campion et al., 2014; Lievens et al., 2008; Oostrom et al., 2015; and Whetzel & McDaniel, 2009). Here, we focus on the most important considerations.

Ratings Versus Rankings

SJT items comprise a stem (situation description) followed by a set of response options, typically four to eight, but sometimes as few as one (Crook et al., 2011). Respondents can either rate or rank options. The number of rating categories typically ranges from two (e.g., “effective” vs. “ineffective”) to seven or more (e.g., “not at all effective” to “very effective”). Rankings can be full (“rank all options from best to worst”), partial (“choose the best option and choose the worst option”), or single choice (“choose the best option”). Arthur et al. (2014) concluded that ratings were superior to rankings for SJTs based on their higher correlations with personality,

but personality measurement is ratings based and therefore susceptible to spurious associations with ratings-based SJTs. The disadvantages of ratings are discussed in “Self-Report Ratings” and the advantages of rankings over ratings are discussed in “Forced-Choice and Ranking Methods.”

Best-Choice (Knowledge, “Should Do”) Versus Self-Prediction (Behavioral Tendency, “Would Do”) Instructions

Best-choice instructions ask respondents to choose, rank, or rate each option for its effectiveness. Self-prediction instructions ask respondents to choose, rank, or rate options by how they match to what they would do. Best-choice instructions lead to comparatively higher correlations with cognitive ability. Self-prediction instructions lead to comparatively higher correlations with personality (McDaniel et al., 2007). Best-choice instructions are less susceptible to faking than self-prediction instructions (Broadfoot, 2006; Nguyen et al., 2005; Peeters & Lievens, 2005), although responses to what others would do may be even less susceptible to faking (Lievens et al., 2009; Oostrom et al., 2017). Because of their resistance to faking and because knowledge instructions seem to be conceptually more straightforward than self-prediction instructions for eliciting responses, for some applications best-choice instructions may be better suited for SJTs than behavioral tendency instructions from a validity interpretative argument perspective.

Dimensionality and the Constructs Measured by SJTs

SJTs are typically found to be empirically unidimensional, even when constructed to reflect multiple dimensions. Oswald et al. (2004) wrote SJT items reflecting 12 dimensions of college student performance (e.g., leadership, artistic, career, perseverance, ethics), but found a strong general factor accounting for three times the variance of a second factor and only uninterpretable lower order factors. This is common for many constructs in which tests are developed to a framework that specifies several dimensions but a strong general factor accounts for most of the variance among items (Haberman et al., 2009). PISA 2012 specified a number of mathematical content (change and relationships, space and shape, quantity, uncertainty and data) and process (formulating situations, employing concepts, interpreting outcomes) dimensions (OECD, 2013, pp. 28–36), but found little empirical support for their differentiation, instead finding very high latent correlations among process types (all $r \geq .96$) and among content areas (all $r \geq .84$) (OECD, 2014, Table 12.9, p. 231). In such cases, dimensions serve to ensure construct coverage even though empirically they do not identify separate factors. The persistent empirical finding of unidimensionality has prompted discussions of broad factors underlying SJTs. Christian et al. (2010) reported that SJT developers targeted leadership (38% of SJTs), interpersonal skills (13%), personality (10%), teamwork (4%), job knowledge (3%), and heterogeneous composites (33%). However, SJTs might merely reflect broad tacit knowledge and practical intelligence (Chan & Schmitt, 2005; Sternberg & Horvath, 1999) or general domain knowledge (Corstjens

et al., 2017). Responses may alternatively reflect implicit trait policies, beliefs about the effectiveness of responses to situations based on effective trait expression (choosing an agreeable response when the situation calls for Agreeableness) (Motowidlo & Beier, 2010). There have been attempts to address multidimensionality in SJTs through construct explorations (Guenole et al., 2017; Westring et al., 2009). Still, it seems empirically that unidimensionality is found in SJTs even when multidimensionality is intended.

Scoring

Scoring SJTs can be more complex than scoring typical standardized tests: There can be disagreement on the best response to a situation, providing no single correct answer, and response options may vary continuously in appropriateness. SJT scoring approaches have been reviewed focusing on either ranking (Bergman et al., 2006) or rating methods (Weng et al., 2018; Whelpley, 2014). Bergman et al. (2006) discussed empirical keying (based on an outcome measure), theoretical scoring (based on keying options to a theoretical framework), expert scoring (keying to expert judgments), factor scoring, and subgrouping (based on clustering response patterns). Ratings-based scoring methods tend to focus on determining a profile similarity match between a test taker's rating and aggregate expert profile (McDaniel et al., 2011). De Leng et al. (2017) compared 28 ratings-based (profile similarity) measures, varying the reference group (experts versus the test-taking sample), agreement (simple percentage versus consensus), consensus standardization approach (raw/no standardization versus within-person standardization versus rating scale dichotomization), distance metric (absolute versus squared profile distances), and reference group aggregation method (mean, median, mode). Raw consensus, which credits responses by the proportion of the reference group selecting that response (e.g., if 20% of the reference group selects "agree," then respondents who select "agree" are credited .2 score points), led to higher alphas, particularly when the sample was the reference group and their judgments were aggregated using the mean. But Weng et al. (2018) found that raw consensus scoring led to lower correlations with external measures and suggested that extreme responses were problematic and that the value of midrange items was low.

Problems in SJT scoring may partially be attributable to the inherent problems with rating scales. Forced-choice or ranking approaches mitigate these problems and may therefore be better suited for SJTs. Zu and Kyllonen (2020) compared several observed score (including consensus) and IRT scoring methods for scoring forced-choice/ranking SJT methods. They found that consensus methods (using either experts or the sample as the reference group) were the best observed score approaches, but the best overall approach was the NRM with the sample as reference group. Guo et al. (2019) showed that although the NRM is a data-driven method, it produced an invariant scoring key across cohorts. Guo et al. (2016) demonstrated the value of a nonparametric item analysis approach for understanding SJTs, because SJTs often do not have a clear right or wrong answer, and of NRM for scoring.

Reliability

A well-known limitation to SJTs is their low internal consistency reliability (test–retest reliability is higher; Neubauer & Hofer, 2022). Kasten and Freund's (2016) meta-analytic reliability generalization study of SJTs in 271 studies found an average reliability of $\alpha = .61$ (standard deviation, $s = .20$). Factors depressing reliability were high-stakes use, item complexity, high fidelity, fewer items, pick-only response format, and earlier publication dates (i.e., the community is getting better at writing SJTs), but there were no effects for instruction type (knowledge versus behavioral tendency). These findings support the idea that SJTs are typically too short for operational use and that strategies for extracting more information (e.g., pick best and worst) are useful.

Rating measures tend to be more reliable than ranking methods. But reliability of rating methods confounds construct-irrelevant response style variance with construct-relevant trait variance, whereas ranking methods do not. Therefore, this apparent rating advantage cannot be interpreted as providing better measurement.

Validity

There is a strong argument for the validity evidence based on content supporting inferences drawn from SJTs. The development methodology typically involves a careful analysis of the performance situation SJTs are intended to reflect or predict, using critical incidents (see the section on behaviorally anchored rating scales, which uses the same analysis) or related methods to define the intended construct (Sternberg et al., 2000). The method itself asks respondents either what they would do or what the best response to the situation would be; either question should elicit useful respondent information allowing for a straightforward interpretation. The option ratings version of SJTs has the same conceptual problems as rating scales have generally (see the section on rating scales), and therefore the option ranking approaches have interpretive advantages from a validity standpoint.

There are several challenges to the interpretation of SJT responses in a straightforward manner. One is that SJTs ask respondents what they would or should do, but both of those are distinct from an actual response in a real-world situation. Ployhart and Ehrhart (2003) found relatively low correlations between responses in would-do and should-do formats. However, at least with best-choice (knowledge) instructions it could be argued that knowledge is a prerequisite to behavior. With behavioral tendency (would-do) instructions the matter is more muddled because some participants might respond as if to knowledge instructions (should-do) for fear of admitting to poor judgment.

Another challenge relates to a long-standing debate in the literature on what SJTs measure. Oswald et al. (2004) developed SJT items based on 12 college performance dimensions (e.g., leadership, artistic). Interrater agreement on item dimension assignment supported the distinctiveness of 12 dimensions (items with less than 75% agreement were removed), but factor analysis of response data did not, resulting in the adoption of a single score from the measure (Schmitt et al., 2009). Evidence for a general SJT factor is a common occurrence. D. J. R. Jackson et al. (2016) conducted a generalizability theory analysis on three different SJTs and over 10,000 job candidates

finding candidate (person) main effects, with little variation due to dimensions and situations, suggesting a general judgment factor across job situations. For many SJTs the situation descriptions themselves may not be central to what construct is being measured (Schaepers et al., 2020).

A general judgment factor is not the same as the general factor in cognitive tests. SJTs typically add to the prediction given by cognitive tests, as well as to the prediction given by personality measures. McDaniel et al.'s (2001) meta-analysis found a correlation of $\rho = .34$ between SJTs and job performance and $\rho = .46$ between SJTs and cognitive ability; SJTs add incrementally over cognitive ability in predicting outcomes (O'Connell et al., 2007). In education, several studies (Hedlund et al., 2006; Oswald et al., 2004; Schmitt et al., 2009) found that the general judgment factor added to other variables in predicting college outcomes, indicating SJTs are capturing something other cognitive variables are not.

Fairness

A consistent SJT finding is smaller subgroup differences compared to cognitive tests (Arthur et al., 2014; Clevenger et al., 2001; Oostrom et al., 2015; Oswald et al., 2004). There have been few measurement invariance studies of situational judgment, but Prasad (2017) found evidence that interests and socioeconomic status might be related to differential item functioning. For SJTs especially, one might expect culture differences. However, Prasad et al. (2017) found evidence for differences between Chinese versus U.S. respondents on some scales from a college performance SJT, but no differences overall.

Performance Measures of Noncognitive Skills

The assessments reviewed thus far can be called *descriptive assessments*, ones based on how respondents describe themselves (or how others describe them) or what they say they would or should do in a situation. Descriptive assessment approaches are different from cognitive tests in which respondents are asked to perform—to solve problems, recall information, or make a decision—which can be called *performance tests*. There are descriptive cognitive assessments. Mathematics self-efficacy items (“How confident do you feel about having to do the following mathematics tasks? ‘solving an equation like $3x + 5 = 17$.’ Very confident, Confident, Not very confident, Not at all confident”) and mathematics self-concept items (“I learn mathematics quickly. Strongly disagree, disagree, agree, strongly agree”; PISA 2012) are descriptive cognitive assessments. Data from performance tests compared to descriptive assessments undoubtedly inspire more confidence from stakeholders in assertions about student proficiency. This difference between descriptive assessments and performance tests might even account for the slow acceptance of noncognitive assessments despite demand for noncognitive skills. An important question is whether it is possible to make a performance-based noncognitive test.

Performance measures of noncognitive attributes have a long tradition; Cattell and Warburton (1967) referred to them as T-data (test data) measures. French (1948) presented students with a difficult number-series test with instructions stating that some problems had no solutions and that they could receive full credit by marking them as such. It was a disguised persistence test. French found that persistence scores were unrelated to other cognitive tests but were correlated with grades. A modern version is Alan et al.'s (2019) grit game. It comprises two versions of a number grid task in which the goal is to find three pairs of numbers that add up to 100. An easy version has 10 numbers, 5 of which are multiples of 10 and 2 of which are single digit (almost all students successfully completed this task). The difficult version has 20 double-digit numbers and only 1 is a multiple of 10 or 5 (the success rate was much lower). The reward for solving the problem within a short time limit is one gift for the easy version and four gifts for the hard version. Following a treatment designed to improve noncognitive skills by changing students' beliefs about the importance of effort, treated students were found to be more likely to choose the difficult version and 2 years later experienced a $d = .2$ effect on a standardized mathematics achievement test.

Segal's (2012) Coding Speed test, a word-number-lookup-matching task, was administered under low-stakes conditions to 12- to 16-year-old National Longitudinal Study of Youth participants. Segal interpreted the score from this test as a measure of intrinsic motivation because (a) an experiment found that performance improved for a subset of participants when given a financial (\$10) incentive, whereas others (the intrinsically motivated) performed at the same level regardless; and (b) test takers taking the test under high-stakes condition outperformed a more highly educated group taking it under low-stakes conditions. Segal found that performance on this test in the low-stakes National Longitudinal Study of Youth condition, controlling for cognitive ability, predicted earnings 23 years later, such that a 1 standard deviation increase in Coding Speed test performance was associated with a 9.5% increase in earnings.

In behavioral economics, *real-effort* tasks, such as Alan et al.'s (2019), are ones on which the respondent works, and the outcome depends on that work. This contrasts with *stated-effort* tasks in which respondents indicate the amount of effort or actions they would take in a situation (Charness et al., 2018). This distinction is analogous to the revealed versus stated preference distinction (Schl pfer & Fischhoff, 2010) and to the distinction we draw here between descriptive assessments and performance tests.

Real-effort task examples include solving mazes and anagrams, adding two-digit numbers, counting zeros in a grid, transcribing meaningless symbols, cracking walnuts, data entry, classifying Amazon reviews, packing quarters into boxes, playing a labyrinth game, digit span, filling envelopes, dragging a ball on a screen, typing alternating keys, and repeatedly typing the same paragraph, among others (Charness et al., 2018). Some of these also measure other factors (cognitive ability, physical skills). However, many could be used as performance tests of factors such as persistence.

Kyllonen and Kell (2018) reviewed tasks that can be understood as performance measures of noncognitive skills. They suggested several categories: cognitive test performance under low-stakes conditions (Segal's 2012 Coding Speed); objective personality tests in the Cattell–Warburton tradition (Kubinger, 2009; Ortner & Proyer, 2015; Ortner & Schmitt, 2014); economic preference tasks, such as time, risk, and social preferences (A. Falk et al., 2015, 2016); and confidence judgments for their calibration to actual performance (Stankov et al., 2013). They also reviewed measures based on test and survey behavior, such as survey effort as indicated by skipping or careless answering on background questions (Hitt et al., 2016; Zamarro et al., 2018), item position effects reflecting less effort on later items (Debeer et al., 2014; Weirich et al., 2017), and hasty response time reflecting lack of effort (Y.-H. Lee & Jia, 2014; Wise & Gao, 2014).

Several other lines of research evaluate performance measures of noncognitive skills. Collaborative problem solving (Hao et al., 2017) combines cognitive and interpersonal skills (OECD, 2017b). A current challenge is assigning credit to individual members (Hao et al., 2019; Martin-Raugh et al., 2020). Idea generation (Bennett & Rock, 1995) can be considered a standard cognitive task, but there are additional dispositional aspects in choosing to respond with more than one solution or more than one answer to a question. Critical thinking also involves dispositional aspects.

Two additional performance measures of noncognitive skills, attitudes, or worldviews have been researched. Implicit association tests (Greenwald et al., 1998) involve interpreting patterns of response times on classification tasks as indicators of underlying attitudes and beliefs. Although mainly known as an implicit bias measure, it can be used to measure personality (Grumm & von Collani, 2007). Conditional reasoning (James, 1998; LeBreton et al., 2020), measures a personality disposition or worldview through multiple-choice answer selection to a reading passage with two correct answers. One answer is consonant with one belief system or worldview and a different answer with a different belief system.

Reliability, Validity, and Fairness

Performance measures are diverse, making summary statements about psychometric issues difficult. However, tasks discussed can be treated with standard psychometric procedures (e.g., IRT; some have, Debeer et al., 2014). Also, fairness concerns are typically ignored. As the use of performance measures increases, we are likely to see increased attention paid to these issues, following guidelines such as those captured in the *Standards for Educational and Psychological Testing* (AERA et al., 2014).

Challenges associated with these measures include alternative interpretations. Many real-effort tasks likely reflect both the target construct, a personality factor, and construct-irrelevant cognitive or physical ability factors. Watts et al.'s (2018) review of the marshmallow test, an indicator of a child's ability to delay gratification, found that much of its association with later education and work achievements was attributable to sociodemographic and cognitive ability factors. Controlling for

construct-irrelevant influences may be especially important for performance tasks. Construct underrepresentation is another challenge. Skipping an item on a background questionnaire may be a weak indicator of Conscientiousness, but there are other elements of Conscientiousness not captured with such a measure. It will likely prove fruitful to combine multiple and diverse such indicators to create composite construct measures.

Biodata, Documented Accomplishments, and Administrative Records

Choices made and experiences had influence life directions. Choices and experiences might be gathered from an informant who knows the target, captured with a questionnaire (or personal statement), or reflected on one's resume or bio. Life record data (L-data) was one of three data types identified by Cattell (1965), with T-data and Q-data (questionnaire data). L-data is defined as "behaviour in the actual, everyday life situation" such as "number of automobile accidents over 20 years,' 'frequency of engagements,' 'number of societies to which the person belongs,' 'marks in school,' and so on" (Cattell, 1965, p. 61). Cattell suggested that someone who knows the person well might be able to provide such data.

Organizational psychology has a long history of research on biodata (biographical data), responses to survey questions about one's own background and experiences. Oswald et al. (2004) included a biodata measure along with the SJT to reflect 12 dimensions of college experience (see the section on SJTs). Some biodata questions were, "How often have you signed a petition for something you believed in? very often/often/sometimes/seldom/never" (citizenship) and "How many times in the last year have you tried to get someone to join an activity in which you were involved or leading? Never/once/twice/three or four times/five times or more" (leadership). Stricker and Rock (1998) reported on an accomplishments questionnaire (designed for graduate school applicants) with items such as "conducted a band, orchestra, or vocal group at a public performance"; "wrote poetry, fiction, or essays that were published"; and "was elected to a major class office in college." These were drawn from dimensions of academic achievement, leadership, language, aesthetics expression, science, and mechanical. Mumford and Owens (1987) and Mumford et al. (2012) reviewed the history, measures, and methodology of biodata, referred to as background data. Biodata measures have been found to be comparable in their predictions of outcomes to Conscientiousness ($r = .30$), although they overlap considerably with cognitive ability, $r = .50$ (Schmidt & Hunter, 1998). Related are behavioral measures of personality (Breil et al., 2022; J. J. Jackson et al., 2010; Soto et al., 2022) based on the specific behaviors individuals engage in, and ambulatory assessments (Trull & Ebner-Priemer, 2013), such as diaries and event sampling.

Also related are work-sample tests for college admissions. The measure is not what one claims on a survey but a sample of actual behavior. Niessen et al. (2016; Meijer & Niessen, 2015; Niessen & Meijer, 2017) provided several suggestions for how such a

behavioral-sampling system could be implemented, such as trial studying approaches (applicant attends a lecture, studies material, takes an exam), and multiple mini-interviews (similar to SJTs) in which applicants are presented with problems they might encounter in professional practice and asked how they would approach them.

As organizations and schools continue to develop increasingly sophisticated and comprehensive data storage systems, such as New Jersey's longitudinal student data warehouse (NJ Smart) or the U.S. National Student Clearinghouse (transcripts and enrollment data), biodata studies can be conducted solely with administrative records without burdening students or teachers. Kautz and Zantoni (2024) combined grades, accumulated credits, absences, and disciplinary infractions, all obtained from school records, to create a noncognitive composite that was as strong a predictor of a variety of future outcomes (11th-grade grades, absences, arrests, graduation, college enrollment, college graduation) as cognitive ability scores were. K. Jackson (2018) combined absences, suspensions, course grades, and grade repetition as a supplement to achievement test scores to create a teacher value-added measure that was more predictive of lagged student outcomes than were test scores alone, which is the typical value-added measure. (Value-added modeling is a controversial approach in educational accountability; see American Statistical Association [2014] and Ho and Polikoff (this volume); the point here is to show that including noncognitive information can potentially improve such measurement. See also C. K. Jackson et al., 2021.)

With advances in data collection technology and statistical methods, big data and machine learning approaches (e.g., regularization techniques to handle wide data [more variables than people]; gradient boosting machines for better out-of-sample prediction), and psychometrics (e.g., latent classes and mixture models to replace biodata's subgrouping methods), there is an opportunity to make advances in biodata measurement. In the early 21st century, such data are much easier to gather through administrative records retained routinely in database systems or on the web. Time spent studying or working on homework is an important determinant of learning (Cooper et al., 2006; Grodner & Rupp, 2013) and is now easier to capture with online learning systems. Variables like registration latency as indicators of procrastination can be captured (Novarese & Di Giovinazzo, 2013). Social media activity relates to personality factors (Kosinski et al., 2013; Youyou et al., 2015), as do contents of offices and workspaces (Gosling et al., 2002). Mobile sensing data from phones, wearables, and beacons differentiate workplace performance levels (Mirjafari et al., 2019). Stress levels can be detected through speech (Slavich et al., 2019). There likely will be rapid developments in these areas.

CONCLUSION AND PROSPECTS

This chapter reviewed noncognitive constructs and methods for assessing them. Noncognitive skills are important determinants and outcomes of education and are in high demand in the workplace. An education benefit is noncognitive in addition to

cognitive skills development, but this benefit is not always apparent because we do not routinely monitor noncognitive skill development. Instead, we infer this relationship because the positive benefits of schooling on a variety of workforce and life outcomes greatly exceeds the benefit attributable to the development of cognitive skills alone. We also know from research involving the administering of noncognitive measures, almost exclusively self- or others reports collected with rating scales, that such measures predict a wide variety of education, workforce, and life outcomes. This relationship is sometimes as strong as and sometimes stronger than the relationship between cognitive measures and those outcomes. However, a recurring finding is that the relationship between noncognitive skills and outcomes is moderated by cognitive ability—the relationship is particularly strong for students of lower cognitive ability and workers. Analyses of the nature of jobs in the workforce, particularly with technology-induced change, suggest that noncognitive skills are likely to increase in importance.

A roadblock to adoption of noncognitive measurement in schools is a widespread but misguided perception that personality is an immutable trait outside the influence of a teacher or the educational system. But ample research demonstrates that personal qualities such as work ethic, social skill, and productive attitudes are as amenable to change due to good teaching and a supportive climate as curricular achievement is. Another barrier has been simple terminology—throughout this article we have used a variety of terms such as personality, social-emotional learning, soft skills, noncognitive skills, interpersonal and intrapersonal skills, attitudes, values, and beliefs almost interchangeably. Each term has a distinct history and constituency but there is a growing recognition that all these terms refer to skills that are fundamentally in the same realm as cognitive skills are. What has largely distinguished noncognitive skills is not the nature of the constructs per se as much as it is the measurement method—cognitive skills tend to be measured with tests and noncognitive skills with ratings. Since 2015 there has been an expansion of frameworks, accompanied by compendia of measures, outlining the nature and extent of noncognitive skills, and we now have a good understanding of what some of the most important skills are.

The literature and practice of noncognitive assessment has been almost completely devoted to the use of rating scale measures, primarily self-ratings. This is due to their ease of development, administration, scoring, and reporting, but there are serious limitations to rating scale measures. They are subject to various unmonitored and uncontrolled biases (reference, response style, social desirability) and the adoption of self-reports limits their use to low-stakes applications. Alternative approaches have benefits—others' reports, forced-choice and ranking approaches, anchoring methods, SJTs, various performance tests of noncognitive skills such as real-effort measures of Conscientiousness, as well as biodata and administrative records, and big data (data mining) approaches. Any measure has advantages and disadvantages in certain situations and it is important to consider the relative strengths and weaknesses of alternatives to determine their suitability for particular applications. Reliability, validity, and fairness analyses can help. Modern psychometric methods—CTT, generalizability theory, IRT (see Cai et al., this volume,

for a discussion of models)—are suitable for almost all noncognitive measurement, even though adoption of proper psychometric methods is not yet widespread. An interpretive-argument perspective on validity is an appropriate filter through which to evaluate noncognitive measurement methods, the data they produce, and the inferences we wish to draw from those data. A major distinction is between low-stakes use, as is currently widely implemented in schools, and high-stakes use, which is growing in workforce personnel selection and increasingly in higher education. Likert-scale self-measurement is inadequate for high-stakes use, but alternatives, such as others' ratings, forced-choice methods, and SJTs, may be adequate for high-stakes use, particularly when treated with appropriate psychometric methods and after pilot testing for susceptibility to coaching and faking. It may also be important to use multiple measurement methods and indicators to mitigate the weaknesses of any one method.

A general theme throughout this chapter has been that the level of interest and value attributed to noncognitive skills in both education and workplace settings, from both the practice and the policy communities, has outpaced the field's ability to provide adequate measures of those skills. We have evidence that interest and perceived importance are likely to grow. It is essential that the educational measurement community meets that interest with appropriate tools.

ACKNOWLEDGMENTS

Preparation of this chapter was supported by funding from the ETS Research Institute, National Science Foundation Award 2201888, and National Institutes of Health Award R01 HD107079. We thank Ida Lawrence, the editors Linda Cook and Mary Pitoniak, and reviewers Fred Oswald, Rob Meijer, and Suzanne Lane, for their inspiring, supportive, constructive, and often extensive comments, which improved the manuscript immeasurably.

NOTES

1. Selection due to death could explain some of these findings, as it has with cognitive ability (O'Toole & Stankov, 1992).
2. Meta-analyses typically report both a raw Spearman correlation (r) and a disattenuated correlation adjusted for measurement error in the predictor (ρ).
3. Alternatively, standardized alpha is based on average interitem correlation rather than covariance. C. F. Falk and Savalei (2011) discussed the differences in meaning between the two alphas with respect to personality measures. If a composite is the sum of the raw item scores because items are on the same scale, alpha is justified; if a composite is the sum of standardized item scores, as a result of items being on different scales, standardized alpha is justified.
4. Other more general IRT treatments can be found in Embretson and Reise (2000) and de Ayala (2009). Specialized treatments covering polytomous (multiple-category) IRT models can be found in Thissen and Wainer (2001) and Nering and Ostini (2010).

Large-Scale Assessments in International Contexts

Henry I. Braun
Boston College

Irwin Kirsch
ETS (Retired)

Broadly defined, international large-scale assessments (ILSAs) are survey-based studies designed to assess the knowledge, skills, experiences, behaviors, and attitudes of populations in an international, comparative context. Depending on the population of interest, ILSAs can be characterized as school based or household based. School-based ILSAs select participants (e.g., students, teachers, school principals) based on their school membership and location, whereas household-based ILSAs select participants based on the location of their households.

For school-based populations, ILSAs produce estimates of distributions of learning outcomes in key domains for subpopulations defined by various combinations of individual characteristics and contextual factors. The data collected by school-based ILSA enable estimation of the strength of the relationships between learning outcomes and students' backgrounds and school-related factors. Moreover, administering an ILSA periodically enables tracking over time of learning outcomes, as well as changes in the patterns of relationships of learning outcomes to selected individual characteristics and background factors. Analogous statements pertain to household-based studies, usually referred to as surveys of adult populations, with the modification that the focus on school characteristics is replaced with educational, social, and labor market outcomes. In addition, because adult surveys encompass a broad age range, they enable comparisons across age cohorts, yielding useful information on secular trends.

Today's ILSAs can trace their origins to pilot studies that began in the late 1950s and, by the early 1960s, had led to the creation of the International Association for the Evaluation of Educational Achievement (IEA). From a methodological perspective, ILSAs are also beneficiaries of efforts in the United States during the 1960s that culminated in the National Assessment of Educational Progress (NAEP). Prior to these initiatives, no systematic or standardized comparative effort had been undertaken to determine what different student populations knew or could do in various cognitive domains, including language arts and mathematics. This newfound attention to educational outcomes marked a major enhancement of reporting efforts that heretofore had focused primarily on educational inputs, such as the number of schools, teachers, and students in a particular country and how these numbers changed over time.¹

The sponsors and developers of IEA assessments and of NAEP believed that the ongoing, systematic collection and analysis of outcome data, as well as patterns of relationships between those outcomes and various factors, would yield valuable insights. The interest in using the information generated by large-scale assessments to track trends in outcomes and to acquire deeper understandings about the relationships between outcomes on the one hand and individual or contextual characteristics on the other hand marked a milestone in an evidence-based approach to educational policy. Over time, the complex dynamics between ILSAs and the ever-changing education policy landscape have had important implications for the methodologies used to develop and deploy these assessments, as well as for data analysis and reporting results, topics we will return to later in this chapter. It bears mentioning that a key feature of ILSAs is that they always report score distributions and patterns of relationships at a group level,

in contrast to traditional testing programs that report individual-level results. This feature also has important implications for the design and analysis of ILSAs and is the reason why such large-scale assessments are often referred to as group-score assessments.

Since their inception, ILSAs have experienced remarkable growth in participation and salience, reflecting, we believe, perceptions of increased utility of comparative information among policy makers and key stakeholders. Perceived utility is fueled in large part by mounting concerns about the levels and distributions of human capital² and how they are associated with longer term outcomes for individuals and societies. Of course, the actual utilization of the information gleaned from ILSAs depends on a host of political, economic, and other factors that vary across countries, as well as within countries, over time (Feuer, 2012, 2013; Ritzen, 2013).

At the same time, because of the cross-sectional nature of ILSAs, there are limitations to the inferences one can make regarding the relative efficacy of different educational systems in building human capital as well as the consequences for individuals as they make their way through the educational system and then later transition into adulthood and participate in the labor market (Singer & Braun, 2018). Although ILSA outcomes, especially league tables for school-level results, generate headlines and lead to calls for action, the road from evidence to constructive policy impact is strewn with potholes. In particular, because of their cross-sectional approach to data collection, attempts to employ ILSA data to establish causal linkages are at best speculative and at worst misleading. Unfortunately, these limitations are not always understood or respected in policy discussions. The increased visibility of ILSA results along with occasional, ILSA-based, overly broad prescriptions for education reforms have given rise to criticisms of the influence of ILSAs on education policy—particularly with regard to the “homogenization” of national education systems (e.g., Benavot & Smith, 2020; Meyer & Benavot, 2013). A related criticism concerns the applicability of education policies in one nation to the systems of another—especially if the nations differ markedly with respect to history, culture, and governance (Carnoy et al., 2015). These concerns are addressed in this chapter’s section on “Policy and Political Challenges.”

In the case of adult surveys, interest in the results is distributed across many governmental departments, each being concerned with one or another aspect of the study. We can expect that as a consequence of pandemic-related disruptions, there will be increased attention to the need for upskilling or reskilling. Concerns about the use of data for policy in this realm appear to be milder than those in the realm of K–12 education policy.

In the early 21st century, ILSA results enter policy landscapes characterized by complex interactions among multiple stakeholders with access to a variety of sources of information. Accordingly, it is not a simple matter to evaluate whether changes in ILSA instrumentation and procedures are enhancing the value of the assessment enterprise as a source of policy-relevant information. To this task, we advance the notion that a deeper understanding of the utility of ILSAs can be obtained through consideration of a framework introduced by Messick (1987). Messick argued that large-scale assessments

were a form of policy research and, accordingly, should be judged by their contributions to policy analysis and policymaking. His framework was intended to decompose policy utility into its constituent components to provide clearer guidance to assessment sponsors and assessment designers. In this chapter, Messick's framework is refined and extended to take account of more than 30 years of further development and, especially, the transition to digitally-based technologies. Employing this framework, we argue that digital technologies have the potential to further increase the relevance and utility of ILSAs, contributing to their continued growth.

Increased participation in ILSAs, along with the greater prominence of their results, has led to a number of challenges. The task of accommodating increased heterogeneity in the distributions of proficiency and in the languages of the assessments, within rigid constraints of time and budget, has heretofore been accomplished through significant process innovation and methodological advances (as will be detailed in the section "Transitioning to Digitally-Based Assessments"). For example, countries can choose in which language or languages they want to assess and report results. For school-based surveys, these results are typically related to the language(s) of instruction, whereas for adult assessments, they are related to the language(s) of the society. Nonetheless, there are surely limits that will soon be reached and alternative strategies will be required.

A second challenge is that increasing heterogeneity among participating countries has given rise to concerns that cross-national comparability has been compromised to some degree. More specifically, in the case of school-based ILSAs, comparative analyses are complicated by the fact that, across countries, substantially different proportions of a birth cohort are enrolled in school and, of those enrolled, not all have been exposed to the same educational experiences, varying both in quantity and in quality. In the case of adult surveys, different proportions of the target populations are accessible through household surveys. Helping stakeholders understand the implications for policy analysis of these challenges to comparability remains a work in progress.

Following this introduction, we provide a brief description of several key large-scale student and adult assessments. Then we place these assessments in their historical context noting two key inflection points—the first marked by significant innovations in measurement and psychometrics and the second by significant innovations in administration and data collection resulting from the introduction of digital platforms. With the emergence of these assessments as significant sources of credible evidence for policy makers and other key stakeholders, we next introduce and extend a framework proposed by Messick (1987) that provides both developers and users of ILSAs with a set of design criteria to evaluate the potential utility of these surveys.

With the transition to digital platforms, we then focus on the key role of digital platforms in the management, development, and implementation of ILSAs and how new technologies are impacting their workflow and related processes. Next we address methodological advances impacting the scaling and analysis of the data, and also the production and dissemination of different data products. Then we focus on a range of issues concerning ways to evaluate the impact of ILSAs and some key technical

challenges that must be addressed in future cycles, as well as a number of the political challenges their growth and influence have raised. We conclude with a summary and final conclusions.

OVERVIEW OF KEY INTERNATIONAL ASSESSMENTS

A major focus of this chapter is on the three major school-based ILSAs: Trends in International Mathematics and Science Study (TIMSS), Progress in International Reading Literacy Study (PIRLS), and Programme for International Student Assessment (PISA). The first two are sponsored by IEA; the last is sponsored by the Organisation for Economic Co-operation and Development (OECD). However, it also describes a number of other ILSAs covering a range of domains and populations.

These assessments each include two sets of instruments: one for measuring cognitive outcomes and one for eliciting information on a range of background characteristics and contextual factors. Cognitive outcomes include the core domains of reading, literacy, mathematics, and science knowledge and skills, as well as other domains that are assessed with less frequency or are introduced as innovative domains (e.g., problem-solving, financial literacy). Instruments for eliciting background characteristics are targeted to the participating students, their teachers, school principals, and their parents. It bears mentioning that the IEA assessments employ a curriculum-based model for defining their assessment frameworks. In contrast, PISA employs more of a literacy-based model. Although these studies may appear to be very similar, deep conceptual differences manifest in many ways, including sample selection, item development, and instrument design. Table 20.1 contains information on each of these assessments, providing a brief description of content area, numbers of participants, and years conducted.

TIMSS is administered on a 4-year cycle to students in Grades 4 and 8.³ Students are assessed in both mathematics and science. Participating countries include countries, subnational jurisdictions (e.g., states and provinces), and even school districts. In 2019, TIMSS began a transition to computer-based assessment delivery. About half the countries used digital devices for the assessment. TIMSS 2023 completed the transition to computer-based assessment, facilitating the introduction of innovative item types for more comprehensive coverage of the TIMSS mathematics and science frameworks. Scores in each TIMSS cycle are placed on a scale originally established in 1995.

PIRLS is a literacy assessment administered to fourth graders on a 5-year cycle.^{4,5} In 2016, the IEA introduced ePIRLS, a computer-based assessment of online reading. PIRLS participants had the option of also participating in a pilot test of ePIRLS. For participating countries, students typically took PIRLS one day and ePIRLS on the following day.⁶ For the 2016 administration, the IEA also introduced PIRLS Literacy, a reading assessment intended for countries with lower levels of reading proficiency. Through a linking strategy based on common items, scores on this assessment are placed on the main PIRLS scale.

Gamoran (Eds.), *Methodological Advances in Cross-National Surveys of Educational Achievement* (pp. 80–117, Table 4.1), 2002, National Academies Press.

^a IEA = International Association for the Evaluation of Educational Achievement; OECD = Organisation for Economic Co-operation and Development.

^b Subject in parentheses is the focal domain for that administration.

PISA assesses 15-year-old students in the core domains of reading, mathematics, and science literacy on a 3-year cycle. In each country, eligible students are those enrolled in Grade 7 or above. During each cycle, one of the three core domains is the focal domain and therefore more testing time (i.e., items) is devoted to that domain than to the others. During the 2015 cycle, PISA completed the transition from a paper-based assessment to a computer-based assessment while maintaining a limited

paper-based option for countries not selecting the computer-based option. During the 2018 cycle, PISA also introduced multistage, adaptive testing as part of the computer-based assessment. In PISA 2018, each student was tested in two of the three core domains. As options for countries participating in the computer-based assessment, PISA currently assesses an innovative domain beyond the three core domains as well as the domain of financial literacy. Beginning with the 2025 cycle of PISA there will be an optional foreign language assessment that will alternate cycles with the optional financial literacy assessment.

In addition to these school-based surveys, this chapter also discusses one major assessment of adult skills, the Programme for the International Assessment of Adult Competencies (PIAAC), sponsored by the OECD. The assessment of adult literacy began with a number of national assessments in the United States.⁷ The design of the International Adult Literacy Survey (IALS), conducted in three rounds between 1994 and 1999, drew on the frameworks developed and refined by these earlier national surveys. Information on IALS and subsequent international surveys of adult literacy can be found in Figure 20.1.

PIAAC, first fielded in 2012, is a computer-based assessment for adults ages 16–65 in literacy and numeracy and a measure of problem-solving in technology-rich environments. This household survey was administered in three rounds over a period of 5 years (2012, 2015, and 2017). These rounds enabled more countries to participate within

	Population	Assessment Domains	Mode
IALS 1994–1998	Ages 16–65 19 countries Three rounds (1994, 1996, 1998)	Prose, Document & Quantitative Literacy	Paper & Pencil Open-Ended Response
All 2003–2008	Ages 16–65 11 countries Two rounds (2003, 2008)	Prose & Document Literacy, Numeracy, Problem-Solving/Analytical Reasoning	Paper & Pencil Open-Ended Response
PIAAC 2012–2024	Ages 16–65 Cycle 1: 2012 38 countries Three rounds (2012, 2014, 2017) Cycle 2: 2024 31 countries	Cycle 1: Literacy, Numeracy, Reading Components, & Problem-Solving in Technology Rich Environments Cycle 2: Literacy, Numeracy, Adaptive Problem-Solving, Reading & Numeracy Components	Computer-Based Assessment Adaptive Simulation Tasks Cycle 1: Laptop delivery Cycle 2: Tablet delivery

FIGURE 20.1

International Adult Assessments

a cycle and allowed countries (e.g., the United States) to do further national studies between cycles.

Laptops were used for data collection in all three rounds. For those respondents who were unwilling or unable to take the assessment on a laptop computer, a paper-and-pencil option was available for the assessment of literacy and numeracy only. In addition to the cognitive instruments, PIAAC incorporates an extensive background questionnaire, capturing information on a broad range of issues including demographics, education, labor force status, work experience, occupation, use of cognitive skills at home and at work, and incomes.

PIAAC is developed and implemented on a 10-year cycle. At the time of writing, PIAAC is conducting Cycle 2 with 31 participating countries, all of which are employing tablets for survey delivery.

It should be noted that in addition to the well-known global assessments that are discussed in this chapter, a number of other international (but regional) assessments play important roles in regional conversations related to education by providing information for credible cross-national comparisons. Information about those assessments can be found in a recent World Bank report (Clarke & Luna-Bazaldua, 2021).

Finally, the IEA also sponsors two periodic, specialized assessments: the International Computer and Information Literacy Study (ICILS) and International Civic and Citizenship Education Study (ICCS). The ICILS instrument assesses students in the eighth grade (or its equivalent) with regard to their computer literacy and information literacy. An optional module assesses computational thinking. Through the collection of additional background information, ICILS reports describe how these components of digital competence relate not only to one other, but also to relevant school and out-of-school contexts.⁸

The ICCS assesses students in the eighth or ninth grades. It reports on students' knowledge and understanding of concepts and issues related to civics and citizenship, as well as their beliefs, attitudes, and behaviors with respect to this domain. In addition, ICCS collects rich contextual data on the organization and content of civic and citizenship education in the curriculum, teacher qualifications and experiences, teaching practices, school environment and climate, and home and community support.⁹

HISTORY OF INTERNATIONAL ASSESSMENTS

Comparative international assessments had their genesis in a pilot study involving a mathematics assessment in six countries in the late 1950s, followed by a 12-country study, comprising five subjects, conducted by the IEA in 1964 (Husén, 1967; Suter, 2019). These early studies were motivated by the recognition that the education systems and policies of different countries constituted a natural laboratory, and by using a common assessment, international comparisons could yield insights on what strategies and

policies deserved further study. By the same token, the structure of the accompanying background questionnaire was motivated more by models of learning than by considerations of education policy.

Subsequently, the IEA sponsored a series of studies through the 1970s and 1980s, focusing primarily on mathematics and science (assessed separately), culminating in the Third International Mathematics and Science Study (TIMSS)¹⁰ in 1995 with 45 participating countries. Building on its Six Subjects Study (1970–1971) and its Reading Literacy Study (1990–1991), the IEA introduced PIRLS in 2001.

It is remarkable that in the late 1980s, in anticipation of the growing importance of international assessments, a number of U.S. federal agencies established, under the auspices of the National Academy of Sciences, the Board on International and Comparative Studies in Education (BICSE).¹¹ The main focus of BICSE was to evaluate the technical quality of these studies and to assess their policy relevance—all, presumably, to provide high-level guidance on how to enhance both (Bradburn & Gilford, 1990). As described by Heyneman and Lee (2014, p. 41), BICSE made a strong case for the utility of international studies. Echoing the original impetus behind such studies, it argued that variations in policies and practices among countries provided a natural laboratory in which to study the consequences of such differences. Further, BICSE noted the value to the United States of cross-national comparisons that could bring to light new concepts or an empirical basis for challenging long-held assumptions. These considerations have retained their cogency over the ensuing decades.¹²

The OECD introduced PISA in 2000 and PIAAC in 2012.¹³ PIAAC built on two earlier assessments of adults ages 16–65: IALS, which was administered in multiple rounds from 1994 to 1999, and the survey of Adult Literacy and Lifeskills, administered between 2003 and 2008 (see Kirsch et al., 2017, for a history of adult assessments). As will be elaborated, PIAAC is distinguished by the fact that it was the first ILSA to be designed from the outset to be delivered by computer. To fully appreciate the evolution of the systems that support ILSA efforts, however, it is informative to review the history of NAEP.

The history of NAEP has been addressed at length elsewhere (Beaton & Barone, 2017; Jones & Olkin, 2004). Building on substantial planning and development work, the first NAEP assessment was conducted in 1969. Bowing to political constraints related to the primacy of states and local districts in matters of education, the NAEP team had to ensure that the assessment design and sampling plan were such that no summative test scores could be developed, no individual-level results could be reported, and no population groups could be described at the state or local level. This mandate was further reinforced by the decision to report results only at the item level, with each item connected to a particular learning objective so that it could be judged for relevance by both professional educators and individual citizens.

Over the next decade, the context for education and education policy evolved considerably—resulting in a greater federal role in education alongside a growing concern that many schools across the country were neither serving well the needs

of particular subgroups nor accommodating changes in society and labor markets. Policy makers and other key stakeholders began to argue for the need for the kinds of information that the original NAEP design was unable to provide. This led to the establishment of a national commission with the goal of evaluating NAEP and identifying its strengths and weaknesses. Its report (Wirtz & Lapointe, 1982) emphasized the limitations of the existing NAEP design with respect to the interpretability and utility of the results. Drawing on this report, researchers from ETS developed an approach that would enable a new NAEP to address a set of important questions that included the following:

- Are all students learning the skills and flexibility they will need for their own and society's well-being in the 1980s and beyond?
- Are all students being well prepared, and do they have similar opportunities to develop needed knowledge and skills?
- What are the relationships between school factors and student outcomes, especially those related to test-based achievement?

The ETS team proposed a novel design for the NAEP instruments and introduced a number of methodological innovations that changed the face of large-scale assessments. The proposed design was properly titled "A New Design for a New Era" (Messick et al., 1983). The innovations and the subsequent refinements of this design have been reviewed by Mazzeo et al. (2006). With respect to instrument design, the assessment frameworks became more directly tied to the underlying constructs (Kirsch, 2003), enhancing construct validity.¹⁴ Among the methodological innovations were the use of balanced incomplete block (BIB) designs for the booklets administered to students (Mazzeo et al., 2006) and item response theory (IRT) in order to be able to report the results from multiple forms onto a common scale. Subsequently, ETS introduced latent regression models and Bayesian inference procedures to generate multiple imputations of the results in the form of "plausible values" that are now used to obtain population estimates and their corresponding measurement errors (Braun & von Davier, 2018; von Davier & Sinharay, 2014).

The novel NAEP design and methodology marked a key inflection point in the history of large-scale assessments. It set NAEP on a new trajectory that continues to this day. Moreover, these innovations were adapted by the different emerging ILSAs and, to this day, are at the core of the ongoing evolution of designs, methodologies, and platforms (see Mullis & Martin, 2019, for an extended case study). The coordination of these innovations and extensions led to an ever-rich body of information that ILSAs provided to policy makers, researchers, and other key stakeholders whose information needs have been evolving in tandem with changes in the social and economic landscape.

Indeed, starting in the 1990s, there was a growing appreciation of the significant connections between human capital and important outcomes both for individuals

and for the societies in which they live. In the United States, for example, the report by the Secretary's Commission on Achieving Necessary Skills (Kane et al., 1990) focused on identifying the skills needed for the country to enjoy a high-skills, high-wage, high-productivity economy. At the international level, the OECD (1992) noted that low literacy levels were a serious threat to economic performance and social cohesion. And the Definition and Selection of Competencies project provided a theoretical and conceptual foundation for a broad range of competencies that individuals would need to meet the changing demands of modern societies (Rychen & Salganik, 2001, 2003).

As a result, policy makers began to ask new questions focused on adult populations: How are educational attainment and cognitive skills related? How are literacy and numeracy skills related to health and well-being, as well as to participation and success in the labor force? What factors may contribute to the acquisition and decline of skills across age cohorts? How are literacy skills related to voting, trust in institutions, and other indices of social participation? (Kane et al., 1990; OECD, 1992). More recently, there have been organized efforts to develop taxonomies of 21st-century skills in an international context (e.g., Rychen & Salganik, 2001). Binkley et al. (2012) provided an extensive review. As noted earlier, this growing interest led to a series of international assessments focusing on adults, culminating in PIAAC.

Much like the 1983 design for NAEP that put large-scale assessments on a new trajectory, PIAAC marked the beginning of a significant cycle of innovation. As the first ILSA to be designed from the outset as a fully digitally-based assessment, PIAAC expanded what could be measured. It included, for example, technology-based tasks that more directly reflect the changing nature of how people access, use, and communicate information (Leu et al., 2021). In the workplace and in everyday life, it is increasingly important for adults to be able to navigate, critically analyze, and problem-solve in complex, data-intensive digital environments—and the PIAAC platform has made it possible to measure such skills. In addition, PIAAC introduced methodological innovations such as multistage, adaptive testing and more flexible routing for the background questionnaires that have improved the design and delivery of the survey, laying the foundations for future assessments (Kirsch et al., 2017). Other PIAAC innovations include the implementation of interactive stimuli and automated scoring of tasks administered in more than 30 languages, including character-based languages. Consequently, we regard PIAAC as marking another inflection point in the history of large-scale assessment surveys.

Countries now participating in international student and adult assessments represent the majority of the world's gross domestic product, with participation from low- and middle-income countries continuing to grow. That growth is fueled in large part by sponsoring organizations such as the World Bank, UNESCO, and the Inter-American Development Bank (Lockheed, 2013). These organizations regard international assessments as a cost-effective way to monitor the efficacy of their

educational investments in countries where national assessment systems, if they exist, are of variable and at times questionable quality. Their investments represent a growing recognition of the importance of monitoring learning and skill acquisition in support of economic and social development. This shift is also reflected in the United Nations' Sustainable Development Goals (specifically SDG 4 on quality education), which include learning targets and not just time spent in school as evidence of having achieved this goal.

There is a concomitant interest in enhancing the policy utility of ILSA data: Policy makers and other key stakeholders, including researchers representing a broad range of disciplines, are calling for these assessments to measure new and important cognitive domains to provide richer background and contextual information. The intent is to provide deeper understandings of how skills develop and how they relate to educational, social, and economic outcomes. These policy-driven questions provide the impetus for what we refer to as a virtuous spiral (Figure 20.2). Such questions lead to the formulation of new assessment frameworks that guide the development of new instruments. The desire to measure novel constructs such as collaborative problem-solving, as well as to expand the measurement of existing constructs (e.g., incorporating electronic texts in the literacy domain), drives further advances in assessment designs and statistical

FIGURE 20.2
The Virtuous Spiral

models that facilitate richer analyses and deeper interpretations of the data. These, in turn, elicit increased interest among a wider group of stakeholders, leading to further questions. The result is that ILSAs evolve along this spiral of increased relevance and policy utility.

THE MESSICK FRAMEWORK, EXTENDED

Inasmuch as the primary purpose of an ILSA is to provide credible evidence to inform policy makers and other stakeholders, Messick (1987) proposed a framework consisting of several design criteria that could offer guidance for the design, development, and implementation of large-scale assessments. These include comparability, interpretability, and relevance. An overall judgment of the potential for policy utility is then largely dependent on evaluating the strength of these criteria with due regard to purpose, context, and the population(s) of concern (see Kirsch & Braun, 2020, for an exposition of the original Messick framework).

Now, 35 years later, paper-based instruments have given way to digitally-based assessments that build on the past but draw on technological innovations in various domains. These include the use of digital platforms and new electronic tools, along with innovative workflows and processes. They also comprise advances in measurement science and improved methodologies to analyze complex data originating from multiple cultural and linguistic sources (more so than ever before). This point in time is an opportune moment to extend and refine Messick's three design criteria and to examine how they are impacted by technology, both directly and indirectly. This analysis leads to suggestions for innovations that could substantially enhance the policy utility of ILSAs.

Comparability refers to the degree to which the results obtained from a range of reporting groups, representing different cultural and linguistic contexts, have the same meaning in relation to the underlying constructs. In the context of an international assessment, achieving comparability is essential to policy utility. However, the demands are significantly greater than in a single national context because of the much greater heterogeneity that must be addressed. For example, sponsors and developers must make every effort to ensure that the samples of respondents in the different countries are approximately equivalent in the statistical quality of their representations of the corresponding target populations. The degree of success depends on such factors as the nature of the auxiliary information available for the survey design, the degree of cooperation among sampled units, and fidelity of implementation (Rust, 2014). These factors vary across countries, and weakness in any one of them undermines sample quality and, therefore, comparability. If approximate equivalence fails to hold, the country's results must be either reported separately or not at all.¹⁵

Further, the data generated by the cognitive instruments and background questionnaire must have equivalent meanings (measurement invariance) across cultures and languages (Dept et al., 2025; van de Vijver, 2018; von Davier & Sinharay, 2014). Accordingly, the survey instruments, including the background questionnaire, undergo an

iterative process of development, translation/adaptation, verification, and review (Ebbs & Wry, 2016; OECD, 2016, 2020). Following data collection, psychometric analyses reveal the extent to which the goal of measurement invariance has been achieved. If certain items appear to function differently in a particular country (or set of countries), appropriate adjustments are made to the psychometric models that are used to estimate item parameters and generate the reported scale scores for that country (Fishbein et al., 2020; OECD, 2016, 2020).¹⁶

Comparability also has a chronological dimension, namely, that cognitive scale scores, as well as composite scale scores derived from the background questionnaire, can be meaningfully related to the corresponding scores from earlier administrations. In the cognitive domain, this generally entails conducting scale linkage procedures that place new items from the current administration on the established scale. On occasion, a new scale is defined and the items from previous administrations are rescaled and placed on this new scale. In either case, the relevant procedures are well known, as are the checks on the validity of the linkage (Mazzeo & von Davier, 2014). With regard to the background questionnaire, the chief requirement is to retain the item set contributing to the composite scale or—if changes are absolutely necessary—to make only minimal alterations. Significant changes may disrupt the ability to continue an existing/earlier scale and require that a new scale be established. This problem arises because the number of items contributing to a scale is typically very small; hence, the loss of one or two items can have a substantial impact.

Interpretability depends, in large part, on the extent to which the instruments administered have been developed through a fully coherent process so that the reported scores can be given substantive or normative meanings that are credible, defensible, and accessible to a range of stakeholders.

The term *full coherence* signifies that each of the key operations of design, development, scoring, scaling, and reporting are not only appropriately linked to the intended measurement goals, but also functionally integrated through continuing collaboration among teams specializing in each of those operations. Thus, the term implies strong, evidence-based support for the desired interpretation(s) or, in other words, demonstrable construct validity (Messick, 1989).

Indeed, validation of the desired interpretations, whether of the cognitive scores or of the background scales, requires a thorough explication of the assumptions underlying the interpretations and an evaluation of the evidence supporting those assumptions (Kane, 2013). In this regard, Pepper (2020) argued that validity efforts in the ILSA context fall short of the guidelines in the 2014 testing standards (American Educational Research Association et al., 2014) and the requirements of the validity argument as articulated by Kane (2013). Pepper took as a case study the mathematics self-efficacy scales in PISA 2003 and PISA 2012, arguing, for example, that essential validity evidence that would be generated by (cognitive) response process analyses is entirely absent. Clearly, further work in this direction should become more of a priority for future assessments.

Relevance is the extent to which (a) the evidence elicited by the cognitive instruments and the background questionnaire is germane to current policy questions and decisions and (b) the assessment design yields results that can be analyzed in such a way as to address current priorities. Foundational to relevance is the designers' reliance on the assessment and questionnaire frameworks developed by international experts and reviewed by participating countries—with an eye on the most construct-relevant and policy-appropriate elements of each domain and construct that are measured. Of course, relevance is strongly dependent on both comparability and interpretability; that is, a deficiency in either one directly undermines the utility of the data in addressing the questions of interest. Judgments of relevance are made by the various stakeholders in each country, as well as by secondary analysts, and are contingent on the particular purposes at hand. The voluminous technical reports accompanying an ILSA provide useful descriptions of instruments and methods, as well as data displays to inform those judgments.

In addition to ensuring comparability and interpretability, ILSA designers adopt different strategies to enhance relevance. One example is modifying the operational definition of *legacy constructs* and extending the corresponding assessment frameworks. Often, new item types are introduced to target new or neglected facets of the construct. Recent reading literacy frameworks in PISA and PIAAC are good examples: The implementation of digitally-based assessments facilitates the introduction of electronic texts into the assessment. Such texts are an increasingly important source of obtaining and communicating information and, hence, deserve the emphasis they receive in the most recent assessment frameworks. For another example, TIMSS (which is now fully digital) has introduced problem-solving and inquiry tasks to simulate problems arising in laboratories and in the real world that require students to apply a combination of procedural skills and content knowledge. In the case of the background questionnaire, examples include the development of measures of certain aspects of learning contexts (or other background factors) that research indicates may be associated with the development of cognitive skills.

We believe that the improvements to be described here contribute to greater comparability, interpretability, and relevance, resulting in increased utility for policy makers and key stakeholders. Increased utility will continue to drive the salience and growth of these surveys that, in turn, will raise new questions, requiring further innovations on the part of developers and contractors. It is this productive dynamic that we have termed the *virtuous spiral*, depicted in Figure 20.2.

From an operational perspective, digital technologies provide the field with a powerful new infrastructure (platform) that both inspires and facilitates the development and refinement of new tools, processes, and workflows. Accordingly, the transition can impact all major phases of ILSAs: management, design, development and delivery, data handling, analysis, and data product generation. Although each of these phases exists with paper-based assessments, their development and implementation in

technology-based platforms now requires higher levels of coordination and integration to achieve the anticipated gains in efficiency and data quality.

TRANSITIONING TO DIGITALLY-BASED ASSESSMENTS

In a digitally-based, large-scale assessment, a well-designed platform makes it possible to introduce efficiencies that positively impact the development and conduct of the survey, including delivery, data capture, and processing operations. For example, the platform facilitates innovations in assessment design and delivery, allowing for embedded routing and branching capabilities that control how respondents move through the various components of the assessment. In particular, the implementation of multistage, adaptive testing models makes it possible to carry out more efficient measurement.

Platforms may also include a portal that functions as a centralized location for monitoring the workflows associated with key tasks related to the conduct of the survey, along with the interactions between contractors and each participating country. These enhancements serve to improve standardization of each stage of the work and allow for prompt interventions and adjustments, should they be necessary. They also can provide (a) item writers with capabilities for new item types and response modes to improve the measurement of legacy constructs or the introduction of new constructs and (b) translators with an improved infrastructure for translating and adapting assessment materials as well as receiving feedback from the verification process.

From the perspective of participating countries, the digital platform can not only support but also improve operational activities. The possibility of automatic data capture and scoring introduces efficiencies in terms of a reduced data entry and scoring burden along with more consistent scoring across countries and languages. Digital platforms also introduce new capabilities such as the capture of a full range of process data associated with respondent actions when interacting with assessment tasks, as well as accommodations that lead to greater accessibility for students and adults participating in the surveys. A full description of the potential efficiencies of a digital platform is beyond the scope of this chapter. This section, however, discusses the platform's role in a subset of key activities. Collectively, these enhancements can have significant impacts on the relevance, comparability, and interpretability of an ILSA, thereby increasing its overall utility to policy makers and key stakeholders.

Survey Instrument Development

The platform must possess the functionality to support item development and authoring for both the cognitive instruments and the background questionnaire in multiple languages and orthographic systems. Consequently, platform developers engage at the outset with domain experts and instrument developers to understand

the technical implications of (a) measuring new constructs, (b) revised and extended frameworks that broaden what can be measured, (c) delivering new item types, and (d) the approaches required to address a greater range of respondents' proficiencies due to the expansion in participating countries. At the same time, domain experts and instrument developers take into account the range of displays, item types, and interaction modes that the platform supports, resulting in some modifications of item types and/or response modalities. This collaboration often results in timely platform development and enhancements that contribute to the relevance and interpretability of what is being assessed.

Assessment designs for paper-based surveys are limited by operational constraints related to time and costs associated with assembling, checking, printing, shipping, and handling multiple paper forms. By contrast, digitally-based assessments, especially when combined with some form of adaptive testing (see the section "Survey Administration"), offer many advantages. First is the potential to eliminate errors associated with the assembly and distribution of multiple paper booklets both within and across languages. Second, the digital platform can accommodate designs involving complex routing algorithms that entail a very large number of virtual forms. In particular, it can assign an appropriate, predesigned form to each participant, precisely following the assessment design (a practice that is particularly germane to adaptive testing). Moreover, the platform can support both instrument administration in different formats and data capture for a range of response modalities. Finally, greater efficiency in the estimation of proficiency distributions, in combination with new item types, makes possible both broader construct coverage of existing domains and the assessment of new constructs, topics we address in the sections "Developing Coherent Cognitive Assessments" and "Background Questionnaires."

Developing Coherent Cognitive Assessments

Following a coherent process for assessment development enhances the interpretability of the findings. In this regard, a construct-centered or evidence-centered approach to assessment development is most helpful (Messick, 1994; Mislevy et al., 1999). Successful implementation yields a consensus on an operational definition of the target construct; thus, it provides assessment developers with a road map for the design and development of the tasks, as well as for the collection of evidence that can be used to represent performance in relation to the construct. This process yields a reporting scale that can be more appropriately interpreted.

The assessment framework for each domain contains specifications for item development: (a) the identification of key task characteristics to be varied singly and jointly, (b) the numbers and types of items (stimulus materials, response formats, and levels of difficulty) required to populate the item pool, (c) guidelines for instrument assembly, and (d) considerations related to scoring open-ended items (see Lennon & Kirsch, 2025, for an example). In advance of field testing, item quality is evaluated in terms of the items' links to the assessment framework and a judgment that

their formats, layouts, and content follow established design principles. Subsequent to the main assessment, as well as the scaling and analysis of the cognitive data, the assessment framework facilitates the creation of item maps and the validation of task characteristics. These are often used to characterize proficiencies at different points along each cognitive scale.

In an international context, development of cognitive assessments that yield scores that are valid and comparable requires that every effort be made to establish the items' cross-cultural, cross-linguistic, and cross-national validity. In that regard, the digital platform should facilitate (a) flexible content management, so that development files can be shared as needed; (b) item previewing, so that items can be examined in both source and target languages, along with the corresponding item layouts; and (c) consistency in item translation/adaptation across the item pool. Thus, the platform must support the active involvement of participating countries, with continuous coordination among geographically dispersed teams, comprising domain experts, test developers, psychometricians, platform developers, and graphic designers.

Background Questionnaires

ILSAs also yield information on a set of constructs that are measured through the background questionnaires. In addition to standard demographic information, the constructs targeted by the background questionnaires are based on frameworks developed through collaborative efforts among representatives of participating countries, international content experts, and questionnaire developers. One goal is to assess important characteristics or factors associated with students, teachers, and schools for surveys focused on in-school populations and important social, educational, and labor market factors for adult assessments. In addition to these context-related constructs, school-based surveys also target students' attitudes and behaviors along with family-related characteristics. Although these constructs are of interest in their own right, they are particularly valuable because of the insights that can be gleaned from their relationships with the cognitive outcomes, as well as the differences in those relationships across populations and through time.

Since the mid-1990s, background questionnaires have become more comprehensive in scope and their development more systematic. For example, rather than focusing on authoring individual items, the trend has been to develop sets of items whose responses can be combined into a scale that relates directly to a target construct, placing a new burden on item developers and the committees that advise them. Scale construction by means of IRT modeling is now accepted practice, with due attention to model fit, reliability, and validity (Martin et al., 2014).

As stakeholders have come to appreciate the value of the background questionnaire, it has gained in importance, thereby putting more pressure on improving the assessment of existing constructs while accommodating new indicators—all within strict time constraints for administration. The result is an ongoing tension between introducing these new indicators and maintaining trend for (at least some) existing indicators. This

tension provides the impetus for methodological developments, such as incomplete designs analogous to those employed for the cognitive instruments. PISA 2022 implemented a within-construct rotation design for the background questionnaire. However, implementing incomplete designs for the background questionnaire makes strong assumptions about conditional independence of context variables and has implications for the scaling of the cognitive domains that have not yet been fully resolved (von Davier, 2014).

Nonetheless, this dynamic provides yet another instance of the virtuous spiral introduced in Figure 20.2. As with the cognitive instruments, the platform plays an important role in supporting more complex designs and routing patterns often associated with current background questionnaires. These improvements support the relevance of the information that is gathered, as well as the quality and consistency of the information that is captured.

Translation/Adaptation/Verification of the Instruments

An essential step in establishing cross-national comparability is the translation, adaptation, and verification of the items in the cognitive instruments and the background questionnaire. This process is difficult, costly, and time-consuming. By supporting new workflows, the digital platform contributes to making the process both more accurate and efficient. As noted earlier, the platform accommodates the full range of languages used by participating countries (including right-to-left and ideographic languages) in addition to supporting the coordination of the work of test developers, linguists, and cross-cultural survey methodologists. This team produces informative translation and adaptation notes that both explain the underlying constructs and offer guidelines for use during the test translation and adaptation process. These improvements in this work process help to improve quality control, thus facilitating standardization and resulting in improved comparability.

In the case of PIAAC, for example, the item-by-item translation and adaptation guidelines (a) explain what the item is intended to measure; (b) specify which adaptations are mandatory, desirable, acceptable, or ruled out; (c) draw the translators' attention to terminology problems, translation traps, and patterns in response options; and (d), in the case of recurring elements or elements already present in trend materials, indicate how to access previous translations of these elements.¹⁷

For the cognitive items, the guidelines provide information on certain crucial assessment-related features such as literal matches (e.g., between stimuli and questions) that need to be maintained in the translated national versions, level of language difficulty, distractors, and so on.

A specially developed set of integrated tools in the platform makes it possible for these guidelines to appear in the translation tool when a translator on the national team (or reconciler, or verifier) processes a text segment. This is a technical innovation offering significant added value by streamlining processes, reducing the number of documents and tools required, and providing a translation environment that unites

all relevant information—thus enabling translators to better attend to key elements of the translation task at no additional cost for countries. We expect that forthcoming artificial intelligence–based tools will offer further enhancements and efficiencies to the translation/adaptation process.

Population Sampling Operations

The primary goal of an ILSA is to obtain credible and comparable estimates of population distributions of proficiencies in cognitive domains. The essential first step in sampling is a clear definition of the target population. Then a probability (random) sample of units is selected from the population, because randomization justifies using the machinery of probability theory to make inferences from sample characteristics to population characteristics. An added benefit is that with a well-conducted survey it is possible not only to obtain approximately unbiased estimates of population parameters (e.g., means, variances, percentiles), but also to quantify the uncertainty attached to those estimates (e.g., estimates of the standard errors of the parameter estimates).

Because of considerations related to cost and logistics, as well as reporting requirements, large-scale surveys almost never draw simple random samples of the units of interest (students or adults); rather, they employ complex sampling designs such as multistage cluster designs.¹⁸ An important design consideration is the trade-off between the amount of information derived from a sampling unit and the cost of obtaining that information. The key is that, at least in principle, there is a known probability used for the selection of each unit. These probabilities are used in the calculations leading to the estimates of population parameters and their variances.

The principles and techniques of population sampling are treated in many texts (e.g., Lohr, 2010). Rust (2014) presented a comprehensive treatment of considerations in ILSA sampling. TIMSS and PIRLS sample schools and students in such a way as to be able to estimate proficiency distributions for particular grades. Consequently, they typically employ multistage cluster samples where schools are first grouped into relatively homogeneous categories (termed *strata*) characterized by such factors as geographic region, political status, and school type, as well as characteristics related to mean school achievement. At the country level, the choice of characteristics to classify schools for the purpose of selection also depends on the information available, the interest in the reporting accuracy of the results at various subnational levels, and considerations of efficiency. Within strata, schools are selected with probability proportional to size.¹⁹ The clusters are randomly chosen classrooms within the schools providing instruction in one or both of the target grades. The assessment instrument is administered to all students within the selected classrooms. This approach is efficient, is minimally disruptive to the school, and facilitates estimating relationships between student achievement and their teacher or classroom characteristics. The final sampling plan represents the ideal plan adapted to the real-world constraints particular to each country.²⁰ ILSAs recognize that achieving a sampling plan with 100% coverage is not realistic. Typically, countries are not annotated if they have no more than 5% exclusions. At the school level, reasons

for exclusions include schools located in difficult-to-reach regions or particularly small schools; at the student level, reasons may be nonofficial language speakers and students with disabilities.

By contrast, PISA estimates proficiency distributions for a particular age cohort (i.e., 15-year-olds). Accordingly, its design must take into account not only that students of the same age may be enrolled in different grades, but also that those grades may be located in different system levels (i.e., lower secondary and upper secondary). Consequently, there may be curricular differences that, along with other factors (e.g., differential participation and coverage), can impact cross-national interpretability of the results.

The sample design for PISA 2018 also utilized stratification for school selection. As with the IEA studies, the choice of stratification factors depended on the country. Within each selected school, a random sample of students is obtained from the student population in the targeted age cohort. The number of students selected within each school varies from 35 to 42 depending on the assessment options chosen by the country (see OECD, 2020, chap. 4, for further information).²¹

PIAAC is a household survey. For some countries it employs a type of multistage, clustered area sampling with households as the ultimate sampling unit. Within a selected household, the instrument is administered to a randomly chosen adult whose age falls within the target range of 16 to 65. In other countries with registries of either households or individuals, sampling is conducted directly from the registry. Consequently, the actual implementation of the sampling procedure varies by country, depending on the structure and completeness of the sampling frame. The type of procedure employed also affects variance calculations (see OECD, 2016, for more detailed information).

As is the case with all fieldwork, the obtained sample in a school-based survey differs from the ideal sample in a number of ways. An especially challenging problem is the existence of schools that are not included in the sampling frame. For those schools in the sampling frame, selected schools may refuse to cooperate and selected students within schools may be absent, refuse to cooperate, or not fully respond to the cognitive instrument and/or the background questionnaire.²² In the case of household surveys, the sampling frame or the registry may be inaccurate or incomplete. Once households are selected and visited, there may be no one at home or the selected respondent may refuse to participate or only partially respond to the survey.

Inasmuch as the utility of cross-national surveys is critically dependent on the quality of the samples drawn, each ILSA has a set of procedures to address sample quality issues. These procedures are documented in the technical reports referenced above (see Rust, 2014, for general considerations about sample designs and procedures). Procedures may include replacement sampling for noncooperating units and technical adjustments for various types of nonresponse. Notwithstanding the use of such procedures, substantial differences across countries in response rates at the various stages of design implementation reduce the credibility of comparisons of proficiency distribution estimates as well as other targets of inference. ILSAs typically set thresholds for response rates; results for countries not meeting the threshold are reported separately

or not at all. Nonresponse bias analysis is also conducted to estimate the effects of these issues on the overall estimates.

When information about the population of interest is lacking or incomplete, ILSA teams face significant challenges in ensuring sample quality within each participating country.²³ This may be a particular concern with household surveys. Because many of these countries have limited experience and capacity in conducting large-scale surveys, they require both extra support and more careful monitoring. In some countries, information to develop adequate sampling plans for national samples may be insufficient. At the same time, ILSA participation offers country representatives intensive training and the opportunity to garner field experience in the selection of probability samples that can be employed for later in-country surveys as well as future ILSA administrations.

ILSA teams are always seeking ways to reduce survey error. A model for improving data quality is the total survey error (TSE) framework, originally developed by Hansen and explicated by Hansen et al. (1953). The TSE framework covers all types of errors that may arise in survey design, sample selection, data collection and processing, scaling and analysis, and creation of data products. The TSE framework makes a distinction between sampling and nonsampling errors. Sampling error results from variability in the estimates stemming from the selection of a random fraction of the target population. Nonsampling errors may be introduced at any phase of the survey process. Consequently, they must be taken into consideration throughout survey operations and management (including development and implementation) as well as data collection, handling, and analysis. Operationalizing the TSE framework requires striking a balance between enhancing data quality and operating within survey constraints (Biemer et al., 2017).

The transition from paper-based to digitally-based interviews and assessments has enabled many advancements in error control. One strategy is to establish processes that detect various sources of nonsampling error during data collection and to remedy them when possible. In this regard, the digital platform plays a key role through its capacity to collect and present what is referred to as *para-data* in a timely manner (Mohadjer & Edwards, 2018).

Para-data are the survey process data that are generated during data collection. For example, in carrying out the PIAAC household survey, the para-data may include the record of contact information, instrument timings, voice recording of interviews, geolocation of the interview, and interviewer work activities (hours and travel routes). They contribute to indicators of data quality, costs, and interviewer effectiveness. Because para-data can be quite voluminous, they are collected and summarized in a performance dashboard comprising a set of survey control charts and data graphs that monitor sample yield by interviewer and overall response rates at different levels of aggregation, highlighting unusual outcomes. With real-time transmission of information, the performance dashboard allows survey managers to react to operational challenges in a timely manner, facilitating what is sometimes termed an adaptive data collection strategy.

Survey Administration

In this section we review two modes of administration—paper and pencil and digitally based.

Paper-and-Pencil Administration

In preparation for this mode of administration, the item pool for a cognitive domain is organized into disjoint sets of items, termed *blocks* or *clusters*. For each ILSA, blocks are created according to specific criteria related to the number of items or item sets, content coverage, distribution of item difficulties, and timing. In a matrix sampling design, students are presented with a booklet that comprises two or more blocks, along with a background questionnaire. For example, in the case of booklets containing two cognitive blocks, the blocks are systematically paired into booklets. They are usually organized according to a BIB or partially balanced incomplete block (pBIB) design (Mazzeo et al., 2006; L. Rutkowski et al., 2014). In a full BIB design, each block is paired once with every other block.²⁴ This ensures that it is possible to compute covariances for all pairs of items, thereby facilitating placing estimated item parameters on a common scale (see the section “Scaling, Population Modeling, and Proficiency Estimation”) and using statistical analysis techniques that require the use of a complete covariance matrix, such as factor analytic techniques. Because of logistical constraints, it is not always possible to employ a full BIB design and designers resort to using pBIB designs, in which not every pair of blocks appears together in a booklet. Nonetheless, with modern psychometric theory, it is still possible to place all estimated item parameters on a common scale.

As one might expect, there are many variations on a theme. In a focused BIB design, each student receives blocks assessing a single subject (e.g., reading in PIRLS). In an unfocused BIB, students are assessed in two or more subjects (e.g., mathematics and science in TIMSS; reading, mathematics, and science in PISA). In the latter case, it is possible to compute correlations between cognitive domains. Of course, the intended interpretations of the results of the psychometric analyses depend on the assumption that the responses to each item (block) have been produced by randomly selected samples of students.²⁵ This assumption is met by various spiraling strategies for booklet distribution (Mazzeo et al., 2006). Detailed descriptions for each ILSA can be found in the corresponding technical reports.

To accommodate the increasing heterogeneity in country-level distributions of proficiency, ILSAs have adopted different strategies. For example, in PIRLS 2021, the proportional distribution of booklets by difficulty varies by country. Booklets are categorized as more or less difficult, depending on the distributions of item difficulties in the component blocks. Countries with (assumed) higher levels of proficiency receive a greater proportion of the more difficult booklets, while countries with (assumed) lower levels of proficiency receive a greater proportion of the less difficult booklets. By orchestrating a better overall match between the assessment and the country’s students, it is possible to obtain more accurate estimates of the overall proficiency distribution within the constraints imposed by paper-based administration.

Digitally-Based Administration

As noted earlier, the transition to digitally-based administration facilitates the introduction of new item types as well as new strategies for administration. With regard to the latter, it is certainly possible to organize the sets of items for administration in predetermined sequences of approximately equal difficulty (as is done in paper-and-pencil administration) and assign each set to randomly equivalent samples of respondents. Of greater interest is the introduction of adaptive testing. Adaptation can be done at the level of the individual item or of sets of items.²⁶ The latter is usually referred to as multistage, adaptive testing.

In multistage, adaptive testing, after a set of items has been administered and responses have been evaluated, an algorithm implements a decision rule that, for the next stage, routes the respondent to one of a number of possible item sets. The algorithm accounts for the student's performance on the previous item sets as well as content and other constraints. The intent is to improve the final estimation accuracy by better matching item difficulties to the current estimate of the respondent's proficiency, which is especially important when dealing with substantial heterogeneity in proficiencies within and among countries. In particular, adaptive testing reduces the chances that students will be exposed to items that they find extremely easy or extremely difficult.

Happily, it appears that adaptive testing induces greater respondent engagement, as indicated by lower rates of nonresponse or random responding. In conjunction with timing data that enable making distinctions between omitted items and items not reached, greater accuracy in proficiency estimates is achieved. At present, one difficulty is that in some ILSAs many item sets include one or more items that require human scoring. In that case, the decision rule must rely solely on responses to the machine-scored items. As a consequence, the selection of the next set of items is based only in the performance on these machine-scored items. This results in somewhat less improvement in efficiency than would be the case if the responses to all items were used.

With the large item pools typical in ILSAs, the number of item sets (or testlets) is correspondingly large, and consequently for multistage, adaptive testing, the number of different item paths (sometimes referred to as *virtual forms*) can run into the many thousands. Clearly, having such a large number of forms in a paper-and-pencil administration would be both infeasible and unaffordable. At the same time, the key innovation in matrix sampling has been retained, namely, that each respondent is only administered a small proportion of the full item pool.

Adaptive testing in an international context was first carried out in an individual-level test of adult literacy, setting the stage for later, more advanced implementations—first in PIAAC and subsequently in PISA. Yamamoto et al. (2018) discussed some advantages of multistage, adaptive testing over fixed form tests, especially in the ILSA context. They also note a number of challenges including (a) avoiding (to the extent possible) items that require human scoring in the decision-making process,²⁷ (b) ensuring that each virtual form meets construct representation requirements, (c) maintaining desired levels of item exposure control, and (d) employing appropriate analytic procedures. Indeed, implementing multistage, adaptive testing adds considerably to the complexity of the

assessment system. Yamamoto et al. provided a comprehensive discussion of these complexities and their resolution in the context of PIAAC and PISA.

Accommodations for Testing

Comparability of national samples is an essential element of ILSA utility. One potential threat to comparability is related to the assessment of individuals with disabilities, inasmuch as countries' practices differ in a number of ways: how they identify students with different types and degrees of disability, the nature of the accommodations typically employed during testing, and their protocols for exclusion from an ILSA. Attempting to harmonize these practices across participating countries is evidently infeasible.

On the one hand, the baseline strategy adopted by TIMSS and PIRLS is to review the accommodations proposed by the countries and to approve them, unless there is a clear threat to the validity of the assessment. For example, reading questions to a blind student may be acceptable in TIMSS but not in PIRLS. Clearly, allowing variation in accommodations represents a different level of standardization of assessment administration. On the other hand, the purpose of test accommodations is to allow students to demonstrate what they know and can do, but with only minimal changes to the target construct (Thurlow, 2014; see also Zwick and Rodriguez & Thurlow, both in this volume). To the extent that this is the case, and if students are afforded accommodations with which they are familiar, then a certain level of comparability is achieved—in the sense that each student has a fair opportunity to meet the challenges presented by the assessment. From an international perspective, this protocol prioritizes obtaining better estimates at the national level (for a country that includes these individuals in their target population) at the expense of some loss in cross-country comparability in estimates of proficiency distributions.

PISA does not employ accommodations in the main assessment, with two exceptions: (a) allowing for extra time and (b) administering a shortened (1-hour) version of the full assessment with a restricted set of response formats. Schools designate which of their selected students are eligible for one or the other of these accommodations, which are available for math and reading only. For PISA 2025, all items in the shortened assessment will be fully accessible, though not all item types will be represented in the assessment. The data from these items do not contribute to the estimation of the international IRT parameters, but they do so in the estimation of the plausible values (PVs) for the national distributions.

With the advent of digitally-based assessments, new policies and protocols are under development. For example, the OECD sponsored a small pilot study to investigate the feasibility of offering accommodations for students with a range of disabilities (Laitusis et al., 2018). The results were mixed with respect to practicality and efficacy, especially for more complex item types such as simulations. In any case, the report's findings and recommendations will inform subsequent phases of implementation research for PISA 2025, as well as for TIMSS and PIRLS as they transition to digitally-based assessments. It is expected that future administrations will explore the feasibility of implementing affordances such as varying font size and text to speech.

Overall, accessibility will be enhanced as new items are developed according to the principles of universal design and added to the item pools. At the same time, this approach is more feasible for some item types than for others. For the latter, special modifications will be required to enhance accessibility. Because of cost constraints, the number of such modified items will be limited; hence, they may be located in a small number of forms that can be administered when particular accommodations are requested.

In this regard, one other aspect of ILSA administration in school settings bears mentioning. The number of different devices that students are using day to day is growing. Current planning contemplates allowing students to bring their own devices, as long as they meet certain interoperability standards, as well as building a platform that will host those devices, provided they conform to a number of requirements. Carrying out this plan will be quite challenging. It remains to be seen to what extent the profusion of devices with different capabilities introduces construct-irrelevant variance and impacts score trends.

SCALING, POPULATION MODELING, AND PROFICIENCY ESTIMATION

IRT scaling, population modeling, and proficiency estimation are essential components of the ILSA workflow. The accuracy of the model parameter estimates, as well as the estimates of the precision of those estimates, constitutes the statistical foundations for generating the appropriate, individual-level proficiency distributions that are ultimately transformed into population-level results. Accurate estimates are essential to achieving comparability across all relevant reporting groups and, hence, valid interpretations of the results.

Introduction

It is customary to provide countries with standard, mandatory software that is used to manage, integrate, and validate their national data. Participating countries employ the software for data processing as well as to run checks to ensure, as much as possible, that the within-country data capture and integration accurately reflect the values given by the sampled persons and/or the interviewers.

In particular, the software is able to produce a series of reports that give an overview of the data quality and field operations progress. Each country is required to generate and review these reports during field operations and again prior to submitting the database to the contractor for international processing. Along with the national database submission, each participating country submits supporting data documentation that provides the ILSA team with detailed information regarding issues or technical difficulties in the administration of the assessment.

For each country, the input to this segment of the workflow is a set of validated data files. The output is a set of files containing, among other things, the estimated parameters

of the score distributions for the overall population and for designated subgroups. By this point in ILSA history, the statistical and psychometric procedures have evolved considerably in complexity from those employed in the early years of NAEP. Paraphrasing von Davier and Sinharay (2014), current methods may be viewed as sophisticated imputation approaches that combine the several advantages of IRT with an explanatory approach based on collateral information to produce accurate subgroup results—despite the relatively short testing time and the sparseness of the data. The use of collateral information is especially important when participants are asked to respond to multiple domains within the same limited time. Further details can be found in von Davier and Sinharay (2014), as well as in the technical reports published by each ILSA. Analysis teams also expend considerable effort in checking the intermediate results at each stage of the process to ensure accuracy and comparability of the results while accounting for possible country-by-item interactions. Moreover, these procedures are continually refined to improve efficiency and to accommodate new demands from sponsors and participating countries.

For simplicity, the discussion that follows assumes a single latent trait for the domain of interest.²⁸ With the primary goal of producing unbiased estimates of score distributions for populations and subpopulations, ILSA assessment designers are faced with the formidable challenge of meeting the requirement of full construct representation under the constraint of limited testing time. For paper-and-pencil administration, various types of matrix sampling are employed (see the section “Survey Administration”). Such plans are characterized as “missing by design,” and the use of matrix sampling has implications for subsequent analyses. In practice, a limited number of forms are developed and the design can be represented by a matrix that displays the fraction of the full item pool that is contained in each form. Forms are distributed in such a way that each form is administered to random sets of respondents of approximately equal size.

For digitally-based assessments and, especially, with the advent of adaptive testing algorithms, the matrix designs have become increasingly complex. As is the case with paper-and-pencil administration, respondents respond to a relatively small fraction of the total item pool. However, on average, the forms administered to a group of respondents will be better matched to the group’s proficiency distribution. The desired group-level estimates can be obtained through the use of advanced statistical methods—assuming that each item or item set has been administered to a proper probability sample of respondents, that the sample sizes are sufficiently large, and that there are satisfactory linkages across forms.

The analysis proceeds in four stages:

- Stage 1, item calibration: estimation of the parameters of the item response model
- Stage 2, population modeling, including latent regression analysis
- Stage 3, generation of plausible values
- Stage 4, linking plausible values to the established reporting scale

Item Calibration

All ILSAs make use of IRT to calibrate the items in the item pool. Calibration involves estimating the item parameters that characterize the probabilistic relationship between test-taker proficiency (i.e., their location on the scale corresponding to the latent trait) and performance on the item. The items may be scored dichotomously (two possible scores) or polytomously (three or more possible scores). The psychometric models employed differ across ILSAs: TIMSS and PIRLS use the three-parameter logistic IRT model for multiple-choice items, while PISA uses the two-parameter logistic IRT model. The general partial credit model is used by all ILSAs for calibrating all other items. (For a discussion of the models used in IEA assessments, consult von Davier et al., 2020).

Field trial instruments incorporate designed collections of new items or new item sets, along with a set of previously administered items that will be used to estimate trends. The total pool of items is administered to large convenience samples to estimate the measurement invariance of the trend items, as well as to obtain preliminary item parameter estimates for the new items. These analyses are used to furnish initial estimates of how well the trend items and new items function, both within and across participating countries with regard to comparability and overall quality.

If the items are selected for operational use, then the response data obtained from the main data collection are used to update the item parameter estimates for the new items and to evaluate the degree of comparability across countries. Operationally, if an item appears to have substantially different psychometric properties for a particular country, it is calibrated separately for that country.²⁹

With regard to the background questionnaire, item sets addressing constructs such as attitudes, dispositions, and behaviors are used to generate scales for secondary analysis. The process is also carried out by employing IRT models. The models take account of the fact that most of these items use ordered response categories. Both PIRLS 2016 and TIMSS 2019 have used the Rasch partial credit model to conduct item calibration employing the full data sample, with each country contributing equally to the analysis. Subsequently, the reliability of the derived scales is evaluated and the scales are subjected to validation procedures, such as tests of unidimensionality.

For both the cognitive instruments and the background questionnaire, the field tests and main administrations are essential to the maintenance and replenishment of the item pools. The transition to digitally-based assessments, particularly with the introduction of multistage, adaptive testing, necessitates an increase in the sizes of item pools for the cognitive domains, with the demands for piloting and calibrating new items becoming correspondingly greater. Increases in the item pools are also driven by the need to accommodate greater heterogeneity among participants with respect to proficiencies in the focal domains. Further, with the concomitant exponential increase in the number of (virtual) forms, more complex assessment designs are needed to obtain sufficient information for calibration and evaluation of differential item functioning (Yamamoto et al., 2018). Such designs, made feasible by the

digitally-based assessment platform, evidently contribute to improved construct representation.

It bears mentioning that both PIRLS and TIMSS use country-level adaptive designs (and sometimes benchmarking population adaptive). Such designs employ rotations of harder/easier booklets with the proportions based on prior information from a previous cycle. The goal is to improve estimation, particularly at the low end of the proficiency scale.³⁰

Population Modeling

The background questionnaire incorporates a set of questions related to constructs believed to be associated with (cognitive) proficiencies. These include both background characteristics and contextual factors. The second stage of analysis makes use of these additional data to obtain more accurate estimates of proficiency distributions. Specifically, this stage involves estimating the parameters of a so-called latent regression model (Mislevy, 1991; Mislevy et al., 1992; von Davier, Khorramdel, et al., 2019; von Davier & Sinharay, 2014) in which an individual's unobserved proficiency is regressed on a suite of variables derived from their responses to the background questionnaire. This model is usually referred to as a *population model*. In practice, the full suite of background and contextual variables is replaced by a smaller set of principal components that account for approximately 70% to 80% of the observed variance.³¹ The reduction in the number of explanatory variables yields more stable estimates of the regression coefficients and the variance–covariance matrix of the model, but with negligible reduction in accuracy (Oranje & Ye, 2014; Thomas, 2002; Wetzel et al., 2015). It is also customary to assume that the residuals about the regression plane follow an approximately normal distribution. The entire system is placed in a Bayesian framework with the introduction of a unit normal prior for each individual. The prior is successively updated with each full cycle of the expectation–maximization algorithm that is employed in the estimation procedure.³²

Concatenating the IRT model and latent regression model yields the marginal probability distribution for the observed item responses, given the transformed set of background variables, the estimated item parameters, and the parameters of the latent regression. Multiplying the marginal distributions across respondents results in a likelihood function. The corresponding log-likelihood function is then maximized with respect to the parameters of the latent regression, while the parameters of the IRT model are held fixed at the parameter values obtained in the first stage of the analysis (to impose comparability constraints across participating countries).³³

We note in passing that maximization of the log-likelihood function is a very difficult exercise in numerical analysis and considerable effort has been expended in devising different approaches to carrying out the computations (von Davier & Sinharay, 2014). The output is an estimate of the conditional distribution of the maximum likelihood estimate (MLE) of the vector of regression coefficients, as well as the MLE of the variance of the distribution of an individual latent trait. The latter is held fixed at its estimated value in all further computations.

Plausible Values

As noted earlier, the methodology employed by large-scale assessments is not intended to yield point estimates of ability at the individual level but, rather, estimates of group-level distributions of ability. This task is accomplished by producing a collection of parameter estimates that are used to generate a set of imputed values for each individual. In this context, these imputed values are PVs. Collectively, the PVs associated with an individual make manifest the available information regarding their proficiency in the domain. The average of the PVs is an estimate of the expected score were someone with their vector of principal components to be administered the full item pool. The variability among the PV is used to estimate the total measurement uncertainty associated with an estimate of a group-level parameter.

To obtain a single set of PVs (one for each respondent in the sample), it is necessary to approximate the proficiency distribution for each respondent. Since that distribution is assumed to be normal, it is only necessary to estimate its mean and variance. An estimate of the variance was obtained in the previous stage. The mean depends on the covariate values associated with the respondent and the (estimated) vector of regression coefficients of the latent regression model. That estimated vector has a posterior distribution that is approximately multivariate normal, with mean equal to its MLE and a variance–covariance matrix equal to the estimated variance–covariance of the MLE.

A random draw from that posterior distribution produces a vector of regression coefficients, enabling full specification of the proficiency distribution for each respondent. A single independent, random draw from that proficiency distribution yields 1 PV for the respondent. These steps are carried out for each respondent to generate a full set of PVs for the sample. The entire process is then repeated N times to produce N full sets of PVs. The number N of imputations was decided by most ILSAs following recommendations by Little and Rubin (1987) for multiple imputations. Early choices of 5 or 10 were limited by computing power, data storage, and time constraints. As computing power increases, 20 or more sets of imputations will be common.

Linking

An important use of ILSA data is tracking changes in skill distributions over time at the national and subnational levels. Such comparability over time requires linking the proficiency scale of the current assessment to the scale established in prior assessments. Linking is accomplished by embedding so-called trend items in the survey instrument. Trend items are those items employed in the current assessment that were also present in earlier assessments. Roughly speaking, by comparing performance across administrations on these items, appropriate scale transformations can be estimated and applied. However, actually carrying out the procedure involves a range of technical issues related to both design and analysis (Mazzeo & von Davier, 2014). Note that trend items contribute to proficiency estimation just as nontrend items do. In this regard, a PISA study (von Davier, Yamamoto, et al., 2019) deserves mention. In this study, PISA data from 2000 to 2012 (comprising more than 2 million students) were reanalyzed in a single

linking model to better understand aspects of linking, as well as issues related to model fit. One consequence was improved procedures that maximized the use of trend information over more than two cycles.

Although every ILSA adopts a somewhat different approach to scale maintenance, each faces similar challenges. In particular, designers must consider such factors as the degree of construct representation exhibited by the trend items, the number of trend items, their colocation in blocks, and block placement. Further information can be found in Mazzeo and von Davier (2014) and in the technical reports associated with each ILSA.

Ideally, successive assessments (and the corresponding item pools) are constructed according to the specifications of a common assessment framework. The set of trend items should be both fully representative of that framework and sufficiently large to support stable estimates of the linear regression parameters that transform the current scale into the earlier one. Consequently, it is not unusual for the trend items in paper-and-pencil administration to constitute approximately 50% of the item pool.

For trend items to function as intended, and to minimize the (unwanted) contributions of sources of variation unrelated to the focal domain, the context for each item is held constant to the extent possible. In the case of individual items, their location within a block, as well as the psychometric characteristics and speededness of the other items in the block, should be controlled. An alternative strategy is to employ intact item sets or item blocks from earlier assessments. Although this controls the local context, it may make full construct representation more difficult to achieve. In paper-and-pencil administration, block position within a booklet must also be considered. Further complications arise when considering the different designs employed for administering a single content domain to a student (e.g., PIRLS) or for administering two or more content domains (e.g., TIMSS, PISA). For example, designs for the latter situation possess some advantages from a measurement perspective because they make it possible to take advantage of the correlation of proficiencies between domains. However, they make keeping the within-instrument context for trend items constant more difficult because it is now necessary to also consider the paired domain as part of the context.

Finally, the human scoring of constructed response items must be strictly comparable across administrations. Accordingly, the training of scorers for the current administration must replicate the training conducted in the previous administration. Close monitoring of scorer behavior is essential. One approach is to seed responses with known scores from previous administrations into the current workflow and to compare the scores assigned at the two time points. Systematic discrepancies trigger retraining and rescoring and, occasionally, eliminating the item for the discrepant group.

As is always the case with IRT, there is a fundamental indeterminacy in fixing the latent trait scale after calibration. Either by comparing the item statistics on the trend items in adjacent administrations or by concurrently recalibrating the items in the two administrations, it is possible to resolve that indeterminacy in the newer administration

so that item parameters are placed on the scale established in the earlier administration. A linear transformation then places the performances in the current administration on the reporting scale established at the outset of the ILSA. This process enables valid comparisons of score distributions across administrations.

Notably, there is an underlying tension between scale maintenance and the desire to expand the assessment framework and/or introduce new item types. Similar issues of scale maintenance arise when there is interest in making comparisons across cycles for those scales developed from the background questionnaire. For further details, as well as descriptions of the linking strategies employed by the paper-and-pencil administration associated with the different ILSAs, see Mazzeo and von Davier (2014). It is also typical that each ILSA administration poses unique challenges. For example, TIMSS 2019 saw the advent of eTIMSS, which was administered in about half of participating countries. This new administration necessitated a “bridge study” to link eTIMSS to the standard paper version of TIMSS. Further, a number of less difficult blocks of fourth-grade math items were also introduced with the goal of improving measurement accuracy for lower performing countries. Finally, eTIMSS included items (problem-solving and inquiry tasks) that took advantage of the affordances of digital administration but had no counterparts in the paper version. Carrying out the procedures of scaling and linking in this setting was considerably more complicated than in past administrations. For details, consult Martin et al. (2020, chaps. 11 and 12).

Although all ILSAs are transitioning from paper-and-pencil administration to digitally-based assessments, paper-and-pencil administration versions are likely to be required for some time to come: For some countries, the technical infrastructure is not sufficient to support digitally-based assessments, while in other countries with the appropriate infrastructure, some numbers of respondents will not have sufficient familiarity with technology. Consequently, as noted previously in the case of TIMSS 2019, estimating mode effects (i.e., the impact of administration mode on item parameters and the implications for secondary analyses) is an essential step in effecting the transition (Fishbein et al., 2018). Estimation of mode effects and making appropriate adjustments to place scores from the two modes on the same scale can be technically challenging (von Davier, Khorramdel, et al., 2019; von Davier, Yamamoto, et al., 2019).³⁴

As the operational aspects of digitally-based assessments have become more routine, capacity (and incentive) to introduce novel item types to enhance construct representation has grown. These have included items with new response formats (e.g., ranking, multiple response, drag and drop), as well as various types of interactive items such as simulations that are now used in the assessment of science. In each case, suitable psychometric models must be proposed and the item parameters must be properly calibrated. As the divergence between the paper-and-pencil administration and digitally-based assessment instruments increases, the challenge of placing the scores on the same scale will become more formidable and the results more dependent on model assumptions (see the section “Threats to Relevance” for further discussion).

Inasmuch as digitally-based assessments, especially with adaptive testing, can accommodate larger item pools, trend items may constitute only about 40% of the item pool. In the case of an adaptive assessment, it is critical that all the virtual forms administered contain sufficient numbers of trend items.³⁵ Thus, the challenge of successfully implementing a linking strategy is somewhat greater with this mode of assessment. Down the road, as the digitally-based assessment is administered with a greater range of delivery devices, estimating “device effects” will assume greater importance. Depending on the empirical findings, some restrictions on acceptable devices may have to be instituted.

Measurement Invariance

Issues related to comparability have already been mentioned in the sections “The Messick Framework, Extended” and “Population Sampling Operations.” The latter section addressed the procedures developed to obtain statistically equivalent probability samples across participating countries. Equally important is ensuring that the cognitive scores and the responses to the background questionnaire have comparable meaning across participating countries as well. The terms *measurement invariance* or *cross-cultural equivalence* refer to this notion of comparability of meaning.

Measurement invariance is a term that refers to the degree to which the underlying construct retains the same meaning across different settings. For ILSA, the settings are the different participating countries. In the ILSA context, the requirements for strict measurement invariance are very difficult to satisfy. Indeed, a persistent technical problem is the lack of agreement on how to quantify deviations from measurement invariance at the different levels of stringency. One approach in common use is multigroup confirmatory factor analysis. Although a number of fit statistics are available for such models, as well as for recent refinements, their distributional properties in the context of ILSA data are a subject of ongoing research (Byrne & van de Vijver, 2017; L. Rutkowski & Svetina, 2017; van de Vijver et al., 2019). Van de Vijver (2018) reviewed the recent literature and noted that Bayesian approaches (e.g., Carlin & Louis, 2000) may prove useful in this context. In the interim, psychometricians will continue to employ “rules of thumb” with an admixture of intensive data scrutiny. In the cognitive domain, current procedures, such as freeing the globally estimated IRT parameters for those items judged to have strong interactions with countries/languages, may not be sufficient.³⁶

Van de Vijver (2018) proposed a tripartite framework for evaluating and addressing threats to cross-cultural equivalence: construct bias, method bias, and item bias. In the context of ILSAs, he asserted that with regard to the cognitive domains and, particularly, the scales derived from responses to the background questionnaire, method bias is perhaps the greatest threat to comparability. He cited such issues as variations in response styles, familiarity with the types of questions, and even poor reading skills in school-based ILSAs. In the case of PIAAC, because of the nature of the administration, individual differences in listening skills and aural memory are also potential sources of method bias.

In the case of sample surveys, a number of indicators can quantify the degree of departure from the ideal. Similarly, with regard to measurement invariance, there is a tripartite framework for evaluating the level of measurement invariance achieved (van de Vijver et al., 2019). In order of increasing stringency, the levels are configural, metric, and scalar. There are statistical procedures that can be used to distinguish among the levels and, hence, suggest limitations on the interpretability of the comparisons among countries. (Consult van de Vijver et al., 2019, and the references therein for further details.)

Notably, van de Vijver et al. (2019) also discussed steps that are taken to enhance measurement invariance, particularly with regard to the background questionnaire, where linguistic and cultural differences play an important role. They emphasized the importance of developing consensus-based frameworks (at different levels of generality) to guide the overall design and item development. There is considerable overlap with the presentation in the section “Transitioning to Digitally-Based Assessments.” Item-by-country interactions are addressed by Glas and Jehangir (2013) and von Davier and Bezirhan (2022). Further discussion of threats to comparability is contained in the section “Threats to Relevance.”³⁷

Generating Results

With the reporting scale established, it is possible to obtain estimates of the parameters (e.g., means, variances, and percentiles) of the proficiency distributions of the reporting groups of interest (e.g., gender, socioeconomic status, immigration status). Parameter estimates are obtained by aggregating the PVs of the individuals comprising the reporting group. Typically, an interim (weighted) estimate of the parameter is calculated for each set of PVs, and the final reported estimate is a simple average of the interim estimates.

Variance estimation is not as straightforward inasmuch as the estimated variance of a group-level estimate has two components: one due to sampling and the other due to measurement error. The former reflects the fact that the respondents are a probability sample from the population (group) of interest and that, in a full replication, a different sample would have been obtained. The estimate of this variance component is derived using standard methods for sample surveys with proper attention to the nature of the sampling frame and the corresponding sampling weights. Again, different ILSAs use different estimation strategies (Rust, 2014; von Davier & Sinharay, 2014). The second component reflects the measurement error in the estimation of proficiencies. For a specific group-level parameter, this component is proportional to the average of the squared differences between the interim estimates and the final reported estimate.

Building on the process for instrument design and development, in conjunction with patterns of item responses, it is possible to describe, in substantive terms, the differences among performances at various locations along the scale. Such descriptions contribute to greater interpretability, thereby enhancing the utility of the assessment results to policy makers and other stakeholders (Kirsch, 2001; Mosenthal &

Kirsch, 1991). These methods have been applied to the cognitive scales constructed for PISA and PIAAC.

A somewhat different approach, based on the behavioral anchoring methods first developed for NAEP, is employed by PIRLS and TIMSS.³⁸ With this approach, specific benchmarks along the reporting scale are selected and psychometric analyses are conducted to select items that discriminate between adjacent benchmarks (Martin et al., 2020, chap. 15). Identification of commonalities among the items at each benchmark are then used to provide substantively grounded descriptions of performance at the benchmarks.

Design Issues

In ILSAs, it is commonly the case that multiple proficiencies are estimated or that a single proficiency has been decomposed into some number of facets. In that case, multivariate versions of the latent regression model can be implemented. The overall plan is the same, although the mathematical notation becomes more unwieldy and, more important, the calculations become substantially more burdensome (von Davier & Sinharay, 2014). The benefit, however, is that the analysis can take advantage of the correlations among proficiencies (or facets) to yield more accurate estimates overall.

However, this situation can be a double-edged sword. For example, a difficulty arises if multiple skill domains are assessed but are not evenly represented in the assessments administered to individuals. Suppose that each individual is only tested on a subset of the full set of skill domains. In that case, the appropriateness of the PV obtained for the skill that was not tested is strongly dependent on the correctness of the population (statistical) model. PISA is a case in point. For example, the PISA database contains reading PVs for students who received a test form with mathematics and science tasks—but no reading tasks. For these students, generating the PVs for reading depends on the correlation of reading proficiency with mathematics proficiency, science proficiency, and background variables based on data from those students who received a test form that combined reading either with mathematics or with science.³⁹

Consideration of this issue highlights the difference between tests that provide individual-level scores and tests that provide only group-level scores. In the case of the former, fully model-based scores would generally be unacceptable. In the case of the latter, because of the random allocation of domain question sets across the population sample, most of the individuals comprising the group would have been exposed to items from each domain. For example, in PISA 2018, reading was the main domain. Accordingly, all students took some reading items, approximately 54% took some math items, and approximately 54% took some science items. Consequently, the estimated group mean score will largely reflect the contributions of those data. However, the estimated standard error associated with that estimated group mean score will reflect the increased measurement error due to the cognitive data missing from one third of the group.

Supplementary Considerations

As noted earlier, an important use of ILSA data is the estimation of relationships between proficiencies and background data or contextual factors. By including the corresponding variables in the latent regression (or at least their proxies embedded in the principal components), approximately unbiased estimates of those relationships are obtainable if the model is correctly specified (Mislevy, 1991). Achieving this goal is an important aspect of the rationale for including all available information in the latent regression model.

At the same time, there is continuing pressure to include a larger number of scales in the background questionnaire. One suggestion is to adopt rotated (incomplete) designs analogous to those used in the cognitive instruments (i.e., between-construct rotation). However, unlike the situation for the cognitive scales where the assumption of an underlying latent trait induces a set of useful conditional independence relationships, such an assumption is not feasible for the background questionnaire. Moreover, it is not clear how to modify the latent regression model to accommodate such designs without making strong assumptions of conditional independence, whose failure would seriously compromise the quality of the estimates reported (von Davier, 2014). Nonetheless, efforts are underway to use within-construct rotations for some background questionnaire indices with a large enough set of constituent items.

An additional consideration arises from the fact that, in the context of a digitally-based assessment, it is possible to collect process data, and the log files that are generated can record every keystroke. The sheer amount of such data is overwhelming; research is being conducted on how such data might be compressed into a small number of indicators that could be incorporated into expanded latent regression models to improve estimation accuracy (Bergner & von Davier, 2019; Kroehne et al., 2016; von Davier, Khorramdel, et al., 2019). Another approach would be to use such indicators to assess the quality of the data before item calibration. For example, individuals whose log files suggest aberrant response processes or patterns could be removed. Models for capturing the speed/accuracy trade-off may prove useful here, as well as in secondary analyses (van der Linden, 2007; Yamamoto & Lennon, 2018). See the sections “Impact” and “Technical Challenges” for further discussion.

DATA PREPARATION, DATA PRODUCTS, DATA ANALYSIS TOOLS, AND RELATED ACTIVITIES

At the conclusion of the analysis stage, each participating country receives a set of databases specific to that country. Ultimately, an international database is constructed, combining certain country-specific databases. The sponsoring organizations, countries, researchers, and other key stakeholders employ the international database for a variety of purposes. ILSA contractors, in conjunction with the sponsoring organization and the participating countries, carry out a number of procedures leading to the dissemination

of the data that have been produced. They also engage in activities that promote the use of the data for a variety of purposes. This section briefly describes five key areas of activity: data preparation, data analysis and reporting tools, data products, data security and confidentiality, and data quality.

Data Preparation

Internal Data Processing

The main objective of this stage is to ensure that the data files adhere to international formats, that the data accurately reflect the information collected by each country, and that the different survey files can be linked appropriately. Upon receipt of the national databases, the contractor archives the data to a preliminary international database. The initial review of the national databases includes the evaluation of the supporting documentation and the required consistency among data sets. Each country is consulted during this step so as to address any issues or concerns.

Once the data files have been made consistent with the international database structure, as specified in the international codebooks, a set of programs is applied to conduct “data cleaning.” This process consists of three activities:

- checks related to the identification codes associated with the variables;
- checks related to linkage of variables within a data set and records between data sets, with particular attention to any discrepancies between the observed and expected data patterns; and
- checks related to cognitive and background variables.

Further quality reviews of the submitted data sets are conducted according to the technical standards and guidelines that are associated with each ILSA. These occur at multiple stages of the data preparation workflow. Typically, the contractor supports countries in issue resolution and uses an automated reporting mechanism to communicate with countries regarding the status of data submissions, quality review, and any data quality issues encountered. Once data cleaning and restructuring are completed, the files that include sampling information and the sampling weights are merged into each national database.

Creation of Derived Variables

After the international variables have been harmonized and all data validated, a set of derived variables is computed and added to the data set. A derived variable is typically constructed by combining two or more variables, resulting in a new variable or a scale score. These variables are fully documented, as required for further analysis and reporting activities. Derived variables undergo checks using state-of-the-art quality control methods.

Simultaneous with the creation of the derived variables, the cases in the data file are inspected to ensure that they are appropriate for inclusion in the data file. As a part of this evaluation, case sampling weights are computed and linked to the cases.⁴⁰ This

augmented data file is merged into the preliminary international database to yield a fully integrated international database (master database). Extracts from this database are then sent back to each country for its own use and forwarded to those responsible for data analysis.

Analysis and Reporting

Preparation of Databases

To support the export of data products meeting the needs of various users, different data versions can be generated. These usually comprise three files:

1. The national file submitted by the country and processed by the sponsoring organization. This file has all the data collected within a country, including additional subpopulations and variables that were part of the national data collection activities and samples. These files are typically only available from the national center and only to the sponsoring organization and the contractors.
2. A restricted user file with all the variables and cases intended for use in international comparisons. This file is typically used for secondary analyses. It is published by the sponsoring organization and usually available provided assurances of confidentiality are made by the user.
3. A public user file (PUF) contains all the variables and cases intended for use in international comparisons but might have some variables or values for them suppressed or masked. The intention of suppressing or masking values is to prevent the identification of participating individual or subgroups (i.e., schools, neighborhoods). These PUFs are posted on the Internet and can be accessed and used with no restrictions.

Once these databases are completed and have undergone preliminary quality control, standard programs are applied to generate multiple tables that will ultimately appear in technical reports and other documents associated with the ILSA.

Preparation of Public Use Files

Following the initial data-cleaning process, an iterative process of data review and correction takes place—initially among the contractors and later involving the participating countries as well as the sponsoring organization. By default, the PUFs maintain all international variables approved for release. They only include those records that fulfill criteria set for cases to be used in weighting and analysis.

Some procedures are specific to the sponsoring organization. For example, for OECD ILSAs, any and all national variables identified by a country for deletion are dropped. In addition, all international variables earmarked for suppression by a country are blanked (i.e., set to the appropriate missing value for all cases). By contrast, for TIMSS and PIRLS (sponsored by IEA), national variables are typically not included in the international database, but are made available to the nation asking these additional questions so the data can be merged. However, the international source versions

of context questionnaires can include items specifically created for that purpose. As an example, a small number of international variables can be provided for countries to include additional home possessions variables that could contribute to an indicator of socioeconomic status. These variables are labeled “country specific” in the database, and their English back translations are listed in a National Adaptations Database included with the user guide. Any context variables earmarked for suppression by a country are blanked. However, cognitive items may be first reviewed in consultation with the country. All such cases are documented in the user guide or in the technical report.

Each country’s database is included in the following types of electronic files:

- Data files in SAS and SPSS formats, with separate files for each respondent (student, teacher, principal, parent). Other formats are available for different ILSAs. This file (or multiple data files containing appropriate linking information and instructions) will contain all the variables approved for release to the public.
- For PISA and PIAAC, a data codebook document file in either PDF or EXCEL format. This two-part document contains a brief listing of the name, position, format, and description of each data variable, plus an expanded listing for the discrete variables that have coded information, including their code values, descriptors, and (unweighted) frequencies within each data set.
- For TIMSS and PIRLS, a codebook that provides a list of variables with the corresponding labels and formats. Additional information about variables is provided in the user guide or in the technical report. Finally, data almanacs contain frequency distributions and summary statistics for all variables.
- For TIMSS and PIRLS, a software package (IDB analyzer) is available for R, SPSS, and SAS versions. It is updated to include special routines to load and analyze data from IEA assessments.⁴¹
- Documentation that describes the contents and structures of the data files, explains how to employ the other resource files in the product, and provides the technical information needed to support users in conducting analyses of the data. This includes the names and uses of the key variables in each data set, as well as indicators of sample quality (e.g., response rates).

Preparation of Data Tables, Compendia, and Reporting Tables

SUMMARY TABLES FOR COGNITIVE ITEMS AND BACKGROUND VARIABLES One set of tables contains weighted summary statistics for each participating country on each cognitive item and on each variable in the background questionnaires. For the latter, summary tables display the international averages for each variable, with each country weighted equally. For each variable, the summary tables display the question that was asked, the location in the corresponding questionnaire, and the variable name in the data file. Note that the table format depends on whether the data are categorical or continuous.

The cognitive data summary tables (sometimes referred to as item analysis tables) contain summary information about the responses to the cognitive items. For each country, they contain weighted summary statistics, including variable identification, sample size, number of valid cases, weighted percentages of individuals corresponding to each valid response, weighted percentages of individuals who did not select any of the valid response options, and the average score on each of the cognitive domains. Standard errors are also included, where applicable. The item analysis tables are used by both the team and countries for further quality control, verifying data structure accuracy, and validation purposes.

Unweighted item analysis results are also generated because they are particularly useful in verifying the accuracy of the data structure. When necessary, for internal quality control, the team may produce separate analyses to compare item statistics for respondent groups taking different modes of assessment (for example, paper-and-pencil administration and digitally-based assessments) or for respondent groups determined by selected background variable categories.

COMPENDIA Using the international restricted user file and PUFs as the source data, compendia are sets of tables that provide the distribution of students or adults according to the variables collected by the questionnaires. The public version is essentially a redacted version of the summary data tables. The purpose of the public compendia is to support PUF users so they can better appreciate the contents of the PUF and, importantly, use the compendia results to verify that they are performing PUF analyses correctly. For confidentiality reasons, some countries may decide to alter their data or remove respondent records from their PUF files. In such cases, individual country summary statistics reported in the compendia may differ slightly from statistics used for international reporting.

INTERNATIONAL REPORT TABLES These report tables are publication-ready tables that support the international report. Typically, approximately 350–400 international report tables of varying length and complexity are generated. These tables can be used directly by the sponsoring agency or by countries as a means of quality control if they choose to conduct their own analyses and table production.

Preparation of the Technical Report

The technical report summarizes and describes all aspects of the study, including development of the frameworks for the background and context questionnaires, as well as for the cognitive domains; design and development of the survey instruments; development of the computer platform to manage, develop, and deliver the survey; translation and verification processes and procedures; survey operations and quality control procedures; sampling and weighting, data collection, and data processing; scaling, analysis, and preparation of data products; and reporting the results.

The technical report also includes any additional information related to the implementation of the psychometric and statistical methodologies at a level of detail that allows researchers to understand and replicate the analyses. To the extent possible, the report also addresses a range of common questions that both more and less advanced users of these complex databases might pose.

Tools and Training

A number of publicly available tools have been developed for use by countries, sponsoring organizations, and secondary researchers. For ILSAs sponsored by the OECD, two tools are available: One is a Data Explorer that allows users to navigate a secure, hosted database that includes all assessment cycles. The second is the IEA's International Database Analyzer (IDB Analyzer) that was adapted to work with OECD ILSAs. It enables local computer access and analysis of public-use and restricted-use databases.⁴²

Each tool addresses a slightly different set of needs and audiences. The Data Explorer is a web-based application that is usually hosted either by the sponsoring organization or by a government entity. It protects the underlying database while allowing relatively easy point-and-click navigation of the database to generate publication-ready summary cross-tabular tables and graphics.

The IDB Analyzer can be used in conjunction with restricted-use or public-use versions of the international database and uses microlevel data stored in a local computer (IEA, 2021). The IDB Analyzer satisfies the three main technical requirements that an analysis of these data must meet. They are (a) the use of sampling weights, (b) accommodating in variance estimation the complex multistage cluster sample design that was implemented, and (c) the use of multiple imputed proficiency estimates (i.e., the PVs).

Most commonly, the analyzer is used to generate data tables and graphs, as well as to execute either normal theory regressions or logistic regressions. The primary benefit of employing this tool is that it efficiently performs the required analytical computations, thus relieving the user of the programming burden. This process is especially critical in the computation of variances of estimates. In addition, the tool is accompanied by sufficient technical information and references to support both more- and less-advanced users in performing statistically correct analyses of the complex survey sample data.

To enhance data utility, sponsors and contractors organize and conduct workshops in various venues with different cost structures. The workshops focus on understanding the structure of the international database, the use of the IDB Analyzer and the Data Explorer, or other tools including standard statistical software. The participants in these workshops include staff from each participating country and interested representatives from the sponsoring agency. The sessions are arranged and coordinated by the contractor using staff members who are involved in or knowledgeable about the project design, the database preparation, and the appropriate analysis of the international data. The goals of the workshops are to help the representatives from each participating

country to understand the strengths and limitations of the data and to ensure that they are comfortable using the analytic tools that will be available and will report the results of the analyses with the relevant context and appropriate cautions.

In addition, the contractor or other organizations offer countries or interested researchers a fee-based option to organize and conduct regional workshops based on country-specified topics dealing with the technical aspects of using and analyzing a particular database. Additional workshops, presented under the auspices of the IEA–ETS Research Institute, the Institute for Education Sciences (U.S. Department of Education), and international donor organizations, are intended for interested researchers to expand the pool of knowledgeable users.⁴³ For example, the Institute for Education Sciences funded a multiyear set of training workshops on the use of the PIAAC data that resulted in dozens of research projects and publications. In addition, the IEA has constructed a website containing information about many ILSAs.⁴⁴

Data Security and Confidentiality

Data protection and confidentiality are essential to the conduct of all major ILSAs. Organizations wishing to conduct these types of assessments must comply with the national requirements of participating countries, along with international requirements associated with entities such as the European Union. Typically, all staff who work with these databases are required to sign a statement that they have read the information protection policy and that they understand and agree to abide by its provisions.

A growing number of organizations have adopted the International Organization for Standardization (ISO) 27000 series as their information security framework. ISO 27000 is an international series of standards that drives all aspects of the information security program and the way services are delivered. In the future, any organization wishing to develop or implement ILSAs will have to demonstrate that it is following applicable legal and regulatory obligations, with particular attention to the protection of personally identifiable information.

Typically, ILSA contractors have adopted stringent security policies, standards, and practices to maintain the confidentiality, integrity, and availability of data. These controls are continually reviewed to ensure they align with industry best practices. In addition, contracting organizations need to support secure transfer protocols, including file-based technologies to securely exchange data over the Internet. This enables them to effectively manage and protect data transmissions with secure file transfer protocol.

Data Quality

International large-scale assessments are complex surveys that require the development of a set of procedures for all major phases to help ensure that the sources of bias and variability in survey results are kept to a minimum so that reported results are relevant, comparable, and interpretable. Here, we distinguish two ways in which large-scale assessments address issues of data quality: the technical standards and guidelines that are developed and/or refined at the beginning of any assessment and the data

adjudication process that is conducted at the completion of the data collection and analysis process.

Technical Standards and Guidelines

At the beginning of each ILSA cycle, the ILSA team collaborates with the sponsoring organization and participating countries to develop and/or refine a set of technical standards and guidelines to ensure that all aspects of the survey satisfy accepted quality assurance guidelines. These standards and guidelines represent policies or best practices that must be adhered to in the development and conduct of the survey. Where compliance is not possible, countries may apply for derogations from the standards, as long as they are judged not to compromise the survey objectives. The overarching goal is to minimize total survey error (see the section “Population Sampling Operations”). The standards and guidelines cover a wide range of topics, including ethics, sampling, instrumentation, translation and adaptation, the use of hardware and software (if it is a technology-based assessment), data collection and training, data capture and processing, and data confidentiality and security.⁴⁵

Data Adjudication

Compliance with the technical standards and guidelines is an important component of ensuring the quality of the national data through the various stages of the workflow. At the conclusion of the workflow, yielding the databases described previously, data adjudication is implemented. Its objective is to render a judgment regarding the overall quality and fitness of the data of each country and to impose, if necessary, any limitations that should apply to the public dissemination and use of these data. In other words, the intent is to go beyond compliance with the standards and guidelines and determine whether the national data are of a sufficient quality to support their intended interpretations and uses. Adjudication typically involves three key areas: sampling and coverage of the target population, data collection and instrumentation, and quality of the translation/adaptation procedures.

For the OECD programs, the contractors develop an adjudication report that is reviewed and discussed at the final meeting of the Technical Advisory Group. If questions arise during the meeting, a sampling referee is available to offer advice as needed. The Technical Advisory Group then prepares a final set of recommendations to the sponsoring organization regarding the fitness of the data for publication. For IEA programs, the adjudication is carried out by a team comprising the different contractors and IEA staff.

IMPACT

Messick (1987) argued that large-scale assessments are a type of policy research and should be judged as such. In that light, if we regard policy utility as having the potential to inform, influence, or impact policy, then it is reasonable to ask to what extent—and

in what ways—that potential has been realized by ILSAs. As noted in the section “The Messick Framework, Extended,” the overall judgment of the potential for policy utility is dependent on evaluating the strength of an ILSA with respect to the design criteria of comparability, interpretability, and relevance—along with due regard to purpose, context, and the population(s) of concern. For the most part, users of ILSA results assume that the level of comparability is at least adequate for their purposes and that they (or their staff) have reached appropriate and defensible interpretations of the data. Ultimately, the judgment of relevance provides at least part of the motivation to cite the data in discussions and policy debates. However, the contexts in which ILSA data are employed and their actual impact on education policies and practices are the result of complex dynamics that vary widely over time and space. Thus, the evaluation of impact requires considering a broad range of cases from which a few generalizations can be gleaned.

Background

To best address the question of impact, it is helpful to both distinguish different types of impact and then systematically evaluate the various kinds of evidence that are available. In this regard, D. Rutkowski et al. (2020) presented a framework for evaluating ILSA influence on policymaking. The framework comprises a causal model for tracing the impact of ILSAs on a particular policy and a logic model for evaluating the evidence for such impact.

Drawing on D. Rutkowski et al. (2020), we define impact as occurring when it is possible to connect (in some way) ILSA data, technical reports, or secondary analyses to changes in policy and/or practice in a participating country or even shifts in the content of conversations about policies in education, workforce development, or labor market regulation at the national or cross-national levels. However, as Wagemaker (2014) pointed out in discussing school-based ILSAs, it can be problematic to judge policy impact because

major policy initiatives or reforms are more likely to result from a wide variety of inputs and influences rather than from a single piece of research. Research is also more likely to provide a heuristic for policy intervention or development rather than being directly linked, in a simple linear fashion, to a particular policy intervention. (p. 12)

Two further challenges are (a) a frequent time lag between ILSA reports and policy decisions and a further lag between policy initiation and its effect (if any) on measured achievement or skills and (b) variations in policy implementation across the target units within a country that can reduce estimates of policy impact (Braun et al., 2006; Burdett & O'Donnell, 2016). Thus, correctly judging impact involves triangulating different kinds of evidence, including statements of key actors, stakeholders, and others as to the role of ILSAs in policy decisions, formulations, and implementation (Fischman et al., 2019). Accordingly, we discuss two types of impact: direct and indirect.

Direct Impact

Direct impact occurs when results released to the public (appear to) have a relatively clear, and even immediate, influence on policy makers' discussions, priorities, and actions. Some actions may address governance and funding; others relate to curriculum, teacher training, pedagogy, and assessment; and yet others involve achieving greater harmonization across different units within the education system.

The literature on school-based ILSAs is replete with examples of how ILSA results precipitated intense discussions that led to substantial policy changes. Perhaps the most celebrated example is the impact of PISA 2000 results on Germany (Ertl, 2006). The relatively poor performance of German students (following their poor performance on TIMSS 1995) resulted in unprecedented cooperation among the federal government and all the German states, leading to changes in curriculum and assessment. The need for such changes was supported by results from PIRLS 2001, which indicated that children from immigrant families on average performed substantially more poorly than their peers. In response, the national research agenda shifted toward more empirically based studies with direct relevance to practice (Schwippert, 2007).

However, Pons (2017) suggested that this type of analysis may be too simple. He argued that before reaching a judgment on the "PISA effect" (or its equivalent), it is necessary to consider multiple factors, including the prior policy context and education-related political debates. On this point, he asserts, "PISA uses in the policy process greatly depend on the dynamics of the domestic policy debate and on the preexistence of specific structuring controversies that PISA results illuminate in a new way" (Pons, 2017, p. 139). This is consistent with the perspective offered by Ritzen (2013) and Braun (2013). Indeed, there are many types of "policy borrowing," ranging from fairly direct adoption to adapting certain policy features as part of a broader policy formulation (Burdett & O'Donnell, 2016).

Heyneman and Lee (2014) cited additional examples of direct impact in countries as diverse as Denmark, Macedonia, Kuwait, and Japan. They also provided an extensive list of direct impacts on policies in other countries, as well as on subject-specific policies and practices. Less noticed, but perhaps equally important, ILSA results have also been used to provide support for existing policies. Heyneman and Lee (2014) cited the example of PIRLS 2001 in England. The relatively strong performance of English students was used as evidence of the effectiveness of the National Literacy Project that was introduced in 1996. Similarly, the performance of students in Australia and New Zealand on PISA has been taken as support for existing educational policies. Breakspear (2012) called out countries such as Singapore and Spain that use PISA to complement (and to validate) the results of their national assessments. Canada participates in most ILSAs, often with oversampling, and makes systematic use of the results to guide policy at the national and provincial levels (Volante, 2013).

Singapore represents an interesting case study (Ng et al., 2020). Singapore has participated in IEA studies since the 1990s and employs ILSA results to inform curriculum and pedagogy, as well as to evaluate the efficacy of various reforms. The authors stress,

however, that these results are only one of many sources of evidence that policy makers and education leaders consider in deciding on policy strategies and education initiatives. They also note that to discourage score corruption, the Ministry of Education uses the scores only to inform system-level decisions and not for any form of accountability.

Baird et al. (2016) conducted an intensive study of the impact of PISA on six countries.⁴⁶ Based on both a comprehensive document review and multiple interviews, they concluded that in five of the countries (excluding England), some of the policy changes could reasonably be attributed to the impact of PISA results. For example, the two federal systems (Canada and Switzerland) initiated a process of greater harmonization of achievement standards and assessments across provinces and cantons, respectively. In the case of France, PISA prompted substantial curricular changes, as well as initiation of a sample-based national assessment modeled on the ILSA design.

With regard to PIAAC, there is little evidence of direct impact. On the one hand, this may be because different ministries focus on one or another aspect of the results and then evaluate them in light of other relevant information, as well as political considerations. On the other hand, the assessment of adults' cognitive skills, as well as their distribution at different levels of educational attainment, has proven revelatory.

Indirect Impact

Indirect impact occurs in a variety of ways. First, ILSA findings may be used to justify, legitimate, or build public support for policy prescriptions that have already been formulated and even initiated (Fischman et al., 2019). Second, the results of one or more ILSAs over multiple cycles can change the nature of the discourse regarding important aspects of education, skills, and skill development. In addition to the achievement results themselves, subsequent to the release of the PUFs, analysts delve into the ILSA databases to investigate patterns of relationships and how they differ across countries and over time.

The comparative findings can influence policy discussions regarding the need to remedy apparent deficits or inequities. In other cases, researchers attempt to draw inferences regarding the efficacy (or lack thereof) of particular policies or constellations of policies with regard to certain outcomes. Yet others seek to draw attention to possible unintended consequences of employing ILSA data in policy discussions. Such secondary analyses, whatever their nature, appear years after the initial release of the data. Nonetheless, the findings and interpretations may also influence the discourse related to particular policies and, in some instances, even provide the impetus for changes in policy or practice.

As noted earlier, ILSAs have experienced increased participation by medium- and low-income countries. Undeniably, there is some element of coercion by funders. However, in addition to providing critical policy insights and guidance, there are many other salutary benefits. These include constructive changes in regulatory policies (e.g., curriculum content, performance standards) and in so-called behavioral policies (e.g., pedagogy, educator professional development; Lockheed, 2013; Wagemaker, 2014).

A particularly important benefit associated with participation in school-based or adult assessments is the contribution they make to capacity building. By participating in an ILSA, country representatives and technical experts receive extensive training and support in all aspects of managing and conducting large-scale assessments (Meinck et al., 2020). These experiences and the expertise gained can then be used not only in future ILSAs, but also in improving (or initiating) national assessments that are directly targeted at informing education policies of greatest priority. Lockheed (2013) cited numerous self-reports of such impact.

Since 2003, participation in the ILSAs that focus on adults has grown in tandem with a marked shift in focus among policy makers who have moved from viewing educational attainment as an appropriate proxy for skills to recognizing the added value of comparable and valid/relevant measures of skills of interest.⁴⁷ One reason is the accumulating evidence that there are substantial economic returns to skills beyond those accounted for by educational attainment or years of education (Fogg et al., 2018; Hanushek et al., 2015; Kirsch et al., 2007). Such findings not only enhance policy interest in tracking skills, but also highlight the societal perils in tolerating extreme inequalities in skill distributions. Consequently, in many countries, finding ways to accelerate skill growth while reducing inequities have become policy imperatives—fueling greater interest in studying the policy initiatives of “high-flyers” (i.e., those countries at the top of the league tables or those who have experienced large gains over two or more cycles).

Indeed, greater attention in the media and the exponential increase in Internet searches related to ILSAs are testament to their growing role around the world in discussions of education policies and practices. As Ritzen (2013) pointed out, the comparative outcomes derived from ILSAs make these assessments powerful instruments of transparency. Their findings can jumpstart (or accelerate) national conversations regarding quality and equity in education or in labor market dynamics. Over time, such conversations, particularly at the policy level, can lead to shifts in perspectives, new understandings, and the realization that far-reaching system changes are not only possible but also much needed (Conaway, 2020).

Secondary Analyses: Exemplars

There has been an increase in the number and range of researchers using ILSA results for studies addressing important policy issues, with a concomitant increase in the utilization of the IEA's IDB Analyzer. Pons (2017) provided a useful review and analysis of articles employing PISA data. With respect to adult assessments, Maehler et al. (2020) compiled a bibliography of published papers between 2008 and 2019 covering a range of topics including research results associated with PIAAC assessment. Since 2013 when the PIAAC data were first released, the number of publications has increased annually. The current bibliography contains more than 600 publications and 21 technical reports. More generally, the IEA gateway (<https://ilsa-gateway.org/studies/papers>) contains a comprehensive list of articles employing both IEA- and OECD-sponsored ILSAs. For a more recent integrative review, see Hernández-Torrano and Courtney (2021).

Among the issues considered in these analyses are skill gaps within and among participating countries. Of particular import are studies comparing countries with respect to the gradient of performance against a measure of socioeconomic status.⁴⁸ Although a gradient exists in every country among school-age children (i.e., mean performance being positively correlated with a measure of socioeconomic status), there is a wide range of gradient values, some strikingly large (OECD, 2019, chap. 2). As it happens, the gradient in the United States is typically the largest among OECD countries.

There are similar findings for adult populations. For example, Goodman et al. (2015) examined the skills distributions and inequality among millennials in the United States with respect to their overall performance, as well as in comparison to other countries participating in PIAAC. For the United States, the authors considered differences in skill distributions by factors such as educational attainment and race/ethnicity. With regard to gender differences, Braun (2018), employing PIAAC data, demonstrated that in every participating OECD country the earnings of women employed full-time trailed those of men employed full-time, even after adjusting for age, family background, cognitive skills, educational attainment, and occupational category. Again, the degree of disadvantage varied widely across countries. In an empirical study using PIAAC data, Vera-Toscano et al. (2017) demonstrated that, over and above educational attainment, measured cognitive skills have incremental predictive validity for social outcomes such as participation in volunteering activities.

Strietholt and Scherer (2018) argued that combining different ILSAs or linking ILSAs to other data sets increases the range of research questions that can be addressed. They cite, for example, the study by Martin et al. (2013) that took advantage of the conjunction of PIRLS and TIMSS in 2011. Through careful planning, 34 countries and 3 benchmarking countries administered PIRLS and TIMSS to the same fourth-grade students. Thus, each student generated data on skills in reading, mathematics, and science and responded to background, attitudinal, behavioral, and school context questions. Among other things, the authors found substantial heterogeneity across countries in the amount of variation in the cognitive outcomes accounted for by various background variables. By contrast, within countries they found typically small differences in the amount of variance explained across cognitive domains.

Strietholt and Rosén (2016) offered an example of combining different assessments over time. Specifically, they linked the Reading Comprehension Study 1971, the Reading Literacy Study 2001/1991, and PIRLS 2001, 2006, and 2011 to study reading trends over a span of 40 years.⁴⁹ Hanushek et al.'s (2015) study cited previously involved combining data from PIAAC with income data obtained from various national and international sources. In summary, the results of cross-national, comparative assessments, as well as the studies that employ those results, can provoke useful discussions among researchers and stakeholders that likely would not otherwise take place.

Technical Issues in the Study of ILSA Impact

As this section and the references therein have amply documented, ILSAs have had considerable indirect and even direct impact on education and skill development policies around the globe. However, the process of policy formulation, adoption, and implementation has a strong political component that can dominate the influence of ILSA data and related secondary analyses. Indeed, as already noted, impact depends on the readiness of the relevant national actors to take account of the information provided, to decide on which action(s) to take, to articulate policies and plans, and to commit both the necessary funding and the political capital to implement these policies. ILSA information is just one source of evidence (or pressure) among many that can motivate or drive educational change.

Notwithstanding these political realities, technical considerations should (and sometimes do) urge caution on ILSA interpretations and impact. In the early 2000s, critics of ILSAs typically focused on technical deficiencies related to sampling and translation/adaptation that, in their view, substantially reduced ILSA utility (Bracey, 2008; Goldstein, 2004). Later, focusing on PISA 2012, L. Rutkowski and Rutkowski (2016) undertook an analysis of these technical issues with regard to their implications for defensible interpretations of the results and the use of those results in policy discussions. Their principal recommendation was that sponsors should be fully transparent regarding the bias and uncertainty (variance) associated with published results and their implications for the interpretation of such results. Despite the significant improvements in PISA technical quality achieved since then, as well as those realized with other ILSAs, the cautions and recommendations offered by the authors should be borne in mind by both sponsors and users of all ILSA results.

For example, the assumption of cross-national comparability of domain scores and responses to the background questionnaire is only an approximation (see the section “Measurement Invariance”). Consequently, conclusions should be tempered by an acknowledgment that for a particular analysis the assumption may not hold for some countries to an extent that renders the conclusions suspect, at least for those countries. Such cautions may limit the impact or even the influence of the study. On this point, it is beneficial (if not essential) that participating countries have the “in-house” expertise to analyze their data, to explain the findings to various stakeholders, and to contribute constructively to policy conversations. Participation in ILSAs has stimulated many countries to invest in developing such expertise, along with the infrastructure required to support high-level methodological research.

More broadly, success in policy borrowing is difficult to achieve. Education systems are complex: They comprise many component systems with complicated and shifting dynamics. Identifying a particular policy or practice as a key driver of academic achievement may neglect concomitant factors or conditions that are essential to its effectiveness. Even if the identification is approximately correct, adapting the policy or practice to a setting that differs in many relevant ways (e.g., power dynamics, traditions and culture of schools, resources) is

challenging. In the course of technical adaptation and responding to political pressures, the essence of the innovation may be “lost in translation” (Burdett & O’Donnell, 2016).

Furthermore, the information provided by an ILSA is typically more narrowly focused than the general questions posed by policy makers (D. Rutkowski & Delandshere, 2016). For example, policy makers would like an answer to the question of whether observed differences in achievement among countries can be attributed to differences in education policies. However, as pointed out by Braun and Singer (2019),

Although it is the kind of question policy-makers often view as most relevant, most methodologists agree that ILSAs are ill-equipped to provide unambiguous answers. Cross-sectional data based on samples without random assignment of subjects into experimental and control groups do not lend themselves to valid causal inferences. Attempting to infer causation from correlation, even when correlations are high, can lead to false, incomplete, or misleading conclusions. (pp. 79–80)

Because the successful implementation of educational policies across so many different contexts depends on a broad range of relevant factors, both educational and otherwise, it is exceedingly difficult to disentangle the influence of these factors with cross-sectional, observational data. Table 20.2 displays six possible uses of ILSA results with judgments on the general suitability of ILSA data for such uses. Evidently, suitability declines as the uses shift from description to inference.

Table 20.2 Purposes of School-Based International Assessments

Item	Purpose	Capacity of ILSAs to Achieve This Purpose
1	To disturb complacency about a nation’s education system and <i>spur education reforms</i> .	Outstanding
2	To <i>describe</i> and <i>compare</i> student achievement and contextual factors (e.g., policies, student characteristics) across nations.	Excellent
3	To <i>track changes over time</i> in student achievement, contextual factors, and their mutual relationships, within and across nations.	Excellent
4	To <i>create de facto international benchmarking</i> , by identifying top-performing nations and countries, or those making unusually large gains, and learning from their practices.	With caveats
5	To <i>evaluate</i> the effectiveness of curricula, instructional strategies, and education policies.	With extreme caution
6	To <i>explore causal relationships</i> between contextual factors (demographic, social, economic, and educational variables) and student achievement.	Dangerously difficult

Note. ILSA = international large-scale assessment.

D. Rutkowski and Delandshere (2016) argued that causal claims based on ILSA data should be critically evaluated through the lens of a validity framework comprising four facets: construct validity, internal validity, external validity, and statistical conclusion validity. The findings of such an evaluation can be quite sobering, as the examples cited by the authors attest. In general, causal claims can be buttressed both by an *a priori* theory of action and by an argument of the comprehensiveness of the observed variables included in the analysis. Nonetheless, such claims must remain tentative until other supporting evidence comes to light (Singer et al., 2018).

That said, even though ILSAs rarely permit causal inferences, their findings can reveal striking patterns, raising issues that can be carefully examined through further empirical studies. This caution is particularly relevant in moving from tentative causal descriptions to credible causal explanations, with the latter being more relevant to policy decisions and actions (D. Rutkowski & Delandshere, 2016). In this regard, small-scale experimental studies that demonstrate the importance of certain interventions or strategies can then be more broadly validated within and across national samples.

Some Extensions to Discerning Impact

It is sometimes possible to take advantage of auxiliary information to circumvent the limitations of cross-sectional studies. One strategy employs an instrumental variable to obtain an estimate of a causal effect. Unfortunately, it is usually difficult to find a suitable instrument, especially in an international context. Pokropek (2016b) presented one example using data from Poland. Another example was offered by Bedard and Dhuey (2006). They employed school entry cutoff dates as an instrument to estimate the impact of delayed entry into schooling (see also Marchionni & Vazquez, 2019). In other settings, regression discontinuity designs may also prove useful (Robinson, 2014).

A different approach is to conduct true longitudinal studies in which individuals participate in related assessments on two or more occasions. Differences in outcomes can be linked to differences in treatments (or other factors) to yield causal estimates with some degree of credibility. Carrying out such studies always poses substantial technical, logistical, and sometimes ethical challenges, especially in an international context. One strategy is to construct a pseudo-longitudinal study by concatenating different assessments suitably spaced in time. Kaplan and McCarty (2013), employing data for PISA and Teaching and Learning International Survey (TALIS) from Iceland, examined a number of methods for creating a synthetic data file. At the national level, there are a few instances of such studies. In Denmark, for example, a subsample of the PISA 2000 sample was interviewed and tested as part of PIAAC 2012. By linking the assessment data to data from administrative registers, the author was able to account for some of the variation in individual rankings between assessments in terms of both fixed and varying characteristics of the individuals (Rosdahl, 2014). However, the possibility of construct shift suggests caution in interpretation.

An alternative is to combine data from successive cycles of the same assessment (e.g., PIRLS 2016 with PIRLS 2021) and relate changes in the assumed causal agent with observed changes in achievement. This feature has been exploited by Gustafsson (2013), Gustafsson and Nilsen (2016,) and Hooper (2017). The basic idea, attributable to Gustafsson, is to employ the difference-in-differences methodology at the national or subnational level. Needless to say, the validity of the causal claims depends on building the counterfactual case that changes in achievement can only be due to the changes in the hypothesized causal agent. In the differences-in-differences methodology (Cunningham, 2021), other plausible causes are discounted by means of the parallel trends assumption, where trends between similar populations (e.g., countries) are expected to be parallel if an effective causal agent is not present. Parallel trends between similar countries (e.g., Sweden, Norway) occur frequently in economic data where higher level economic trends (e.g., global economy) have a strong influence on lower level economies (e.g., national economies). Parallel trends are less common in international assessment data, where cycle-to-cycle fluctuations in achievement results do not tend to follow a similar pattern across countries, making it more difficult to assume that deviations from parallelism are due solely to the presumed cause. Given the demand for credible policy evaluation, these and other methods are the subject of continuing research.

The study of correlates of student achievement is of long-standing interest. Because TIMSS and PIRLS sample students by class, collecting data on students and their teachers, they provide an opportunity to link teacher characteristics and teacher practices to student achievement at an international level. However, because student achievement is cumulative, its association with teacher characteristics in a particular year may be quite weak. Comparisons among countries with regard to both teacher practices and student achievement can be suggestive of directions for further investigation. O'Dwyer and Paolucci (2019) discussed what has been learned, along with a careful analysis of the obstacles to making inferences about causal relationships.

The challenge of addressing questions regarding the efficacy of reform initiatives with ILSA data has engendered considerable ingenuity among methodologists, leading to new analytic strategies. Similarly, as the section “Transitioning to Digitally-Based Assessments” amply demonstrates, ILSA teams have harnessed emerging technologies to construct innovative platforms to carry out the processes that undergird the ILSA programs. These innovations have enabled the ILSA teams to meet the ever-increasing demands of sponsors and countries while meeting constraints of time and cost. Both developments exemplify the virtuous spiral (Figure 20.2). In the section “History of International Assessments” we noted that the ETS proposal to reinvent NAEP (Messick et al., 1983) represented a creative response to policy makers’ demands for NAEP to provide data that were both more relevant and more interpretable. Certainly, as the global landscape continues to evolve and as ILSAs yield more useful insights, new demands will arise necessitating further innovation. Accordingly, the following two sections discuss some of the technical and political challenges that ILSA teams will likely face in the coming years.

TECHNICAL CHALLENGES

Notwithstanding the remarkable growth in ILSA participation since the 1990s, as well as the bright prospects for ILSAs with a future based on digital platforms, program sponsors and contractors will be confronting a number of technical challenges to policy utility. Many of these challenges arise from the need to maintain (or even enhance) relevance as the context of use and the intended applications continue to evolve. With the corresponding changes in the assessment frameworks, instrument development, and mode of administration comes the need for additional evidence to support validity claims.

Indeed, an underlying theme of this chapter has been the assurance of validity of interpretation and use within a policy setting. A judgment of validity must be made with due regard to the context of use and the particular purpose(s) for which the results will be employed (Kane, 2013, 2016). Much of the relevant evidence is contained in the technical reports that accompany each ILSA and has been discussed in various sections of this chapter. The section “Transitioning to Digitally-Based Assessments,” for example, describes the key phases of the workflow processes, including the specification of the frameworks that guide the development of the instruments and the accompanying quality control procedures that are applied during assessment development, translation/adaptation, and implementation. These methodologies, along with the data generated through monitoring their implementation, constitute evidence for “procedural validity,” forming a foundation for a validity argument.

Similarly, the section “Scaling, Population Modeling, and Proficiency Estimation” provides an overview of the statistical and psychometric models and procedures that transform the raw data into the published results. The mathematical and verbal representations of these models and procedures make explicit the strategies employed to take account of ILSA design features (e.g., planned missingness, group-level reporting) in generating the results. Thus, these strategies can be—and have been—subjected to critical review and ongoing refinement to support the validity claims.

The section “Policy and Political Challenges” addresses some of the political challenges ILSA sponsors and contractors face with the greater salience of ILSA results in national and global educational policy debates. Much of that discussion can be framed in terms of the consequential validity of ILSAs, which is essential to the role of ILSAs as policy research and can sometimes become politicized and highly charged. In contrast, this section focuses on issues having more to do with construct validity (Messick, 1989).

We now review some of the technical challenges confronting ILSAs, using the extended Messick framework to organize the discussion. At the same time, it is important to recognize that challenges represent not only problems, but also opportunities. By appropriately meeting these challenges, ILSAs can continue to traverse the virtuous spiral (Figure 20.2), developing in ways that enhance their utility and impact. We begin by considering direct threats to comparability and interpretability.

Threats to Comparability and Interpretability

One threat, as noted previously, is related to the likelihood that ILSAs will have to maintain dual systems (paper-and-pencil administration and an ever-evolving digitally-based assessment) for some time—both because of insufficient technical capacity in many newly participating countries and because segments of some target populations (e.g., older adults) may not be capable of responding with tablets or other digital devices. To this point, through statistical adjustments based on estimated mode effects, ILSAs have maintained a single reporting scale for results obtained through either paper-and-pencil administration or digitally-based assessments. The construction of a single scale implies that the two sets of scores are linked to substantially the same construct and support similar interpretations.

Over time, however, ILSAs employing a digital platform will continue to innovate by extending the number and scope of construct facets to reflect the broadening of legacy constructs or the introduction of new constructs that capture the ways in which students and adults interact with new technologies. To some extent, these changes will involve new item types and new response formats that leverage the affordances of the technology platform. This will lead to a growing divergence between the paper-and-pencil administration and digitally-based assessment instruments, thereby making the assumption of the comparability of the scores obtained in the two modes progressively less tenable. Consequently, interpreting the scores (and score differences between countries) without regard to mode will become very problematic—especially if the proportions of respondents in the two modes differ substantially across countries.

We can expect that, eventually, separate scales will be required, with the attendant complications for reporting and interpretation. Moreover, the additional cost of maintaining two different platforms is not trivial. For example, one continuing challenge concerns transitioning paper-and-pencil administration trend items to digitally-based assessments.⁵⁰ This requires careful adaptation to keep the information provided by the item in the two formats comparable (Lennon & Kirsch, 2025; von Davier, Khorramdel, et al., 2019).⁵¹ Finally, within the digitally-based assessment orbit, the proliferation of different delivery devices over time will also pose a challenge to comparability both within and across countries.

A second threat concerns the shift to adaptive multistage testing. This move necessitates significant increases in the sizes of the item pools, particularly with the enhancement of construct representation. In conjunction with the growth in the number of participating countries, these increases place greater demands on the capacity of ILSA teams, not only to develop sufficient numbers of items with desired characteristics, but also to carry out the operations of translation and adaptation with the high degree of quality essential for comparability. Furthermore, greater numbers of items to be calibrated necessitate increases in the sample sizes required and/or the number of items administered to each respondent during field trials.

As documented in the section “Transitioning to Digitally-Based Assessments,” ongoing innovations in tools and processes are required to meet these demands, all the while respecting severe constraints on cost and time. Furthermore, adaptive multistage testing substantially increases the complexity of assessment design and, consequently, heightens the need to develop new quality control procedures to ensure that the overall design requirements are properly satisfied. In this regard, automated test assembly software that can be implemented for adaptive testing should prove very useful (Luo, 2020).

Third, the introduction of innovative item types may not only drive a divergence between modes of administration, but also introduce nonnegligible construct-irrelevant variance due to differential familiarity with response formats within and especially across countries.⁵² Whether a nonnegligible fraction of the observed variance is deemed construct relevant or construct irrelevant bears on how to address the issue of measurement invariance (see the section “Measurement Invariance”).

Finally, an ongoing concern will be ensuring an adequate level of measurement precision and comparability of the scores in the cognitive domains in the face of increasing heterogeneity among participating countries with respect to both cognitive skills and relevant background knowledge.⁵³ L. Rutkowski and Rutkowski (2018) discussed a relevant paper-and-pencil administration strategy, termed *design based*, that involves creating booklets with different average levels of difficulty and adjusting the proportions of relatively “easy” and relatively “hard” booklets administered in a country based on an a priori estimate of the proficiency distribution in that country. Indeed, such a group-level, adaptive strategy has been applied on a limited basis in PISA 2009 and PIRLS 2021.

Questions of comparability also pertain to the scales developed from responses to the background questionnaire. The challenges are greater in this setting than with the cognitive scales inasmuch as the number of items contributing to each background questionnaire-derived scale is very small. Consequently, measurement error is substantially greater. Furthermore, in some countries, scores on the reading/literacy assessment indicate that many (if not most) of the students may have some difficulty understanding the questions and responding appropriately.

L. Rutkowski and Rutkowski (2018) also addressed issues of comparability of the scales derived from the background questionnaire. They described a strategy, termed *model based*, that involves somewhat relaxing the measurement invariance requirements (to partial invariance) and encouraging countries to take advantage of the so-called national option to augment the core items for select background questionnaire constructs with items of specific interest to the country (or to a group of countries). The intent is to enhance interpretability and utility. This strategy was demonstrated using the WEALTH scale of PISA 2012. The exercise illustrated the challenge in achieving cross-national comparability even with a group of similar countries.⁵⁴ At the same time, there is a trade-off with comparability across all participating countries. For further empirical analysis, see, for example, He et al. (2019).

Van de Vijver (2018) considered the variation in response styles across countries and cultures particularly problematic with the Likert scale response formats used in many background questionnaire items. In this regard, Kyllonen and Bertling (2013) described some of the problems that arise with items that employ typical rating scale response formats and investigate some alternative response formats. Some formats tend to yield results that exhibit the aptitude–achievement paradox.⁵⁵ This is an area of ongoing research (von Davier et al., 2018). A comprehensive treatment of response format issues in an international context can be found in Kuger et al. (2016). A more general discussion of the validity issues related to items requiring self-report can be found in Karabenick et al. (2007).

As noted in the discussion of translation and adaptation procedures (see the section “Translation/Adaptation/Verification of the Instruments”), numerous efforts exist to enhance cross-cultural equivalence in the measurement of the target constructs of the background questionnaire in the face of greater heterogeneity among participating countries. Nonetheless, credible concerns remain (L. Rutkowski & Rutkowski, 2019). In addition to bias, another consequence is that some countries experience higher levels of measurement error in the scales derived from the background questionnaire that, in turn, attenuate the estimates of the relationships between cognitive skills and the constructs underlying those scales. These issues, singly and in combination, can substantially reduce the amount of useful information generated for some countries.

Notably, cross-national differences in measurement error in background questionnaire scales can result in spurious differences in correlations between such scales and cognitive domain scores. An important question, then, is to what extent observed heterogeneity across countries is due to such statistical artifacts. Gurkan (2021) developed an approach to correcting the bias in correlational estimates that takes account of both the multilevel structure of ILSA data and differential measurement error. The method further posits that the tested population comprises two latent classes with different levels of domain proficiency. When applied to PISA 2015 data to examine the relationships between mathematics proficiency and mathematics self-efficacy, the method resulted in substantially reduced correlational heterogeneity across countries, especially for lower performing countries.

A fifth threat, primarily to school-based surveys, is due to the variation among countries in the ways they identify students with different types and degrees of disability, their rules for exclusion from the survey, and the nature of the accommodations employed during survey administration (see the section “Accommodations for Testing”). On the one hand, some of the variation arises from different national customs and regulations and is difficult to mitigate. Certain subpopulations, such as recent immigrants, may also be treated differently across countries, again resulting in some lessening of comparability. On the other hand, some sources of between-country variation may be susceptible to harmonization, that is, coordinating definitions of factors such as education levels and socioeconomic status. Efforts to that effect in the social science literature

are ongoing, with the goal of increasing comparability of patterns of relationships across countries.

A sixth threat arises from the proliferation of mandated, official school surveys, as well as school-based research studies. This has led to “survey congestion,” resulting in lower participation rates. Although replacement schools can be located and convinced to participate, the overall trend is worrisome because, over time, there can be greater divergence in sample quality among countries. In this regard, Durrant and Schnepf (2017) linked PISA sample data for England to two large-scale administrative databases with information on students’ socioeconomic backgrounds and performance on national public examinations. They were able to characterize both the schools and the students most likely not to respond and, on that basis, made suggestions on how best to select substitute schools. This approach shows some promise if it could be implemented in countries where such linkages are feasible.

In the case of household surveys, such as PIAAC, reduced participation rates may be due to both survey congestion and a general decrease in trust in central authorities. Here again, increasing divergence in sample quality threatens country-level comparability. Lowered participation rates may necessitate offering some incentives on a broader scale.⁵⁶ The COVID-19 pandemic and its aftermath may well exacerbate these challenges. It is possible that in the future some forms of remote assessment will offer a partial solution.

Even among those who agree to participate, there are worrisome trends in motivation. Here the concern is greater with school-based surveys than with household surveys. In low- or no-stakes situations, many students do not engage fully with the instrument—or only do so for part of the assessment. The consequence is less accurate measurement at the population and subpopulation levels, as well as reduced comparability, because diminished motivation will vary in prevalence across subpopulations within and across countries. For an estimate of the impact of differential motivation on NAEP results, see Braun et al. (2011). All these threats to comparability serve to reduce the policy utility of international large-scale assessments. Recent approaches to analyzing item-level data for engagement may prove useful in this context (Ulitzsch et al., 2019).

In the future, log file data should prove to be of use. For example, timing data are already helping in the effort to classify items at the respondent level as either omitted or not reached. Researchers have begun the development of indicators based on the raw log file data that can be used to signal possibly aberrant response processes or patterns suggesting lack of effort (e.g., Goldhammer et al., 2016; Pokropek, 2016a; Pools & Monseur, 2021; Wise, 2020). One strategy would be to develop norms for an indicator (possibly at a national level) and to identify individuals with indicator values that fall in the extremes of the distribution. If that is the case, say, for two or more indicators, then that individual would be removed before scaling and analysis. Of course, empirical work would be necessary to validate a decision rule (Soland et al., 2021). In any case, such indicators could be used to monitor system performance and enhance sample quality.

Another possibility is to employ records of participant response processes to improve item design and to contribute evidence of validity (Ercikan & Pellegrino, 2017; Zumbo & Hubley, 2017). Although these seem to be promising directions, many technical, practical, and even ethical questions remain to be explored (Provasnik, 2021). Technical advances and considerable infrastructure development will be required to make these and other possible applications of log file data practicable. Ethical issues should be considered by broad-based groups of stakeholders, with sufficient international representation, although the different perspectives may well make reaching consensus challenging in its own right.

Finally, comparability and interpretability of ILSA results also depend on whether respondents differentially interpret the tasks that are presented and how those interpretations shape their response behaviors. Assessment practitioners are coming to understand the importance of adopting a sociocultural perspective in the design of assessments, as well as in the interpretation of the data generated by those assessments (Mislevy, 2018). In the ILSA context, such considerations are germane to both the cognitive instruments and the background questionnaire. One implication is that the committees that develop these instruments should have broader participation from the different subpopulations in the various countries to enhance the meaningfulness of the questions to all respondents, thereby reducing construct-irrelevant variance.

Although the logistics of carrying out such a program in an international context are formidable, ILSAs sponsors and contractors do make an effort to include representatives from different countries as subject matter experts, to attend test development workshops, and to contribute items for field testing. Evidently, more needs to be done in this regard.

Relatedly, some critics have suggested that ILSA teams should be open to employing different methods for generating validity evidence. For example, Pepper (2020) pointed out that the validity argument would benefit from conducting cognitive laboratories with both the cognitive instruments and the background questionnaire items.⁵⁷ In an international setting it would be impractical to do so in every participating country. Consequently, some experimental design would have to be employed to generate evidence reasonably representative of the ensemble of participating countries. Classical convergent and divergent validity studies could also be conducted in selected settings. In any case, more thought should be devoted to these and other approaches to obtaining additional evidence. Similar considerations apply to studying the impact on the performance of certain subpopulations with the introduction of new digital devices.

Threats to Relevance

ILSAs also face challenges with regard to relevance. For the most part, the principal strategy to enhancing relevance has been to increase the range of constructs that are measured through the cognitive instruments and the background questionnaire. However, there are technical limitations to pursuing this strategy. Moreover, each cycle brings novel issues to the fore.

One aspect of relevance is the degree to which ILSA assessments reflect the increasing use of different technologies by students and adults. For example, there is ongoing interest in incorporating various 21st-century skills in school curricula (Binkley et al., 2012; Darling-Hammond, 2012). The assessment of such skills often requires complex stimulus materials and student-constructed responses that currently require human raters for evaluation. Including such (or similar) assessments in ILSAs poses a number of challenges, as has already been mentioned. Nonetheless, to maintain relevance, expanding the range of assessment formats remains a high priority for ILSA teams.

Fortunately, the advent of digitally-based assessments makes possible new item types with different response formats to enhance construct representation. As an example, simulation tasks are becoming increasingly popular in school-based ILSAs because they allow for a more authentic assessment in the domains of science inquiry, mathematics, collaborative problem-solving, and even financial literacy (PISA). In the case of science, simulations can provide students with an opportunity to design an experiment (by selecting variables and associated values) and then run the experiment to generate data in order to respond to various questions. Because such tasks can consume considerable time, their appearance in an ILSA may be more common in specialized auxiliary studies.

With the introduction of adaptive multistage testing, it is optimal to have decisions on the next module to be administered based on the maximum amount of information. Currently, information is only available from selected response items and a limited number of other item types that can be automatically scored. Going forward, new item types should be developed and evaluated in conjunction with the corresponding scoring algorithms. This shift requires item designers to collaborate with computer scientists and other specialists to determine the feasibility of developing accurate and efficient scoring algorithms. In some cases, original item designs will have to be modified with a commitment to maintaining construct relevance. Evidently, implementing automated scoring in an international context with multiple languages and scoring guides is an order of magnitude more complicated than in national assessments. Nonetheless, the implementation of adaptive testing in response to demands for greater accuracy along the full score scale, together with the necessary concomitant technical developments, is yet another instance of the virtuous spiral (Figure 20.2) that captures the ongoing dynamic between stakeholders on the one hand and ILSA sponsors and teams on the other.

On another front, ILSAs must be responsive to changes in the school, work, or other environments where the easy availability of online tools (e.g., for checking spelling, grammatical construction, argumentation, information search and display) has the potential to modify the focal construct. Maintaining both relevance and scale comparability across administrations may be increasingly at odds in both student and adult surveys. As Mazzeo and von Davier (2014) pointed out,

The question is whether surface characteristics that change quickly due to technological advances will lead to changes in the requirements of underlying skills and knowledge. If students increasingly use technology in everyday activities, and if

these technologies become easier to apply to everyday problems over time, then the traditional concept of linking assessments over time by means of tasks that stay the same and look the same becomes unsuitable. (p. 255)

This poses a challenge not only to instrument developers and psychometricians, but also to those charged with renovating the digital platform. Investments in continuous innovation in platforms, processes, and procedures will consume substantial resources. More fundamentally, technology-driven changes in the context of measurement can force shifts in how the construct is defined and operationalized. As a result, what may have once been viewed as a source of construct-irrelevant variance may come to be accepted as contributing construct-relevant variance. An example is provided by the construct problem-solving in technology-rich environments, introduced in PIAAC (2012), where the ability to employ the digital tools provided in simulated web, email, and spreadsheet environments is integral to the construct. We can expect that other examples will emerge as different technologies become increasingly embedded in everyday life.

As the number of measured constructs increases in conjunction with the possible introduction of rotated background questionnaire designs, the stability of the key latent regression model may be reduced. This, in turn, would threaten the accuracy of the population model used to generate PVs—especially in the case of sparse designs for the cognitive instruments. Present concerns regarding the impact on proficiency estimates of measurement error in the explanatory variables in the latent regression model will likely become more pronounced (L. Rutkowski & Zhou, 2015). Presumably, at some point there will have to be some trade-offs between relevance and maintenance of the reputation of ILSAs as trustworthy sources of achievement data. Other trade-offs between local fidelity and international comparability will be informed by solid analytic work but will also necessarily reflect policy and political considerations. Consequently, the decisions reached may place additional burdens on the ILSA teams, which will have to accommodate greater variation among the instruments administered in different countries.

Another critical aspect of relevance concerns the degree of alignment between the information provided by the ILSAs and the questions asked by policy makers and other stakeholders. In point of fact, a number of key issues that command some degree of general interest are frequently raised. To improve timeliness, the relevant data could be culled from the comprehensive almanacs and organized and displayed relatively quickly in tables and figures. Further on, targeted secondary analyses could be funded through sponsored initiatives—perhaps initiated even before the public release of the data.

Relevance could be increased by more systematically linking national ILSA data to national databases that contain other types of information (e.g., background data at the individual level). Such an augmented database would support a broader range of secondary analyses, as noted previously in the case of Denmark. Linkages to data at higher levels of aggregation (e.g., at the school or area level) could also prove useful for some analyses. Going forward, designers could build in some connections as a national option to facilitate such linkages.

POLICY AND POLITICAL CHALLENGES

Alongside the technical concerns that relate primarily to construct validity, we now turn to a discussion of some of the political challenges that can be framed in terms of consequential validity. The increased prominence of ILSAs results in policy discussions, as well as the exhortations on the part of some leaders that countries emulate the “high-flyers,” has sparked a backlash. Some researchers and commentators have argued that ILSA results have become too influential in national policy discussions and, in particular, that they are a force for “international homogenization” at the expense of national educational differences that should be preserved (Carnoy, 2015; Grek, 2009; Meyer & Benavot, 2013; Sellar & Lingard, 2013). They cited the broader participation in ILSAs, the increased salience of ILSA results in discussions of education policy, and the utilization of ILSA outcomes for purposes of evaluation and monitoring.

Benavot and Smith (2020) linked increasing participation in ILSAs in part to efforts by the UNESCO Institute for Statistics to develop global learning metrics as a means for quantifying progress toward the United Nations’ Sustainable Development Goal 4: Education. By participating in an international comparative assessment, countries can satisfy the SDG 4 reporting requirements. The authors argue that these requirements have also led to pressure to conform to a system of “global educational governance.” Teacher associations have also weighed in on ILSA participation (Couture, 2016).

A review of the literature, however, suggests that the situation is rather more ambiguous and that a more nuanced view is in order. Successful policy transfer across national boundaries can be difficult—for both technical and political reasons (Atkin & Black, 1997; Braun, 2008; Burdett & O’Donnell, 2016; Oliveri et al., 2018). Drawing on extensive personal experience, Ritzen (2013) observed that the degree of utilization of ILSA results depends not only on a country’s readiness (politically and otherwise) to institute changes, but also on its capacity and commitment to carry out the change process. This observation may be especially true for many low- and middle-income countries, whose participation has been essentially mandated (and supported by) international donor organizations (see also Braun, 2013).

Volante et al. (2017), in discussing the normative impact of the assessments sponsored by the OECD, also noted that there is a wide range of policy responses to ILSA results—from negligible to modest to very substantial. Fischman et al. (2019) conducted surveys of ILSA experts and interested stakeholders. They found considerable diversity of opinion regarding whether ILSAs had an impact on national education policymaking, and if so, whether it was constructive. The observed variation is likely due both to differences in experiences among countries and to differences in the vantage points of the respondents.

These debates can be framed in terms of questions regarding the consequential validity of ILSAs. That is, beyond the attribution of impact (see the section “Impact”), the principal issue lies in what cases the impact leads to long-term positive outcomes and

in what cases it does not—and whether the two can be reasonably well distinguished. This section addresses the issue.

Concerns Regarding Impact

Once a country joins an ILSA collaborative, an obvious benefit of continued participation is the value of tracking performance trends over time. It is impossible to ignore the “league tables” that are published after each ILSA data release. However, a focus on rankings based on aggregate mean scores, or changes in rankings over time, can be misleading and lead to confusion among stakeholders. First, countries with mean scores that are statistically close nonetheless could have quite different rankings. Second, many factors determine a country’s rank in a particular cycle (e.g., the set of countries participating in that cycle) that have little or nothing to do with the efficacy of its education system (Singer & Braun, 2018).

Nonetheless, it is true that some ILSA proponents argue that a country’s best strategy for educational improvement is to emulate the policies of so-called high flyers (National Center for Education and the Economy, 2020; Schleicher, 2018). Kamens (2013) argued that this sort of cheerleading encourages stakeholders to think that there is a “magic bullet” to achieving success. The problem is sometimes exacerbated by misleading media reports that may focus on changes in a country’s rank but ignore the actual change in performance. PISA 2015 offers some examples from East Asia. In Japan, one newspaper highlighted a change in rank from fourth to second on science, even though the mean score declined from 547 to 538. By contrast, in Chinese Taipei (Taiwan), a newspaper bemoaned a decline in ranking on reading, even though the mean score increased.⁵⁸ To counter these and other misinterpretations, there have been some innovative attempts to present country results through visuals that de-emphasize league tables.

Some authors have argued that for the United States, state-level comparisons are likely to be more informative than international comparisons (Carnoy et al., 2015).⁵⁹ For now, that appears to be a minority view. Indeed, these same authors suggested that cross-country comparisons among recognizable subgroups are more informative than aggregate comparisons. For example, they compared countries’ performance in mathematics on PISA 2012 within strata defined by a cross-national measure of family academic resources. They showed that although the United States fares poorly overall, it does relatively well in each stratum. Its comparatively lower aggregate scores are due to the greater proportions of U.S. students in the more disadvantaged strata. This finding leads to consideration of different reform strategies than might be suggested by a singular focus on overall rankings. Similar studies based on data from PIAAC could also yield interesting patterns.

Another widespread concern is related to misinterpretations and misuses that are not directly due to technical deficiencies of the assessment or the failure to provide appropriate guidelines (Kane, 2016). That is, despite the best efforts of sponsors and developers, either policy makers make inappropriate policy pronouncements or decisions or various entities overstate the evidential value of ILSA results with respect to policy and

practice. For example, in some instances, national education goals have been framed in terms of specific improvements in country rankings. D. Rutkowski et al. (2020) cited the example of Australia. The Education Act of 2012, approved by the Parliament of the Commonwealth of Australia, called for Australia to be ranked by PISA 2025 in the “top five” on reading, mathematics, and science. A misguided focus on the rankings competition can lead to suboptimal policy choices.

On the one hand, although they are not directly responsible for such misuses, it is still incumbent on ILSA sponsors and developers to counter specific misuses and misinterpretations of ILSA data. On the other hand, a call to reduce the gaps in scores between high and low performers within a country to a level comparable to the gaps seen in peers with comparable overall performance but greater equity should be seen as a constructive use of ILSA data for purposes of benchmarking.

Responding to Political Challenges

Judgments regarding whether ILSAs exert undue influence on national education policies should take into account the country’s rationale for participation. As noted in the section “Impact,” ILSA results are sometimes used to justify or legitimate pending policies. Wiseman (2013) offered the example of France. Citing Dobbins and Martens (2012), he stated that “the OECD’s PISA was part of a French political agenda to create an evidence base to support a specific policy position. This is not an isolated tactic or unusual use of international achievement studies” (Wiseman, 2013, p. 311). J. Jennings noted that in the United States, the National Council of State Legislators in 2016 seized on the then–most recent PISA results to build support for a wide range of education reforms.⁶⁰ In Ireland, surprisingly weak PISA results provided impetus for the passage of long-stalled education reforms (H. Hislop, personal communication, September 21, 2017). Asserting that these represent constructive uses of ILSA data depends largely on a judgment of the appropriateness of the reform policies.

Wiseman (2013) also argued that, to the extent that ILSAs exert influence on educational policies, the outcome is not necessarily some form of strict policy convergence. Instead, the result may be an “isomorph” of the “model” system, whereby countries extract some key features of the model (e.g., curriculum) but then modify and/or adapt them to better fit the country’s traditions and culture, often taking into account the political strengths of different stakeholders. Thus, despite exhortations in support of emulation, the path from ILSA results to policy responses is neither straightforward nor predictable (Pons, 2017).

Ideally, a country’s decision to participate in a particular, school-based ILSA would be informed by careful study of the ILSA’s avowed purposes and its assessment frameworks, followed by an evaluative judgment regarding their degree of congruence with the country’s goals for its students (Oliveri et al., 2018). Presumably, the reputation of the ILSA for generating data that are accurate, reliable, and valid would also factor into the decision. In this context, careful study of a country’s outcomes could very well appropriately result in changes in curriculum and pedagogy. As described in the section “Impact,” this strategy has been adopted by many countries—in some cases

(e.g., Singapore) in a thoughtful, systematic fashion. Despite the caveats raised in that section, the strategy may be particularly helpful to countries with lower capacity in the realms of curricular design, test development, and educational measurement. This sort of “homogenization” is consistent with Wiseman’s (2013) model of convergence.

It bears repeating that country differences in ILSA-based indicators cannot be directly linked to differences in the quality of their education systems (Singer et al., 2018). More nuanced contextual analysis is in order. For example, the strong performances of students in South Korea and Japan are due, in part, to the pervasive practice of out-of-school tutoring (shadow education), as noted by Heyneman (2013) and others. Countries also differ in their investments in both the well-being of children and teacher quality. These and other differences can contribute to differences in academic achievement, particularly for children living in less advantaged circumstances. A failure to appreciate this complexity can lead to misinterpretations of ILSA results (particularly changes in overall rankings) and, hence, to misguided policy decisions. It is worth noting that such differences—and their misinterpretations—can also occur when making comparisons across population subgroups or geographical regions within a country.

Despite the appropriate concerns regarding the overemphasis on league tables, rankings on other measures can provide useful policy information. For example, one country-level indicator of equity is the difference in the mean scores between the top decile (quintile) and the bottom decile (quintile), with larger differences signaling greater inequality. A related indicator is the slope of the regression of cognitive scores on a measure of socioeconomic status. Again, a steeper slope signals greater inequality. It would be useful to consider disaggregating cognitive outcomes data by other background variables to provide more informative comparisons (Rowley et al., 2020). In school-based ILSAs, for example, reporting results by levels of opportunity to learn (or available proxies) should be considered. In reporting results to their national policy makers, countries should consider presenting a range of indicators. It is particularly striking when countries with similar overall proficiency means differ substantially on one or the other of these indicators. Such reports must include clear, explanatory text to highlight the utility of these indicators and to reduce the possibility of misinterpretations.

To highlight the benefits of participation in school-based ILSAs, sponsors, in conjunction with country representatives and education authorities, should enhance outreach to teachers, curriculum specialists, and education leaders to explicate the ILSA frameworks and how the assessments reflect those frameworks. They could also organize specially designed workshops or webinars that highlight important issues or findings that might help guide interpretations. With a solid understanding of how to interpret the outcomes, the classroom utility of both the frameworks and the disaggregated results would be more evident. Country representatives who participate in the various expert groups during an ILSA cycle are an underutilized resource. They not only help to define and operationalize the various frameworks, but also contribute to the development of described proficiency scales. Thus, they are well positioned to inform education policy discussions within a country.

Similar considerations are relevant to participation in adult surveys. Outreach to various government ministries and other stakeholders could emphasize the value of the data collected by PIAAC for policy decisions related to a range of domains, including education, training, and labor market initiatives. Moreover, the argument can be strengthened by reference to the many secondary analyses already conducted on available data.⁶¹ The results of these analyses enable useful cross-national comparisons that can directly inform policy discussions.

In general, the “duty of care” incumbent on ILSA sponsors and developers to address concerns regarding consequential validity can be framed in terms of ensuring, to the extent possible, that (a) the technical quality of the results supports their intended interpretations and uses; (b) the presentation of the results, along with the corresponding explanatory materials, encourages appropriate interpretations and uses; (c) the text is transparent about possible biases and uncertainties, as well as their implications for interpretation; and (d) the most common, anticipated misinterpretations and misuses are proactively addressed and discouraged. This aspect of validity is all the more important with the increases in ILSA complexity and heterogeneity of participating countries.

CONCLUSION

The inclusion of this chapter in the present volume reflects the growing importance of ILSAs of student and adult populations since the 1960s. From modest beginnings as a set of exploratory studies devised by a small group of scholars interested in international comparative education, school-based ILSAs have grown into a major strand of applied research within the larger domain of comparative education (Suter et al., 2019). As the scope and reach of ILSAs have expanded, they have generated an unprecedented amount of empirical evidence on which researchers and policy makers can draw to analyze education systems and develop strategies to improve student outcomes. Nonetheless, some worry that by virtue of their dominant role, ILSAs have led to a diminished appreciation for the insights that other strands of comparative education have to offer—not the least of which is providing a broader framework within which ILSA findings can be understood and applied (Carnoy, 2019). Indeed, as is evident in the contributions to Suter et al. (2019), these other strands rest on foundations of both theory and rich, empirical studies.

At the same time, the increased attention paid to ILSA scores and rankings, as well as to the results of secondary analyses of these data, is due in large measure to the widespread recognition of the importance of understanding the relationships of education and skills, not only to social and economic development, but also to general well-being.⁶² As globalization and technology have accelerated, the economic interdependencies (and competition) among countries, policy makers, and key stakeholders have seen value in benchmarking performance against peers and near-peers—initially in more developed economies and, more recently, in middle- and lower income countries.

In 1987, following the implementation of the new NAEP design, Messick published a paper in which he asserted that because large-scale assessments constitute a form of policy research, their success should be judged based on their policy utility. Further, he reasoned that an element of uncertainty exists between policy research and policy formation, creating a gap that requires informed judgment. He believed that large-scale assessments could provide information to help bridge this gap through the provision of evidence gathered by careful design and development of instruments, followed by appropriate analysis and reporting of results (Kirsch & Braun, 2020; Lennon & Kirsch, 2025). He did not assert, however, that this empirical information was sufficient to the purpose.

To help understand how large-scale assessments could best fulfill this role, Messick (1987) proposed a framework containing three key design criteria: comparability, interpretability, and relevance. This chapter has presented and extended these three design criteria, arguing that they remain applicable for evaluating the utility of next-generation ILSAs. Indeed, a recurring theme in the chapter has been how changes to ILSAs have contributed to greater utility by strengthening one or more of the design criteria.

For example, to enhance relevance, ILSAs are responding to broad interest in new, more innovative domains such as creative thinking, problem-solving, and others that are most suitable for digitally based assessments. However, as always, there are trade-offs. In this case, countries or individuals who receive the paper-based assessments do not participate in these innovative domains, potentially reducing the utility of these surveys for these countries and groups. Moreover, the evolution of ILSAs in this direction will result in a growing divergence between the two modes in what is being measured and, consequently, weakening the justification for reporting results on a single scale. Unfortunately, both practical and political considerations argue for maintaining two delivery modes, with the attendant complications and additional costs.

In addition to employing Messick's (1987) framework to examine various aspects of ILSA development and subsequent uses, this chapter also has described the ILSA developmental path as a virtuous spiral, that is, a trajectory in which each cycle of an ILSA attempts to meet the evolving interests of policy makers and key stakeholders who continually challenge sponsors and researchers to generate information that is relevant to the changes taking place within and across participating countries. As societies undergo changes, policy makers and other stakeholders pose new questions that lead to both novel and better measures of legacy constructs and the introduction of new domains of assessment.

In this context, we highlighted two key inflection points along this trajectory that have led to marked increases in ILSA utility and salience. The first inflection point occurred in the mid-1980s through the mid-1990s with the introduction of important methodological innovations such as BIB spiraling and IRT scaling. These innovations provided policy makers with interpretable information regarding the distributions of skills within and across countries, along with the ability to examine

the relationships among these skills and a host of demographic and background variables.

Over the next 2 decades, additional methodological and technological innovations ultimately led to the second inflection point, one characterized by the advent of digital platforms that support the design, development, and delivery of next-generation ILSAs. Successfully carrying out digitally-based assessments required the construction of novel tools and the integration of new workflows and processes that benefited from the ongoing collaboration of experts across the different phases. The digital platform facilitated the introduction of new constructs, new item types, and improved methodologies, such as adaptive multistage testing. The result has been an improvement in the overall quality of the data, extensions of what can be measured in both student and adult populations, and greater efficiency in the management, delivery, and processing of the data.

As ILSAs have proven over the years to be a reliable source of credible information, this chapter also described some of the ways in which these assessments have impacted policy. Examples include countries where new policies were implemented based on results from in-school surveys including PIRLS, TIMSS, and PISA. There are other cases where these assessments were used to support existing policies or legitimate proposed policies. Beyond their direct impact, there is also evidence of ILSAs' indirect impact, which is reflected in increased media attention and the documented growth in the number of researchers who are using ILSA databases to inform their research and develop policy papers covering a range of issues relevant to school-age and adult populations. Finally, ILSA participation has jump-started or accelerated capacity building, particularly in many middle- and low-income countries, giving them the capability to conduct national or subnational assessments to inform education policy.

Not surprisingly, the growth in relevance and popularity of ILSAs has also led to a number of challenges and concerns. One challenge arises from the substantial increase in the diversity of participating countries, as well as that of social and economic backgrounds, representing a wider range of skills. Maintaining an adequate level of measurement invariance across countries among both the cognitive domains and the constructs underlying the background questionnaires has become increasingly difficult as participation has expanded.

Compounding the challenges presented by the growing diversity among participating countries is the never-ending pressure to extend what is being assessed. Because technology-based assessments facilitate such extensions, there is continued demand to add to the constructs in the background questionnaire, as well as those in the cognitive domains. Given the constraints on survey administration time, these extensions necessitate the development and deployment of more complex designs, such as within-construct rotation of key variables in the background questionnaire—similar to what is done in the cognitive domains.

Predictably, increases in ILSA scope and coverage lead to rising costs for both contractors and participating countries. Greater operational difficulties due to lower

response rates, as well as to the hiring, training, and retaining of survey staff, also contribute to rising costs. These increases cause concerns among the governments who not only fund the assessments, but also must wait patiently for several years from the initiation of survey development to the final reporting of results.

More recently, the questions that have been raised are of a more political nature and have less to do with technical issues. For example, there are widespread concerns regarding the overemphasis on the league tables of country rankings and their relative changes over time. This attention to league tables is due in part to the (misguided) notion that differences in countries' rankings are a credible indicator of differences in the efficacies of their education systems. A natural conclusion, then, is that a sure-fire strategy recognized for educational improvement involves trying to identify and implement those policies that seem to be effective in high-performing countries (Tucker, 2011).

Aside from technical issues related to data quality (as was the case with Shanghai),⁶³ the difficulty with this advice is that it fails to acknowledge the natural limitations of ILSA data; namely, they can suggest interesting hypotheses but cannot establish them, largely, but not solely, because of the constraints on making causal inferences from cross-sectional data. More intensive studies are needed, requiring consideration of the broad range of factors operating at different levels from conception to the time of the assessment that contribute to student achievement. It is precisely here that the findings from "traditional" comparative education come into their own. Understanding the historical, cultural, economic, and political influences on the structure and functioning of current education systems—and how they differ across countries—is essential to devising workable policies and interventions that mitigate some of the likely difficulties that arise in a policy transfer process.

As noted in the last section, consideration of ILSA impact (both positive and negative) falls under the rubric of consequential validity. The responsibilities associated with consequential validity lie with both the sponsors and the developers, as well as with those who use and interpret the data. The sponsors and developers are expected to, and often do, provide information regarding the overall quality of the data, along with the appropriate uses and interpretations of the results. The media, policy makers, and others are expected to assume some responsibility for misinterpretations or overstatements of what the data say or what decisions can be supported by the results.

These challenges and concerns, both technical and political in nature, constitute healthy tensions that can and should be discussed and debated within the extended Messick (1987) framework. Although it is certain that ILSAs will continue to face a number of challenges, we believe that the path along the virtuous spiral will continue to provide innovations that will enable ILSAs to address new and more complex questions. We expect that answers to these questions will lead to continued appreciation for the utility for such surveys.

ACKNOWLEDGMENTS

The authors wish to thank the editors, L. Cook and M. Pitoniak, for inviting them to contribute a chapter to the volume and for their support throughout the process. Reviewers of our first draft, A. Ben Simon, M. von Davier, and H. Wagemaker, offered a number of useful comments and suggestions that we endeavored to implement. Subsequent drafts were reviewed critically by M. L. Lennon and E. Gonzalez. Both devoted substantial time to the reviews and we benefited tremendously from their many suggestions, almost all of which we were able to follow. On specific matters we were assisted by B. Fishbein, P. Foy, M. O. Martin, L. Suter, and K. Yamamoto. Finally, A. K. Gontz was absolutely thorough in conducting the final editing of the manuscript. To all we are very, very grateful.

NOTES

1. In this chapter, we use the term *country* to signify a participating jurisdiction for which results are reported. This term includes “countries” as commonly understood but may also refer to other types of political entities. In ILSA reports, the latter are variously described as *economies* or *benchmarking participants*.
2. Human capital is often characterized as a broad set of cognitive and noncognitive skills and knowledge that is necessary in modern economies. See Kirsch et al. (2016) for a discussion of the growing importance of human and social capital and their connections to opportunity.

3. Advanced TIMSS was intended to assess students close to the end of compulsory education (e.g. Grade 12 in the United States). It was administered in 1995, 2008, and 2015.
4. Each paying participant obtains a database with its results, and the results are published in the accompanying reports.
5. More exactly, PIRLS is administered to students in the upper of the two grades that enroll the most 9-year-olds. This is the fourth grade in most countries.
6. For PIRLS 2021, ePIRLS booklets were more fully integrated into the booklet structure of digital PIRLS.
7. These assessments were the Young Adult Literacy Survey 1984, the Department of Labor Study of JTPA Trainees and UI recipients 1992, and the National Adult Literacy Survey 1993.
8. The ICILS was conducted in 2013, 2018, and 2023.
9. ICCS assesses students enrolled in the eighth grade, provided that the average age of students at this year level is 13.5 years or above. In countries where the average age of students in Grade 8 is less than 13.5 years, Grade 9 is defined as the target population. The ICCS was conducted in 2009, 2016, and 2022.
10. Beginning in 2003, succeeding assessments retained the acronym TIMSS, with “Trends” replacing “Third” in the title.
11. BICSE was established in 1988 and disbanded in 2002. Throughout its existence, the National Center for Education Statistics provided substantial funding.
12. With a statutory mandate to collect data in the United States, the National Center for Education Statistics, a division within the U.S. Department of Education, has also provided crucial, sustained support for many of the international assessments beyond the contribution required for U.S. participation.
13. These dates mark the beginning of data collection for the surveys. Of course, preparatory work began years earlier.
14. For a contemporary treatment of constructs and test scores, see Haertel (2018).
15. This and other issues are reviewed as part of the adjudication process that is completed at the end of the project cycle.
16. The separate estimation of item parameters for a country (or set of countries) improves the estimated score distributions for those countries. If the number of such items is small, this policy should not materially impact the comparability of the described proficiency scale across all countries. However, if the number of items requiring separate estimation exceeds a certain threshold (yet to be determined), then it may be advisable to construct a unique scale for that country (based on its data only) and sacrifice comparability with the main scale.
17. For a more complete discussion of this activity, see Dept et al. (2025).
18. For example, in school-based surveys, the aim is to estimate score distributions for students, but the school is a relevant level of analysis. Consequently, the

sample design must allow for selecting multiple students within each school, as well as large numbers of schools. Schools constitute the first stage of the design, and students within schools constitute the second stage.

19. To prepare for school nonresponse, replacement schools are selected at the same time as the main sample.
20. For example, in PIRLS 2016 the target population was students in the fourth year of formal schooling. In most countries this was Grade 4. However, if the mean age in Grade 4 was less than 9.5 years, Grade 5 was chosen. For further details, see Martin et al. (2017, chap. 3).
21. If the school has fewer than 35 eligible students, all eligible students are selected for administration.
22. As noted earlier, countries vary in the proportions of the birth cohorts enrolled in school, with implications for the kinds of (comparative) inferences that can be made from the data collected.
23. The problem has become more salient with the greater participation of middle- and low-income countries.
24. Blocks are systematically varied by position within booklets to remove any order effects.
25. More exactly, the students responding to each item have known probabilities of selection so that the raw results can be modified by appropriate weighting. With adaptive testing, the students exposed to different item blocks are not randomly equivalent. Nonetheless, the designs do enable unbiased estimation of item parameters.
26. In many contexts, such item sets are called *testlets*.
27. Items requiring human scoring cannot contribute to the real-time decision-making process; however, they may be essential for construct representation.
28. When there is interest in reporting information at the subscale level, items are grouped by subscale and the item parameters are obtained from the unidimensional scaling employed in scale construction. This strategy possesses advantages when comparing subscale profiles across countries.
29. For more technical detail on addressing item–country interactions, see, for example, Martin et al. (2016, chap. 11) for TIMSS 2015, and Martin et al. (2017, chap. 10) for PIRLS 2016. On occasion, a single separate item calibration is carried out for a group of countries.
30. See also Mullis et al. (2021, chap. 4).
31. As a general rule, the number of principal components retained is limited to no more than 5% of a country's student sample size, thereby reducing the percentage of variance accounted for to avoid overspecification of the conditioning model. (See Martin et al., 2020, chap. 12.)
32. Various versions of the expectation–maximization algorithm are used to obtain parameter estimates for the latent regression model (von Davier & Sinharay, 2014).

33. This discussion assumes there are no missing data in the background questionnaire, an assumption that is rarely fulfilled. Recent research has investigated methods for carrying out the estimation procedures in the face of missing data (e.g., Grund et al., 2021).
34. See also OECD, 2017, chap. 9.
35. More exactly, the key requirement is that there is sufficient information (i.e., large enough sample size) on each trend item so that it is possible to judge whether it is working well in each population for which results are reported—typically a (large) language group within a country.
36. In this context, “freeing item parameters” entails estimating the item parameters separately for each country, rather than having one set of item parameters for all countries. For more technical detail on addressing item-by-country interactions, see Martin et al. (2020, chap. 10) for TIMSS 2019 and Martin et al. (2017, chap. 10) for PIRLS 2016.
37. See also OECD (2017, chap. 9).
38. NAEP no longer uses this approach, having shifted to employing achievement-level descriptors.
39. More generally, in PISA, students who are administered items in the major domain and only one of the minor domains receive PVs for the other minor domain.
40. Recall that sampling weights are used to control the proportional representation of the cases in the estimation of population parameters.
41. See International Association for the Evaluation of Educational Achievement (n.d.-b).
42. Both tools are considered proprietary software developed specifically for use with ILSA data. The current version of the microdata analyzer is called IDBA.
43. Attendees may be required to pay fees to attend, depending on the level of governmental support available.
44. See International Association for the Evaluation of Educational Achievement (n.d.-a).i
45. See, for example, Martin et al. (1999).
46. Canada, France, Norway, Switzerland, England, and Shanghai.
47. Educational attainment is typically quantified in terms of either years of schooling completed or reaching certain milestones, such as completion of secondary school.
48. Developing an appropriate cross-national measure of socioeconomic status is itself a challenging endeavor (Avvisati, 2020; Marks & O’Connell, 2021).
49. One concern with such studies is that the focal construct may be operationally defined differently in each assessment. Such a “construct shift” limits the kinds of conclusions that can be drawn.
50. Although the transition from paper-and-pencil administration to digitally based assessments occurs at a point in time, it may prove necessary to replenish the

paper-and-pencil administration item pools if there is an ongoing need to offer the paper-and-pencil administration option.

51. Maintaining item parameter invariance is one way to achieve such comparability.
52. The lack of familiarity is mitigated somewhat with tutorials and practice exercises that familiarize respondents with new item response formats.
53. The issue is complicated by the fact that the construct definitions and the corresponding assessment frameworks do not always make explicit which types of prior knowledge are part of the construct and which are not.
54. Denmark, Finland, Iceland, Norway, and Sweden.
55. In the ILSA context, an extreme case of the aptitude–achievement paradox occurs when the relationship between a cognitive outcome and a behavioral (or attitudinal) outcome is positive within countries but negative among countries. See Ainley and Ainley (2019) for further discussion.
56. Some countries employed incentives in Cycle 1 of PIAAC and others are planning to use them in Cycle 2. An incentive study conducted in conjunction with the U.S. National Adult Literacy Study found that monetary incentives increased participation rates but not performance (Mohadjer et al., 1997).
57. Cognitive laboratories were conducted for PIAAC, with particular attention on interface issues related to usability. However, they are not standard for school-based ILSAs.
58. We thank Xue Jiang and Shinji Katsumoto, Teachers College, Columbia University, for the translations.
59. To this point, M. Smith (cited in Singer et al., 2018, p. 28, footnote) asserted that in the past, legislators found state-level differences more compelling than country-level differences.
60. Quoted in Singer et al. (2018), pp. 28–29.
61. Consult Maehler et al. (2020) for a comprehensive bibliography.

Part V

Measurement as a Science

On the Nature of Measurement

Derek C. Briggs

University of Colorado Boulder

Andrew Maul

University of California, Santa Barbara

Joshua A. McGrane

Assessment & Evaluation Research Centre,
The University of Melbourne

Measurement, in its many forms, has been an integral part of human civilization since its very inception and is now inextricably woven into nearly every aspect of our lives. Every time we eat food, drive a car, take medicine, check a weather report, make a financial transaction, or engage with society in nearly any other way, we place our trust in the results of measurements. And for the most part, that trust seems to be well earned; over centuries of development, particularly in the contexts of the physical sciences and engineering, the concept of measurement has come to be commonly associated with precision, accuracy, objectivity, and overall trustworthiness.

Against this backdrop, it seems little wonder that the language and logic of measurement has been applied in nonphysical contexts as well. Discourse on measurement has featured prominently in the social and human sciences since their formal inception in the late 19th century, and arguably in economics for even longer than that. Moreover, the language and logic of measurement have often been employed, with varying extents of formality, in relation to *testing*, especially in vocational and educational contexts. This is visible in many ways but is perhaps most obvious when the results of tests are reported in quantitative terms and when the differences between test scores (between or within students) are interpreted in terms of magnitudes, implying meaningfulness of the units of the scales on which the results are reported. We suspect most readers are familiar with many examples of educational test results being interpreted as *measures* of students' knowledge, skills, and abilities (and perhaps, by extension, as measures of aspects of teacher and school quality, or the efficacy of educational programs and interventions), as well as results from surveys and other modes of assessment being interpreted as measures of a range of psychological and social properties (e.g., conscientiousness, self-control, empathy).

However, as we will discuss in this chapter, testing is not necessarily the same as measurement, and the mere existence of a systematic number-generating procedure is insufficient to ground subsequent claims about numeric values to the kinds of epistemic virtues—that is, precision, accuracy, objectivity, and resulting trustworthiness—commonly associated with measurement. This distinction is often not clearly articulated, including, arguably, in previous editions of this volume. As was pointed out by Borsboom (2009, p. 706) in a review of the fourth edition of *Educational Measurement*,

the authors . . . appear to consistently conflate the terms *testing* and *measurement* . . . as if any test score is automatically a measure. . . . Test scores can sometimes be interpreted as measurements . . . but not always and not necessarily so. The question of whether educational test scores can be so interpreted, and under which conditions, receives no attention at all in *Educational Measurement*—which must be considered remarkable.

Stated as simply as possible, a key purpose of the present chapter is to engage with the question of how educational measurement can (and perhaps should) be understood with respect to how measurement is understood more broadly, given the weight this concept carries in terms of interpretations of objectivity and trustworthiness. In doing

so, we do not intend to argue for a single set of necessary and sufficient conditions for an activity to be considered an instance of measurement. We will, however, argue that there are common components of trustworthy measurement processes across domains of application and that recognizing these commonalities can help frame and clarify the central issue of how measurement results are interpreted and how their claimed trustworthiness is justified.

Broadly, and in accordance with the metrological literature (e.g., Mari et al., 2017, 2023), we define measurement as *a process that provides information about a property of an object or event in the world, uses instrumentation designed to be sensitive to differences in this property, produces information in the form of values related to a scale or unit for that same property, and is qualified by information about uncertainty*. In our view, the elements of this process apply regardless of whether the measured property¹ is exhaustively definable in physical terms (e.g., temperature) or not (e.g., reading comprehension ability); our contention is that whether one is speaking of measurement in an educational context, in psychology, or in the physical sciences, the activity will involve a common set of elements that serve to justify its claimed trustworthiness. By drawing attention to these common elements, the challenges and affordances of measurement in a specific domain of application become more apparent.

It is worth noting that there is substantial variation in definitions of measurement throughout the historical and contemporary literature, and here we note just a few. Perhaps most famously, Stevens (1946, p. 667) defined measurement as “the assignment of numerals to objects or events according to rules.” Michell (e.g., 1999, p. 222) defined measurement as the “discovery or estimation of the ratio of a magnitude of a quantity to a unit of the same quantity.” Writing in the context of educational testing, Lord and Novick (1968, p. 17) defined measurement as “a procedure for the assignment of numbers (scores, measurements) to specified properties of experimental units in such a way as to characterize and preserve specified relationships in the behavioral domain.” According to Mislevy (2018, p. 313), “Educational measurement, conceived broadly, is situating observations from an assessment into a mathematical framework to support reasoning about peoples’ capabilities.” Finally, a 2022 task force commissioned for the National Council on Measurement in Education (NCME) produced a report with two distinct definitions for measurement and educational measurement. According to the task force,

Measurement is a systematic process of data collection using instrumentation that results in a quantity intended to support inferences about an attribute or property of an object, event, or phenomenon. Educational measurement involves measurement of knowledge, skills, dispositions, and abilities for some educational purpose, such as supporting learning, certifying learning, or identifying policies and practices that improve learning. (Ackerman et al., 2024, p. 8)

Inspection of and debate over what has been included and excluded in any given definition of measurement can lead to lively exchanges, whether in a classroom setting or in

a pub. It may not always be apparent that different definitions can imply very different philosophical commitments about measurement as a process (c.f., Michell, 1999; Stevens, 1946), and this is something we explore in the “Historical and Conceptual Background” section of this chapter. At the same time, any one-sentence definition of measurement can only be a starting point for a more complete understanding. In our view, whenever we call something “measurement,” we are at least implicitly laying claim to the perceived objectivity and trustworthiness commonly associated with this term. The shorthand definition that we favor is intended to draw attention to the components of a measurement process that serve to underwrite this claim. To go deeper, in this chapter we propose a framework for understanding measurement with respect to four central components: theory (T), instrumentation (I), scales and units (S), and modeling (M). We refer to this as the TISM framework, and we argue that, regardless of the subject matter or domain of application, the practice of measurement requires attention to each of these four components and their interactions.

The balance of this chapter is organized as follows. In the section “Historical and Conceptual Background,” we present an overview of some of the key historical developments that have taken human societies from a time when the terminology of measurement was primarily reserved for applications in the physical sciences to the early 21st century and the context of this edited volume, which is concerned with the methods and practices of educational measurement. We explain how this more broadened conceptualization of measurement came about. We also summarize some of the hallmarks of educational measurement: its practical focus on decision-making, its association with standardized testing, and its emphasis on treating the results of a test as a random variable amenable to statistical modeling.

In the section “Measurement and the TISM Framework,” we present and illustrate the central contribution of this chapter, the TISM framework for measurement. We describe each component of the framework and then illustrate the components in two concrete measurement contexts. We do this first for the canonical example of measuring temperature. We then shift to a more detailed illustration in an educational context for the measurement of reading comprehension. We show that the four TISM components of measurement are present and relevant in both contexts, but tend to pose unique challenges in education. We argue that this is because our theoretical understandings of constructs of measurement are often nascent or in flux and, relatedly, because the scales and units we use to interpret measurement results often have a tenuous connection to this theoretical understanding.

In the section “Challenges and Debates in Educational Measurement,” we discuss how the TISM framework relates to validity and validation. We first briefly review the literatures on these topics and discuss how a focus on measurement (and the TISM components in particular) can be viewed as compatible with and complementary to an argument-based approach to validation: Stated briefly, whenever an argument for the adequacy of a test for a given purpose involves a claim about measurement, the TISM framework helps clarify what kinds of issues would be necessary to attend to

in order to evaluate and defend this argument. We then illustrate this by turning to two examples of educational measurement activities that are challenging because, in our view, they depend on the extent to which one has an adequate substantive theory of the construct (the T in our TISM framework), whether this theoretical conceptualization coheres with the construction of test instruments (I), the scale and unit on which test results are expressed (S), and the choice of a statistical model used to relate observed test scores to the construct of interest (M). Specifically, we consider the activities involved in (a) characterizing the reliability, measurement error, and uncertainty of a measuring instrument and (b) supporting inferences about magnitude relative to the units of a measuring scale. We conclude the chapter with a summary of our main points, an acknowledgment of an important limitation of the TISM framework, and some speculation about the future of educational measurement.²

HISTORICAL AND CONCEPTUAL BACKGROUND

Measurement in the Physical Sciences

Measurement has a long history, stretching back at least 2,500 years across a multitude of cultures. Inevitably, thinking about measurement and its role in science and society has evolved concomitantly with science and society in general. A first observation about the history of measurement is that the vast majority of this history is that of physical measurement; for the most part, it has only been since the late 19th century that measurement-related concepts have been formally incorporated into the study of social, psychological, and educational phenomena. For this reason, much of the vocabulary of educational measurement has been borrowed from the physical sciences, and more specifically, from physics and engineering (McGrane & Maul, 2020). Within these disciplines, a dominant (though not universally accepted) conception of measurement draws from Euclid's *Elements*, sometimes thought of as “the earliest contribution to the philosophy of measurement available in the historical record” (Michell, 2005, p. 288). Euclid defined *measure* in terms of ratios of magnitudes: “A magnitude is a part of a[nother] magnitude, the lesser of the greater, when it *measures* the greater” (emphasis added; Euclid, trans. 2008, p. 130). The process of *measurement* then became understood as the estimation of ratios of magnitudes of empirical properties (see, e.g., Michell, 1999).

The impact of this “Euclidean” understanding of measurement is still evident in the writings of physical scientists more than 2 millennia after Euclid. A paradigmatic example is that of the Scottish physicist James Clerk Maxwell, who opened his 1873 book *Treatise on Electricity and Magnetism* with a section subtitled “On the Measurement of Quantities”:

Every expression of a Quantity consists of two factors or components. One of these is the name of a certain known quantity of the same kind as the quantity to be expressed, which is taken as the standard reference. The other component is the number of times the standard is to be taken in order to make up the required quantity. The standard quantity is technically called the Unit, and the number is called the Numerical Value of the quantity. (Maxwell, 1873, p. 1)

Central to this understanding of measurement is the conviction that magnitudes of quantities exist and that measurement is thus a process of discovery of mind-independent facts about their ratios; this perspective is consistent with *scientific realism*, which, broadly, asserts that there is an objective, spatiotemporally structured world and that at least one of the aims of scientific inquiry is the acquisition of knowledge about this world (see, e.g., Michell, 2005; Rosenberg & McIntyre, 2020). These realist views were (and still are) integral to the development of physics as a quantitative science; to a large extent, the advancement of physics has entailed the discovery of networks of lawful relationships among physical quantities, taken to be invariant features of the physical world.

Maxwell's work laid the foundation for the International System of Quantities, which consist of seven "base" or "fundamental" quantities (so called because they cannot be expressed as a function of other fundamental quantities: length, mass, duration, intensity of electric current, thermodynamic temperature, amount of substance, and luminous intensity) from which other physical quantities may be derived through physical laws (e.g., velocity as the ratio of length and time). Maxwell also helped pioneer the movement to establish the meaning of units of fundamental quantities in terms of invariant physical phenomena—for example, the meter, once defined by the length of a specific physical rod, is now defined in terms of the distance light travels in a vacuum in a given time duration—which facilitates efforts to make measurement results *subject independent*, that is, interpretable in the same way by everyone, regardless of place or time (see, e.g., Maul et al., 2019; McGrane, 2015).

Measurement in the Human Sciences

Some of the earliest applications of measurement to nonphysical human properties were in psychophysics, a program of research that originated through the contributions of Ernst Weber and Gustav Fechner in the mid- to late 19th century (see Briggs, 2021b, for an extensive overview of this history). The psychophysicists were chiefly concerned with the measurement of different kinds of "sensory sensation" through the empirical establishment of law-like relationships (e.g., Fechner's law) between the quantitative levels of a physical stimulus and levels of psychical sensation. Two distinguishing features of the psychophysics tradition came in the use of controlled experiments to provide empirical evidence for these "laws" and in the use of probability theory in general, and the normal cumulative distribution function in particular, to relate sensory "errors" to levels on a sensation continuum. Both features were inspirational in the early development of what came to be known first as latent trait theory and then eventually item response theory (G. A. Ferguson, 1942; Guilford, 1936; Lawley, 1943; Lord, 1952; Mosier, 1940, 1941; Tucker, 1946).

Louis Thurstone reconceptualized Fechner's law as a special case of his "law of comparative judgment" (Thurstone, 1927a, 1927b, 1927c). In contrast to Fechner and classical psychophysics, Thurstone's approach permitted qualitative stimuli as a starting point, so long as the stimuli could be ordered. Thurstone saw that the same mathematical psychophysical models could be applied to discriminating between the weight

of two objects (with weight being a purely physical property), or the legibility of two samples of handwriting (the perception of which involves human psychology). In the former case, the order of the stimuli was known in advance; in the latter case it would need to be inferred from the experiment. But in either case, if it could be established empirically that errors in judgment were well approximated by a normal distribution, a scale with units defined by standard deviations could be established. Although Thurstone showed little interest in metaphysical speculation about the nature of the psychological construct being measured via the law of comparative judgment, just as it had for Fechner, the approach hinged on the assumption that whatever the construct was, if it could be ordered by observational comparison, methods could be used to represent it on a continuum with a meaningful scale.

Another contemporaneous tradition that drove applications of measurement to nonphysical properties is now referred to as “individual differences” research, so called because of its shift of attention to between-person (i.e., *interindividual*) variability as a subject for study, whereas the psychophysicists were primarily concerned with within-person (i.e., *intraindividual*) variability (again, see Briggs, 2021b, for an overview of this history). Francis Galton was the chief architect of this approach in the late 19th century based on his assumption that what seemed to be true of human physical properties such as height and weight—that is, that they were normally distributed—would also be true of psychological constructs, whether conceptualized narrowly, as the ability to discriminate lengths (as in psychophysics), or more broadly, as the ability to solve mathematical problems in an educational context. Galton would justify this assumption as the consequence of a speculative theory about human heredity, positing that all human attributes are the result of a large number of small, independent random events that accumulate and thereby explain why individuals differ with respect to any particular physical or psychological characteristic.

Galton proposed a strategy for his research that he described as “relative” measurement, which only depended on the ability of an observer to accurately rank individuals with respect to some designated measurement construct. If the construct to which the ranks applied was assumed to follow a normal distribution, then the ranks could be converted into percentiles and transformed using the normal ogive into a location on a “statistical” scale with units defined by standard deviations (Galton, 1875). With this view, the primary challenge of measurement was an instrumental one. By 1884, Galton had introduced a proof of concept for how such an undertaking could be accomplished after opening an anthropometric laboratory at the site of London’s International Health Exhibition. For just 3 pence and 20 to 30 minutes of time, 9,337 visitors to the laboratory emerged with measurements of their physical attributes (length and weight), motor constructs (breathing and strength), and sensory constructs (visual acuity, color sense, discrimination of length, and discrimination of angles) recorded on a single sheet of paper. As Galton wrote, “One of the conditions that a standard set of instruments ought to fulfill is that it should admit to being readily packed, carried about

from place to place, and quickly set up anywhere for temporary use by a professional measurer” (Galton, 1885, p. 207).

Galton had advanced the position that mental tests of sensory discrimination were a promising way to measure at least some aspect of human intelligence. It was in the investigation of this position that Charles Spearman introduced many pivotal concepts and methods that remain at the heart of the study of individual differences and the practice of educational measurement (Spearman, 1904, 1907, 1910). In particular, Spearman formalized a distinction between the value of a human construct that one wishes to measure, the value that one observes as the outcome of a measurement procedure, and the difference between the two, attributable to chance error. This was the genesis of the linear error model that remains at the heart of classical test theory (for details, see Clauser et al., this volume; Briggs, 2021b; Clauser, 2021), and an elaborated version of it was at the heart of what Spearman regarded as a model for mental measurement, his theory of two factors.

Spearman (1904) had postulated that performance on any mental test could be modeled as a linear function of two quantitative mental attributes: one that was specific to that test and one that was general to all tests—the latter representing the famous “general intelligence factor,” or *g*. Spearman’s theory of two factors was intended to explain the interesting patterns he had observed among the correlations computed for teachers’ grades across a range of subjects and, later, across batteries of early mental tests. In this regard, Spearman’s theory was agnostic about the instrumentation used to elicit differences in intelligence. In fact, Spearman viewed this as an important feature of his approach to measurement, because it made no *a priori* assumptions about the quality of any given test as a measure of intelligence. Instead, the quality of a test could be judged “objectively” by ascertaining its loading on *g* relative to competing mental tests.

Taking a far more instrumental tact that would usher in a whole new wave of non-physical measurement in the 20th century by way of “intelligence testing,” Alfred Binet, in collaboration with Theodore Simon, developed clever “tests” that were to be administered as part of a short oral interview for the purpose of identifying French children with learning disabilities. In contrast to prevailing mental tests of the time (Cattell, 1890), which emphasized sensorimotor discrimination, Binet’s tests targeted a variety of complex cognitive abilities related not just to sensory discrimination but also to memory, comprehension of language, abstract reasoning, metacognition, and adaptation. Each test was meant to be engaging for the child and easy to administer, but also to provide actionable diagnostic insights into the multifaceted nature of a child’s developing intellect.

Binet referred to his procedure as a “measuring scale” for intelligence because by the time of the 1908 revision, one of its defining features was that it could be used to produce a numeric estimate of a child’s intellectual level expressed in years. This was accomplished in two stages: a first stage in which each test in Binet’s battery could be located with respect to the earliest age at which some proportion of children in a reference population could complete it successfully and a second stage where an individual child’s

intellectual level could be measured relative to this reference population as a cumulation of tests successfully completed. That is, if each test could be given an ordered location on a measuring scale, then the scale could be applied to individual students as if it represented an intellectual stadiometer (an instrument for measuring height). But this was meant to be largely metaphorical because Binet recognized that what he had constructed was a method for classification, and classification fell short of measurement because it did not involve the assessment of magnitude. (For details, see Briggs, 2021b.)

A Broadened Conceptualization of Measurement

In 1932, the British Association for the Advancement of Science appointed a committee (called the Ferguson Committee since it was chaired by the physicist A. Ferguson) to consider the scientific status of psychophysical measurement. The committee consisted of a mixture of psychologists and physicists, including the physicist Norman Campbell, who had recently published two influential books delineating a theory of measurement in the physical sciences (Campbell, 1920, 1928, 1938). Campbell argued that for *fundamental measurement* to be possible, it had to be possible to demonstrate that a property was both orderable and additive. By additive, Campbell meant that given two objects A and B with a common property, it must be possible to form a third object C such that the property of C is the combination of A and B. Only when this could be satisfied would it be defensible to develop a procedure for representing properties of objects with numbers.

Given this understanding of measurement, psychophysics could not be considered an instance of fundamental measurement because there was no way to show that “sensory sensation” could satisfy the requirement of additivity. The Ferguson Committee met on multiple occasions over an 8-year span and released two reports indicative of a stalemate (A. Ferguson et al, 1938, 1940). The physicists on the committee argued that psychophysics was not measurement; the psychologists on the committee balked at the consequences of Campbell’s restrictive conception of measurement but failed to suggest any compelling alternative.

It was this outcome from the Ferguson Committee that prompted the psychologist Stanley Smith Stevens (1946, 1951) to propose a broadened definition of measurement as the assignment of numerals to objects or events according to rules. Stevens’s definition of measurement had accepted from Campbell the premise that the activity of measurement was one of numeric representation, rejected the premise that only additive properties were measurable, and dropped altogether the formal distinction between an object and a property of an object. Stevens argued that additivity was just one of many “rules” that could be used in any experimental procedure that required humans to relate numerals to objects or events. Stevens and other psychophysicists invoked a variety of operational procedures in their experiments to elicit judgments about physical stimuli with respect to order, difference, and ratio.

From here, Stevens made distinctions regarding the “level” of measurement that could be attained as a function of different rules for numerical assignment through a taxonomy of nominal, ordinal, interval, and ratio scales. Stevens also introduced the

concept of *permissible statistics*, arguing that the types of statistical analyses that could be justified depended on the strengths of the scales of the relevant measures. For example, with measures on an interval or ratio scale, it would be meaningful, and therefore permissible, to make comparisons premised on the computation of means and standard deviations, but not for measures on an ordinal or nominal scale. (For more on Stevens, his taxonomy, and his approach to measurement, see Briggs, 2021b; Luce & Suppes, 2002; McGrane, 2015; Michell, 1986, 1999; Stevens, 1946, 1951.)

The distinction Stevens was making between measurement and scaling to a great extent represented a codification of the changing practices of different fields of quantitative psychology between 1860 and 1950. In the influential work of Fechner, Thurstone, Galton, Spearman, and Binet, among others, the terminology historically associated with physical measurement was being extended to any attempt to subject human characteristics to quantitative treatment. While there may have been differences in focus in the methods proposed for the measurement of nonphysical human constructs, it is noteworthy that a consensus remained that the ideal kind of measurement was that which produced measures on what Stevens was defining as either an interval or, preferably, a ratio scale. Moving forward, Stevens's broadened definition became highly influential—it was the definition of measurement invoked by Lorge (1951) in the first edition of *Educational Measurement*, and it has, arguably, remained a tacitly accepted definition in education and psychology to the present day (Michell, 1997).

Measurement in Education

In the early 20th century, the practice of *educational measurement* became synonymous with the development of group-administered and objectively scorable tests of students' knowledge, skills, and abilities that were thought to be acquired in or relevant to school settings. The key technology that made educational measurement possible on a large scale came directly from advances in the technology of testing prompted by group administration and multiple-choice item formats, innovations that emanated from the demonstration that intelligence testing could be used to facilitate the efficient placement of military personnel during World War I (e.g., Jones & Thissen, 2006; Yerkes, 1921). Francis Galton had first collected measurements for roughly 9,000 individuals at his anthropometric laboratory (Briggs, 2021b); just 7 years later, Joseph Mayer Rice had given some 33,000 students common tests of spelling (Kridel, 2000). But nothing came close to the accomplishment of the Army Alpha and Beta exams, administered cumulatively to 1.75 million recruits by the time World War I ended in 1918 (Kevles, 1968).

In the pioneering works that had introduced mental testing to a broader audience (Cattell, 1890; E. L. Thorndike, 1904), the products of mental tests had been referred to as measurements, in (at least) the loose sense that every test could be used to assign a number to a person where no number had existed before. The “educational” modifier seems to have been added to distinguish the measurement of student attainment (E. L. Thorndike, 1912, 1918) from the measurement of the broader suite of psychological

constructs that had become the province of tests of intelligence, personality, and attitudes. Hence, if domain-specific tests of student attainment produced educational measurements (plural), the process of creating the tests combined with analysis of results for comparative purposes fell under the general purview of educational measurement (singular).³

Even before the Binet–Simon scale had been translated into English (Goddard, 1910) and adapted for use with American children (Terman, 1911, 1916), a growing interest in educational measurement had already begun to take root in the United States as part of a broader progressive movement. A key idea being advanced was that public education could be improved systematically by applying the successful methods of the physical sciences—in particular, measurement and experimentation—to the evaluation of curricular and instructional efficacy. Such an approach hinged on the availability of standardized tests to provide educational measurements of the desired “products” of education (E. L. Thorndike, 1912). This was at the heart of the quantitative imperative articulated most famously by E. L. Thorndike, the father of educational measurement, in his “credo”:

Whatever exists at all exists in some amount. To know it thoroughly involves knowing its quantity as well as its quality. Education is concerned with changes in human beings; a change is a difference between two conditions; each of these conditions is known to us only by the products produced by it—things made, words spoken, acts performed, and the like. . . . To measure a product well means to define its amount [so] that competent persons will know how large it is, with some precision, and that this knowledge may be conveniently recorded and used. This is the general Credo of those who, in the last decade, have been busy trying to extend and improve measurements of educational products. (E. L. Thorndike, 1918, p. 16)

It might be easy to miss some important subtleties regarding E. L. Thorndike’s approach to educational measurement. To begin with, the “whatever” Thorndike took to exist as a quantity in educational contexts was not some educational or psychological attribute of a student, but the attribute of an educational product, such as the legibility of a sample of handwriting, the merit of a written essay, or the complexity of an arithmetic problem a student has been asked to solve. What could be known about student learning must be inferred from what could be observed in the products created by students and the relationship between the quality of these products and outcomes of societal value. The role of measurement in this context was to establish scales for the quality of these different products, so that the scales could be used to clarify and standardize goals for instruction and learning. In this sense, what Thorndike referred to as measurement might be what others would today refer to as “scaling.”

Educational measurement has always had a decidedly practical orientation because it is typically undertaken in support of evaluative decision-making with important ramifications for children and young adults in particular. For example, Rice (1913) was one of the first to use standard tests to demonstrate that students exposed to instruction with heavy doses of repetitive spelling and arithmetic drills were no more likely to excel

in their subsequent achievement than students with a lower dosage of this instruction. E. L. Thorndike had developed measuring scales for the quality of written composition to support the argument that drilling students in Latin grammar did not produce transferable skills that helped them become better writers (Woodworth, 1952). These were examples in which educational measurement was being used for comparative purposes in the aggregate. By the mid-20th century, however, a national testing industry had emerged with a focus on the use of educational measurements to also classify and sort *individual* students.

This practical orientation was evident in the chapters of the first edition of *Educational Measurement* (Lindquist, 1951) and has been evident in all the editions that have followed. As E. F. Lindquist wrote in this book's preface, "There has long been an urgent need, particularly in the advanced training of measurement workers, for a comprehensive handbook and textbook on the theory and technique of educational measurement" (Lindquist, 1951, p. vii). What Lindquist seems to have meant by "technique" were the nine chapters in Part 2 of the book devoted to "The Construction of Achievement Tests." This corresponds to the component of measurement that we have identified as instrumentation—the I in our TISM framework that we elaborate in the section of this chapter entitled "Measurement and the TISM Framework." However, what Lindquist meant by theory was not quite the same as the component we identify as the T in our TISM framework and describe as the need to have a substantive theory about the construct of measurement. Instead, the theory he had in mind was the developing wisdom on *test* theory—that is, the use of statistical models and methods to inform the optimal design of tests to achieve their intended purposes in educational contexts. It is to developments in mathematical and statistical modeling of test data that we turn to next in more detail because this represents an area in which the scholarship related to educational measurement has been especially active and productive since the mid-20th century.

Statistical Models and Educational Measurement

Classical Test Theory

Although the core concepts at the heart of classical test theory (CTT) can be said to have originated in the work of Charles Spearman and Francis Edgeworth near the turn of the 20th century, further refinement and formalization of the CTT model to address problems related to educational testing were spurred by Kelley (1923, 1927) and Thurstone (1931). By mid-century, the basic tools of classical test theory were widely accessible in Gulliksen (1950) and R. L. Thorndike (1951). However, it was not until the contributions of Melvin Novick and colleagues that CTT was fully axiomatized as a *mathematical or statistical* model (see Novick, 1966; Novick & Lewis, 1967; and chapters 1–11 of Lord & Novick, 1968). (See also Cai et al., this volume, for a discussion of psychometric models.)

CTT is premised on a definition and a thought experiment. Let x_{ij} represent the numeric score on a unique test that has been given to a unique person. The subscript

i indexes the test; the subscript j indexes the person. The observed test score x_{ij} could in principle result from the score assigned to a single test item or task, but it is more commonly assumed to result from the sum of scores assigned to multiple item responses. The fundamental equation of CTT is

$$X_{ij} = \tau_{ij} + E_{ij}. \quad (1)$$

The terms on the right side of Equation 1 are defined as follows. The “true score” τ_{ij} is defined as the numeric value that results from taking the expected value of X_{ij} . An expected value is a mathematical concept and only has meaning with reference to a random variable. This is where the thought experiment comes in. In what sense can an observed test score, x_{ij} , be conceptualized as the realization of a random variable, X_{ij} ? With the help of a little brainwashing.

Suppose we ask an individual, Mr. Brown, repeatedly whether he is in favor of the United Nations; suppose further that after each question we “wash his brains” and ask him the same question again. Because Mr. Brown is not certain as to how he feels about the United Nations, he will sometimes give a favorable and sometimes an unfavorable answer. Having gone through this procedure many times, we can then compute the proportion of times Mr. Brown was in favor of the United Nations. (Lazarsfeld, 1959, as cited in Lord & Novick, 1968, p. 29)

The idea here is that if it were possible to observe the results from an infinite number of independent replications of a testing procedure, what we would observe would be a distribution of values. Since the mean of this hypothetical distribution is τ_{ij} and since $E_{ij} \equiv X_{ij} - \tau_{ij}$, it follows that the expected value of E_{ij} will be 0 by construction. Hence, in our thought experiment, the reason that x_{ij} deviates from τ_{ij} is because of some random source of error, which we might think of as good or bad “luck.” Without further elaboration (and generalizability theory, discussed next, was developed to provide such an elaboration), the sources of the good or bad luck are unclear. It could be related to some aspect of the testing procedure, some characteristic of the person being tested, or the interaction between the two that could change across brainwashings. But irrespective of the causes of variability in responses, the quantity of interest is $\sigma^2(E_{ij})$. If this variance is large, it indicates that x_{ij} will be an unreliable measure of τ_{ij} . And because $\sigma^2(E_{ij})$ can differ by person, the same test could conceivably offer a reliable measure of one person’s true score, but an unreliable measure for another.

The statistical challenge of CTT is to devise an approach that can be used to obtain an unbiased estimate of the average of $\sigma^2(E_{ij})$ for a population of test takers. For details on how this challenge is met through the derivation and estimation of a reliability parameter—the proportion of variance in observed scores among a population of test takers that is “real” and not attributable to chance—see Lord and Novick (1968), Haertel (2006), or many other didactic presentations of the CTT linear model available on the Internet. Statistical approaches for estimating a reliability coefficient are all premised on some version of the assumption that it is possible to create a second test that

is “parallel” (according to certain criteria) to the test of interest. This might be done by literally constructing and administering a second test, designed to be parallel to the first. Or, in an approach more commonly taken in the computation of “Cronbach’s alpha,” an existing test is conceptualized as one that could be split into a smaller set of parallel subtests such that the full test can be cast as a composite of these subtests (in the limiting case, a single item could comprise a unique subtest).

There is much that can be done with a suitable estimate for a reliability coefficient in hand (see also Lee & Harris, this volume, for a discussion of reliability). The statistic provides a basis for comparing different tests administered to the same population that not does not depend on the scale of the test; all things equal, if two tests designed to measure the same construct differ in their reliability, the test producing more reliable scores is to be preferred. In a related sense, the general Spearman–Brown formula can be used to estimate the number of test items needed to achieve a desired level of reliability. It can be shown that the best way to maximize reliability with the number of items held constant is to select items of moderate difficulty that are strongly intercorrelated (e.g., Richardson, 1936). Beyond this, the reliability coefficient is properly viewed as a means to the end of estimating a standard error of measurement, useful in quantifying uncertainty about the value of an individual test taker’s true score.

But what is τ_i exactly? There are at least two ways of conceptualizing the meaning of a true score within CTT. In the original formulation of the linear error model by Spearman and Yule near the turn of the 20th century, the observed score on a mental test was split into the actual measure of interest and an increment attributable to errors of observation. This corresponds to what Lord and Novick (1968) described as the “Platonic” conception of a true score as the value of an attribute the test was intended to measure. The true score defined above (i.e., Equation 1) represents an alternative, *operational* conceptualization of the true score as the long-run average that one would observe if it were possible to collect the results from independent replications of the same testing procedure on the same individual (i.e., the brainwashing thought experiment). Now, in a practical sense, this may not seem to matter, since either conceptualization can be used to motivate the same estimate of a reliability coefficient. But each conceptualization may correspond to a different approach to establishing a substantive theory that can predict and explain individual differences for the construct of measurement, and this in turn might influence the approach being taken to design and administer a test instrument.

Generalizability Theory

In discussing the construction of the CTT model, Lord and Novick (1968) had anticipated the extension of the model that was already underway in the form of *generalizability theory* (GT; Cronbach et al., 1972). In a section entitled “What Is Error?” they wrote,

The error random variable and the true score are determined by the experiment, not by some hypothetical state of affairs. . . . The error random variable may have a number of components associated directly with the physical measurement process,

others associated with the environment in which the measurements are taken, and still others associated with temporal changes in the person. Differing degrees of control and randomization of these components define different true scores and hence different residual (error) scores. For each definition of a true score, of course, we have a different error score. (Lord & Novick, 1968, p. 39)

To appreciate what they meant by this, we can translate the “components” to which Lord and Novick alluded into a scenario in which a putative measurement procedure had been envisioned in which a target population of students is being administered a set of test items, and the responses to these test items are to be scored by one or more “raters.” Importantly, the particular set of items that appears on the test, and the raters that score a student’s responses to the items, are not fixed. What Lord and Novick referred to as components would become known as *facets* of a measurement procedure in GT parlance. These facets represent distinct sources of “error” in the sense that they vary at random whenever the measurement procedure is being invoked. For the concept of “at random” to be sensible, under GT anything defined as a facet must come with a corresponding population of “admissible” observations (i.e., all items and raters that would be deemed effectively interchangeable for use on a test). The introduction of facets creates the need for a new thought experiment. Whereas under CTT one must imagine the distribution of scores that would be observed if the same student could be given the same test over and over, we now imagine the distribution of scores we would observe if, following each test administration, we could create a new test, constructed by sampling N_j items and N_k raters at random without replacement from the respective populations of items and raters. As such, the true score for a given student now has a different meaning. It is the average score we would observe if it were possible to repeat a crossed factorial experiment in which the test on each replication is constantly changing as a function of the items and raters being sampled. In GT, this true score is renamed as a student’s *universe score*, since it always has the potential of involving the crossing of samples from more than one population of a measurement facet.

From a modeling perspective, GT can be said to represent an extension of CTT because it serves to essentially decompose error variance into specific sources using analysis of variance techniques. In some sense, it is the computation of these variance components that represents the easier part of GT. The harder part is the conceptualization of the facets of measurement, the populations of admissible observations, and the intended universe of scores over which a generalization is desired. The prioritization of the facets over which a score generalization is desired becomes a critical conceptual move because—in principle—it should be combined with an actual experimental study in which both subjects and facets have been randomly sampled to permit the accurate estimation of the relevant variance components (known in GT as a “G study”). In GT, it is the responsibility of those involved in the design and use of a test to operationalize a universe of facet combinations over which score generalizations can be made.

Many important questions arise in the process. How should one define a population of “admissible” test items? Is the population to be narrowly defined and finite (e.g., all the multiplication problems $m \times n = ?$ where $m, n \in [1, 10]$, as described by Markus & Borsboom, 2013)? Or is it broad and potentially infinite (e.g., all items that could be written by crossing what students are expected to know about mathematical concepts with the practices by which they are expected to invoke them to solve real-world problems)? Should the population of items be considered univariate (e.g., all mathematics content in Grade 5) or multivariate (e.g., the specific Grade 5 content domains of number sense, geometry and prealgebra)? What facets of the measurement procedure are most readily manipulable in an experimental sense? Which facets should be fixed? Which are ignorable? Should the facets be conceptualized as crossed (all items crossed by occasions) or nested (items are unique to a given occasion)? For more detail on this and other aspects of GT, see Cronbach et al., (1971), Shavelson & Webb (1991), and Brennan (2003).

Both CTT and GT provide a basis for homing in on the design of a test that can minimize uncertainty in results due to a particular operationalization of “chance error.” In CTT, because error is that which is orthogonal to a true score in any single administration of a test, it represents something of a black box. Indeed, since the CTT thought experiment only involves replications of the same procedure, it is not clear just why one should expect an observed score to change across hypothetical replications of a test given that all the features of the test itself are fixed. This gets elaborated in GT by more clearly specifying a sampling model for test construction, one in which facets of measurement (e.g., items, raters, occasions) are being drawn from their respective populations. In this sense, GT provides some new conceptual tools that can be used to open the black box. It also provides at least some sense in which CTT can be rescued from the criticism that every test must have a unique true score by introducing the concept of a universe score.

At the same time, the ontological status of a universe score retains some of the same fuzziness as the true score. Is it only a statistical parameter, just more esoterically defined than it was under CTT, or is it intended as a measure of some mental construct within the test taker? Because CTT and GT were being formalized between 1950 and 1970, there can be little question that those contributing to the literature on educational measurement took what can be characterized as either an agnostic position about the existence and interpretation of any underlying construct or, in some cases, a more overtly skeptical position, captured rather nicely by Cureton (1951, p. 641), who wrote,

“Generosity,” “kindness,” “skill,” “proficiency,” and the like are words representing abstract concepts. When we ascribe no more meaning to such a term or construct than the common features of the acts summarized by the word, the term and concept are said to be “operationally defined.” So long as we stick to operational definitions in discussing and thinking about the abstract concepts used in educational measurements, we will be on safe ground. . . . The performer whose average score is high is termed mentally able. We must not say that his high score is due to

his high ability, but if anything, the reverse. We say he has high ability because his performance has yielded a high criterion score. His “ability” is simply a summary statement concerning his actions.

In this way of thinking, a test is conceptualized as a device for taking samples from behaviors reflecting educational objectives that students are expected to have mastered. The construct of measurement is thus defined operationally as some composite of the behaviors that have been formally or informally associated with the content objectives being tested. When the construct being measured by a test is defined operationally by the chain of logic that connects it to empirically observable behaviors, the place to look for substantive theory related to the construct is primarily in the articulation of a replicable process used to articulate a universe of admissible observations (e.g., the blueprints for item design, the protocol for rater training) and draw random samples from this universe.

Item Response Theory

Item response theory (IRT) models were developed to answer questions that the CTT and GT models cannot answer—or at least cannot answer within the context of their mathematical formulation. As we have seen, CTT and GT both revolve around models that were created to quantify the uncertainty in a test instrument that is attributable to random errors in an intended measurement procedure. But to the extent that the linear error models of CTT and GT represent measurement models, they are missing something quite important: scales and units to ensure that the numeric values that result from a measurement procedure are meaningful to those attempting to interpret the result and invariant to differences that arise in the facets of measurement across replications of the procedure. The scale of the test scores that results from a CTT and GT model are locally defined and sample dependent: locally defined in the sense that the scale is a direct function of the scoring rules that have been put in place to transform a student’s set of responses on a test into a numeric value; sample dependent in the sense that any statistic one computes for the test depends on the samples of students and measurement facet conditions. In the absence of a common scale that is invariant to these sampling decisions, it becomes quite challenging to use different tests to monitor trends in performance for a population of students over time, compare differences among groups of students, or make diagnostic inferences about an individual student’s strengths and weaknesses.

IRT offers a possible solution to these challenges because, in principle, an IRT model produces an estimated location for a construct of interest on a scale of measurement that is invariant to the choice of items that comprise a test. And symmetrically, the model can be used to produce estimates of the difficulty of test items that are invariant to the choice of subjects that respond to the items. The cost of these benefits comes in much stronger assumptions than CTT, but these assumptions serve to connect CTT back to the factor analysis tradition that motivated its fundamental equation (Briggs, 2021b). In what follows, we assume the reader is familiar with the basic logistic parameterizations

of IRT models for dichotomously and polytomously scored items. For details, see Baker & Kim (2004), van der Linden (2016), and the many didactic presentations available in introductory textbooks and on the Internet.

A critical assumption made in IRT is that of conditional (local) independence. When conditional independence holds, the existence of a continuous latent variable, θ , typically posited to be unidimensional, is taken as a summary explanation for the intercorrelation among test items. According to the model, if one could restrict a population of test takers to those with identical values of θ , all remaining variability in responses across individuals for any given item would be attributable to chance. When an IRT model shows adequate fit to empirical data, it comes with the very appealing property of parameter invariance. Parameter invariance promises that what one learns about the parameters for a set of test items (e.g., their difficulty and discrimination) does not depend on the ability of the particular sample of people responding to the items, provided that the sample is part of the target population. Through this property, IRT models can be used to equate tests using designs that feature different samples of students taking tests in which some items are common, but others are unique. When this has been accomplished, tests with different true scores can be used to produce comparable estimates on the logit scale of the latent variable θ .

Although IRT retains the same emphasis as CTT and GT on using a quantification of uncertainty about the construct of measurement as a criterion for test design, the notion of measurement error is one that depends on the relative locations of test items and test takers on the underlying logit scale. This can be appreciated by the fact that after fitting an IRT model, one can compute the amount of “information” each item contributes at each possible location of the ability continuum. Technically, information is the reciprocal of the precision with which a statistical parameter has been estimated, a concept introduced by the statistician R. A. Fisher in his development of maximum likelihood estimation. Each item contributes some information about the location of an individual on the ability continuum; the sum of item information functions produces a test information function; and the square root of the inverse of this information produces a conditional standard error of measurement function (see, e.g., Baker, 1985, for a nice introduction). A consequence is that given a population of test items with known (i.e., previously estimated) parameters, unique test forms can be constructed that minimize uncertainty due to measurement error at any targeted location on the underlying scale, provided that sufficiently discriminating items exist at the targeted locations. This is the feature of IRT models that has driven the development of computer-adaptive testing, a technology of dynamic test design that would not be possible (or at least much more difficult to accomplish) using CTT or GT.

The latent variables in IRT models are specified as if they were continuous quantities. In this way, the analysts who invoke such models follow the precedent from the foundational work described earlier by Fechner, Spearman, Thorndike, and Thurstone, among others. Indeed, in linking their derivation of the normal ogive version of the two-parameter IRT model to factor analysis, Lord and Novick (1968)

also assumed that observed binary item responses can be conceptualized as the dichotomization of a unique continuous quantity for each unique test item. It is seldom clear whether such assumptions represent a pragmatic⁴ or realist commitment about latent variables as constructs of measurement. Under a pragmatic commitment, one may define θ to be a continuous quantity only because doing so makes it possible to predict, with sufficient accuracy to be useful, what will happen when a student at any given location of logit scale is presented with an item at any other location on the scale. In contrast, when making a realist commitment, one is staking a claim about the structure of the construct of measurement and why it is that individuals are expected to vary on this construct. This would seem to require additional substantive theorizing about the nature of the construct, as well as its relationship with other constructs.

In their original presentation of IRT as a “latent trait model,” Lord and Novick (1968) clearly embraced a pragmatic approach.

Any theory of latent traits supposes that an individual's behavior can be accounted for, to a substantial degree, by defining certain human characteristics called traits, quantitatively estimating the individual's standing on each of these traits, and then using the numerical values obtained to predict or explain performance in relevant situations. (Lord & Novick, 1968, p. 358)

The socially constructed latent trait is to be interpreted in a metaphorical sense:

It is sufficient that a person behaves as *if* he were in possession of a certain amount of each of a number of relevant traits and that he behave as *if* these amounts substantially determined his behavior.” (Lord & Novick, 1968, p. 358, emphasis added)

In general, Lord and Novick (1968) conceptualized a true score and latent trait as representations of the same behavioral composite, but expressed on a different scale of measurement. This seems to follow from the fact that mathematically, after fitting an IRT model, one needs only to compute a test characteristic curve as the sum of item characteristic curves and then use this function to relate a latent trait to a true score. There would seem to be at least one logical problem with this position, articulated by Borsboom (2005) and Markus and Borsboom (2013). As we have seen, a true score in CTT, and its extension, the universe score in GT, are numerical values that are defined by the choice of items that appear on a given test instrument, irrespective of how those items are selected. But there is nothing that would guarantee that the intercorrelation of these items need be explained by a single underlying latent trait, θ , which is the defining feature of an IRT model. Therefore, if θ is known, one can derive a true score specific to any set of items that fits the IRT model. But the relationship is not symmetric—knowledge of a test's true score is not guaranteed to provide insights into a value of θ that will satisfy the IRT assumption of conditional independence. This would suggest that a true score and a latent trait should be viewed as two fundamentally different concepts.

The Rasch Model

Mathematically, the Rasch model can be viewed as a constrained version of a three-parameter logistic IRT model (3PLM; Birnbaum, 1968) with no lower asymptote and item characteristic curves with common slopes, and in this sense it can simply be referred to as a one-parameter logistic model (1PLM; Thissen, 1982; Thissen & Steinberg, 1986). However, from Rasch's perspective, the requirement of no varying lower asymptotes or discrimination parameters needed to be satisfied to construct an educational measuring instrument that had properties of invariance analogous to a physical measuring instrument. In this sense, the model is often associated with an entirely different data-model paradigm for educational and psychological measurement (Andrich, 2004). Under Lord and Birnbaum's IRT paradigm, the choice of model follows from features of the test data at hand. For example, if preliminary classical item analyses suggest that there is significant variability in the correlations between items and the total score on a test, and if the item format involves selected response options that can be answered correctly by guessing, then it would seem sensible to model test item responses according to the 3PLM. In contrast, under the Rasch paradigm, test items must be designed (or refined) until they can be shown to meet the criteria for a measurement model with certain properties.

The property to which Rasch attributed the greatest importance was something he referred to as specific objectivity, but which we might describe in more general terms as invariance of comparisons, or the (invariant) meaningfulness of a unit of the scale on which measurement results are reported. The basic idea is that when the responses from some population of people and items fit the Rasch model, *differences* in the ability of any two people will not depend on the reference set of items used to facilitate the comparison. Symmetrically, *differences* in the difficulty of any two items will not depend on the reference sample of people. Specific objectivity follows from two important mathematical features of the Rasch model known as separability and sufficiency. For details, see Engelhard (2013), Fischer and Molenaar (1995), and Sijsma and van der Ark (2020).

The Rasch model bears an interesting similarity to another innovation that was taking place outside the context of educational measurement as part of the development of what is known as representational measurement theory.⁵ Of particular relevance is the theory of conjoint measurement (Krantz et al., 1971; Luce & Tukey, 1964). One of its instances, additive conjoint measurement, provides a framework for testing the hypothesis that a variable of interest can be located on a quantitative continuum, and as such, whether the variable can be represented on a scale with interval properties. Conjoint additivity applies when it is possible to transform two variables so that their additive combination forms a third variable without any interactions. Just as Rasch had sought to illustrate his model and its property of specific objectivity by reference to classical physics and Newton's second law of motion (Andrich, 1988; Rasch, 1980, pp. 109–125), Luce and Tukey (1964) had taken a similar tact in illustrating the concept of conjoint measurement.

It has been argued that the Rasch model can be interpreted as a probabilistic version of additive conjoint measurement (Bond & Fox, 2015; Brogden, 1977; Perline et al., 1979). A similar argument cannot be made for other IRT models with more complex item parameterizations. Following this line of reasoning, the sense in which the Rasch model produces a scale with interval properties comes not from any distributional assumptions (i.e., normality) made about the latent variable (i.e., θ), but from the interpretation of individual differences in θ with respect to a designated reference interval of item difficulty. Just as one could observe the same acceleration by maintaining the same ratio of force to mass, under the Rasch model one can observe the same probability of a correct response by maintaining a constant trade-off between person ability and item easiness—as one goes up, the other must go down. The analogy, however, quickly drifts into the same thought experimental territory as CTT, since a person’s “ability,” unlike force or mass, is not readily subject to manipulation. What would seem to be required to further realize the analogy between conjoint measurement theory and the Rasch model would be strong substantive theories about learning that could be used to, at a minimum, lead to the design of items according to factors that are strongly predictive of their difficulty. We will consider an example of this in the section “Measuring Reading Comprehension.” For more on Rasch measurement theory, see Wright (1997), Engelhard (2013), Bond and Fox (2015), Andrich and Marais (2019), Wind and Hua (2022) and Wilson (2023).

Statistics, Psychometrics and Computational Advances

Statistics can be broadly defined as the science of collecting, analyzing, presenting, and interpreting data. It follows that statistics and statistical modeling have a role to play any time a test has been administered to facilitate the collection of data, since these data will invariably be analyzed, presented, and interpreted, and this will be the case whether the test is administered in an educational or a psychological context. The development and use of statistical models in a psychological context defines psychometrics as a subdiscipline of statistics. For example, Jones and Thissen (2006, p. 21) described psychometrics as “the disciplinary home of a set of statistical models and methods that have been developed primarily to summarize, describe, and draw inferences from empirical data collected in psychological research.” If one takes a narrow view by identifying educational measurement solely with the application of the models described in the previous four subsections (which, to be clear, we do not), then the primary difference between psychometrics and educational measurement is the context and purpose for which empirical data have been collected. The statistical models and methods of inductive reasoning found in each are the same.

An important distinguishing feature between the models one finds within CTT and GT relative to the taxonomy of models found in IRT (and here we include the Rasch model within this umbrella) is that IRT models involve assumptions that can be tested and rejected when they appear implausible in the face of empirical data. The origin of CTT predated many of the mathematical formalizations of statistical models

with respect to random variables, though this was later retrofitted to justify some of its central results. In contrast, IRT models were formulated from the outset so that a clear distinction could be made between the parameters of the model and the estimation of these parameters from data. What was already clear by the time of Lord (1980) was that while some of the more complex IRT models seemed suitable as a means of addressing a host of practical problems in educational testing context, they could only be implemented at scale by overcoming some significant computational challenges in the estimation of model parameters.

Briefly, to appreciate the estimation challenge, let the term P_{ij} represent the functional form of an IRT model, where i indexes a test selected-response item ($i = 1, \dots, n$) and j indexes a person taking the test ($j = 1, \dots, N$). Let x_{ij} represent one of two possible scores; $x_{ij} = 1$ represents a correct response, and $x_{ij} = 0$ is an incorrect response. When item and person parameters are known, then P_{ij} returns the probability of a correct response from person j to item i . Following the assumption of conditional independence among items and statistical independence among respondents, a joint likelihood function can be written as

$$Prob(X|\theta) = \prod_{j=1}^N \prod_{i=1}^n P_{ij}^{x_{ij}} (1 - P_{ij})^{1-x_{ij}} \quad (2)$$

The original joint maximum likelihood estimation approach proposed by Birnbaum (1968), and implemented in the earliest computer programs (BICAL for Rasch models; Wright & Mead, 1978; LOGIST for the 3PLM, Wingersky et al., 1982), proceeded by taking the log of Equation 2 and then setting simultaneous estimation equations after taking the partial derivative of the log likelihood function with respect to each item and person parameter. Joint maximum likelihood estimation would then iterate between items and persons, treating one set of parameters as known while solving for the others using the Newton–Raphson technique. The iteration would continue until some convergence criterion was met.

By the early 1980s, a tractable alternative to the joint maximum likelihood estimation approach in the context of models with item discrimination and guessing parameters had been introduced by Bock and Aitkin (1981) that involved integrating over the distribution of person ability and then iterating a solution through use of the expectation–maximization algorithm (Dempster et al., 1977). The details of the development of marginal maximum likelihood estimation are outside the scope of this chapter, but see Bock (1997) for an overview and Baker and Kim (2004) for a comprehensive account. What needs to be appreciated is that the innovation of marginal maximum likelihood estimation also introduced new elements with conceptual significance. Importantly, the marginalization of a likelihood function requires an explicit assumption to be made about the population distribution of θ , which has implications for interpretations about the meaning of probability in an IRT model and for the implied source of measurement error when a person comes in contact with a test item (Holland, 1990). The addition of a population distribution would eventually make it easy to envision new ways that the IRT model can be extended by, for example, expressing

the mean of the person population distribution as a function of other covariates (e.g., “latent regression,” see Mislevy, Johnson, & Muraki, 1992). The marginal maximum likelihood estimation innovation also introduced a Bayesian conceptualization of probability into the estimation of person parameters in the form of a posterior distribution. This formalized the idea that what an IRT model can (and perhaps should) provide is not so much a single measure of an attribute, but a distribution of plausible measures, with the range of these values quantifying the certainty of the measurement procedure.

The advent of the personal computer and the exponential increases in storage and processing power throughout the 1990s and early 2000s made large-scale applications of IRT a reality not only for testing companies, but also even for academic researchers. Highly specialized software proliferated, but also may have obscured the connections between IRT and a broader class of statistical models. By the turn of the 21st century, these connections were being made more transparent because it could be demonstrated that IRT models are special instances of generalized linear and nonlinear mixed models (e.g., McDonald, 1999; De Boeck & Wilson, 2004; Skrondal & Rabe-Hesketh, 2004), with parameters that are estimable using mainstream commercial software (e.g., SAS, Stata) and even freely available open-source software (e.g., R). Since 2010, new advances that capitalize on a Bayesian conceptualization of probability and Markov chain Monte Carlo estimation have opened the door to the estimation of complex, multidimensional models that were only a glimmer in Frederic Lord’s eyes in 1980 (e.g., Cai, 2010a, 2010b, 2017).

MEASUREMENT AND THE TISM FRAMEWORK

Having traced some of the key developments that have expanded the reach of measurement terminology and practices from the physical sciences to the human sciences, and ultimately into the domain of evaluative decision-making about teaching and learning, we now return to the general definition of measurement we provided at the outset of this chapter.

Measurement is a process that (a) provides information about a property of an object or event in the world, (b) uses instrumentation designed to be sensitive to differences in this property, (c) produces information in the form of values related to a scale or unit for that same property, and (d) is qualified by information about uncertainty.

Four components comprise this definition, and each one corresponds to a core component of the TISM framework that we now introduce and illustrate in detail.

Theory, Instrumentation, Scales and Units, and Modeling

In our view, the process of measurement necessarily involves interactions between four bodies of knowledge and practice, which we refer to as the four central components of measurement:

1. *Substantive theory.* The generation and refinement of theory (e.g., a physical law, a cognitive model) to define the target property or construct (e.g., temperature, reading ability) and to describe the sense in which this property or construct is instantiated in the relevant object (e.g., a vessel of water, a person). A key feature of such theory is that it is amenable to empirical investigation and potential revision.
2. *Instrumentation.* The development of instrumentation (e.g., a thermometer, a reading test) designed to be maximally sensitive to variation in the target property or construct across objects (e.g., different vessels, different people) and/or time and minimally sensitive to everything else.
3. *Scales and units.* The development of scales and potentially units to ensure that the (usually numeric) values that result from measurement will have an interpretation that is meaningful, publicly explainable, and invariant (within specified limits) to the objects being measured, the instruments used to produce the numeric values, and the person who is interpreting the values.
4. *Modeling.* The application of formal models for the purpose of characterizing the uncertainty of the measurement results.

We depict these four components of measurement and their interactions visually in Figure 21.1.

We find the TISM framework helpful as a way of organizing and analyzing the features of measurement processes that serve to secure and justify the claimed meaningfulness

FIGURE 21.1
Central Components of the Process of Measurement

and trustworthiness of measurement results. One thing that the visual representation of our framework as a Venn diagram emphasizes is that the process of measurement involves two- and three-way interactions among these four components and that, ideally, a coherent perspective on measurement places it at the center of a four-way interaction.⁶ From this vantage point, testing in and of itself is simply a form of instrumentation. The extent to which a given instance of testing is an instance of measurement depends on how test design has been informed by substantive theory about the target construct, the approach taken to place test results on an appropriate reporting scale, and the way that models are being used to characterize uncertainty and evaluate hypotheses about the construct.

In what follows, we show how the TISM framework can be used to unpack the features of a measurement process with two concrete examples. To emphasize the point that the framework can be applied to measurement in both the physical sciences and education, we first briefly discuss the application of the TISM framework to the measurement of temperature. We then provide a more detailed treatment in the context of the measurement of reading comprehension as it occurs in two assessment programs in the United States, the National Assessment of Educational Progress and the Smarter Balanced Assessment Consortium.

Measuring Temperature

Temperature measurement, that is, thermometry, is one of the more recent examples of physical measurement, including the historical development of measuring instruments that represented levels of temperature on ordinal (e.g., thermoscopes), interval (e.g., Celsius thermometers), and finally ratio (e.g., Kelvin thermometers) scales, as the theory and practice of thermometry matured. For two accounts that follow these developments in more detail, see Chang (2004) and Sherry (2011).

Substantive Theory

Contemporary thermometry is underpinned by centuries of empirical observations and experimentation, culminating in the development of the mature scientific field of thermodynamics, which is the T of our TISM framework. Thermodynamics consists of definitions, laws, and models related to temperature and other thermodynamic phenomena such as heat and work. One of the foundational empirical observations in establishing the field of thermodynamics, recognized since antiquity, was the systematic relationship between changes in the temperature of a substance and changes in its volume, which in turn laid the foundations for the development of thermoscopes and, later, thermometers. At first, this systematic relationship between temperature and volume was only understood in ordinal terms, and so thermoscopes, typically some kind of vessel or tube in which a substance like water or alcohol could expand or contract, were developed where their scales only reflected ordered differences in temperature. This all changed between the 17th and 19th centuries with the development of the simple and ideal gas laws, which formalized the relationships between temperature,

volume, and pressure, allowing temperature to be understood quantitatively through these interconnections, which in turn supported the development of the first thermometers (e.g., Celsius, Fahrenheit) that were able to measure quantitative differences (i.e., intervals) in temperature.

The understanding of temperature further evolved with the advent of statistical mechanics, a branch of thermodynamics, which defined temperature as the average kinetic energy of the particles in a substance. This theoretical development led to the conception of an absolute zero for temperature, representing the complete absence of such kinetic energy, enabling temperature measurement on a ratio scale. This was first achieved by converting the scales of existing thermometers to the absolute (e.g., Kelvin) scale, but the maturation of thermodynamic theory expanded the comprehensibility of the concept of temperature and diversified its potential measurement approaches. For instance, the Thomson effect (Thomson, 1851), which describes the relationship between temperature and electrical voltage, provided the theoretical foundation for many digital thermometers that we use in the early 21st century.

Instrumentation

The I in the TISM framework applied to thermometry represents the theoretical and practical knowledge of thermal properties like expansion and conductivity in various materials. These properties are crucial for constructing instruments that can accurately sense temperature changes while minimizing non-temperature-related influences. In a liquid-in-glass thermometer, for instance, it is important to know the liquid's rate of thermal expansion across the thermometer's intended range of use. If this rate is established to be linear across the range, then the expansion of the liquid in the thermometer can be interpreted as reflecting quantitative differences in temperature rather than just ordinal differences. This kind of material knowledge further enabled the technological progression from the early water and alcohol thermoscopes to mercury thermometers that possess such linear thermal expansion.

Creating a liquid-in-glass thermometer also requires specific thermal properties in the glass itself—it must conduct heat to the liquid but show little to no thermal expansion, ensuring that only the liquid in the tube changes volume. Precise engineering is also needed to maintain uniform dimensions across the tube's length. Once these kinds of instrumental requirements are met, the thermometer can systematically transduce quantitative variation in temperature into variation in spatial extent by way of the liquid's volumetric expansion or contraction. These spatial differences can then be assigned temperature values according to the instrument's scale.

Scales and Units

The S of the TISM framework applied to thermometry refers to the theory and practices involved in the establishment of the measurement scales (e.g., Fahrenheit, Celsius,

Kelvin) and ensuring their comparability and convertibility. It also involves the careful calibration of the thermometer to establish its accuracy and precision. For a liquid-in-glass thermometer, calibration entails defining two fixed points on the scale (e.g., the freezing and boiling points of water) and setting equal-interval gradations between them. This, in turn, determines the precision of the scale via the number of gradations between the fixed points.

Converting values between the different scales is made feasible by understanding the differences in the assigned values to the fixed points, as well as their precision. For example, the freezing point of water is approximately 0 degrees Celsius and 32 degrees Fahrenheit, while the boiling temperature of water is approximately 100 degrees Celsius and 212 degrees Fahrenheit, so converting from Fahrenheit to Celsius involves subtracting 32 from the value and multiplying it by $100/180$ (simplified as $5/9$). Using this formula, one can move back and forth between the degrees Celsius and Fahrenheit units while maintaining the invariance of the quantitative temperature differences the values represent.

This primary concern with invariance extends from conversion between scale values to the definition and refinement of the units of measurement over time. Taking the degree Celsius unit as an example, improvements in thermometric theory and technology led to the discovery that the fixed points used in the definition were not invariant across different levels of atmospheric pressure, and so the unit definition was revised to overcome this shortcoming by including points that were defined in terms of both pressure and temperature. Most important for the progression of thermometry, the degree Kelvin was officially adopted as the international unit of temperature in the mid-20th century, which included the absolute zero temperature value as a fixed point in its definition, thereby entrenching thermometry as ratio-level measurement. This unit, now just known as the Kelvin, has continued to be refined to the present time.

Modeling

Finally, the M of our TISM framework includes the various kinds of formal models that are essential to thermometry through, for example, scientific models such as the ideal-gas laws, instrumental models such as the schematic for a liquid-in-glass thermometer, calibration models such as the thermal apparatus used to calibrate the fixed points, and the statistical models that allow us to evaluate the uncertainty of the measurement values. It is the latter that we will focus on given the importance of measurement uncertainty in any specific measurement application.

Measurement uncertainty is generally conceived of in terms of error that has a systematic (i.e., predictable and constant) effect on the values across repeated measurements, versus error that is random (i.e., unknown and unpredictable) in its effect across these values (Bich et al., 2006). In thermometry, systematic errors are typically quantified with respect to inconsistencies between the scientific, instrumental, and/or calibration models and the actual measurement instrument and context, whereas random error

is quantified in terms of a statistical model (e.g., the normal distribution) applied to repeated measurement values.

Taking liquid-in-glass thermometry as an example, systematic error may occur when a thermometer's bulb permanently expands relative to its calibration volume, introducing a systematic negative error in the measurement values. Simultaneously, random error may arise from small and unsystematic differences in the time given to the thermometer to adjust to a thermal phenomenon (e.g., the temperature of a specific liquid) across repeated measurements. While an estimate of the magnitude of this systematic error may be utilized to establish a correction factor for the thermometer's measurement results, it may also be incorporated into the overall uncertainty estimate along with the random error magnitude, typically represented by the standard deviation of repeated measurements. This overall uncertainty estimate may then be used to qualify the thermometer's measurement results.

From Thermometry to Educational Measurement

The use of thermometry to illustrate the four central components of a measurement process might seem to set a rather high bar for the measurement of nonphysical properties (i.e., constructs) to cross. Notice how each component depends on the other. Instrumentation is informed by theory even as theory can only be tested with provisional instrumentation. Substantive theory is formulated with respect to definition and laws, and these are expressed as mathematical models, which are only approximations. Models are also used to quantify uncertainty, but this quantification depends on choices made in regard to scales and units. Finding an example in which the four components can be as seamlessly integrated in educational measurement is indeed a tall order, in particular, because our theoretical understanding of educational and psychological constructs is nowhere near as strong. Psychological laws are few and far between (if they exist at all), and unlike physical properties like temperature, where there was a convergence over time on its current thermodynamic definition that seems unlikely to change, the way that constructs like intelligence, reading ability, and self-efficacy are perceived and conceived can and do change, perhaps even dramatically, over time.

At the same time, many of the pioneers in applying the terminology and methods of physical measurement to the domains of psychology and education quite consciously used the success of thermometry as a reason for optimism (Briggs, 2021b; Galton, 1877). It took centuries before thermometry advanced to the point where the observed effects of differences in temperature could be connected to thermodynamic principles and ultimately measured on a ratio scale. The attempt to do something analogous in the measurement of reading ability is only a little over 100 years old, so who knows what advances might be possible in another 100 years. And as we will show in the next section, contemporary methods used to measure reading comprehension do involve all four of the central components of our framework—even if the coherence of their integration may not always be given as much attention as is warranted.

Measuring Reading Comprehension

We now apply the same TISM framework to an example from educational measurement, namely, that of reading ability as it takes place in two contemporary large-scale assessment programs in the United States. Developing the ability to comprehend text has been a long-standing objective of nearly all systems of public education. In many countries it is one of the two subject domains (along with mathematics) within which the ability of children is ostensibly measured on a periodic basis between the ages of about 6 and 18. As we will show, the measurement of reading ability depends on the successful integration of bodies of knowledge and practice related to theory, instrumentation, scales and units, and modeling. To make this illustration more concrete, we will draw from the National Assessment of Educational Progress (NAEP) and the Smarter Balanced Assessment Consortium. We begin with a brief overview of each assessment program and the salient distinctions in their purposes and contexts for producing measures of reading comprehension.

In the United States, NAEP, known as “the nation’s report card,” (<https://www.nationsreportcard.gov/>) is considered the premier large-scale assessment program designed for the purpose of monitoring trends in student achievement. NAEP tests in reading and mathematics are given every 2 years to nationally representative cohorts of American students at three grade levels (Grades 4, 8, and 12). These tests have been administered in the United States on a periodic basis since 1970, and their results are used to track the progress of successive cohorts of American students. Although individual students are tested, no individual scores are reported. Instead, because the focus is on making inferences about aggregate trends for specific populations and subpopulations of students (e.g., the nation, states, large cities, demographic groups), a great deal of attention is devoted to the sampling of students, and the time requirements for the test are minimized by administering to each student a relatively small sample from the population of available test items. The national trend in NAEP Reading performance of Grade 4 students from 1998 to 2022 is depicted in Figure 21.2, where the horizontal axis represents a year in which the test was administered and the vertical axis represents one of two scales on which test performance is regularly reported.

Smarter Balanced consists of multiple entities (13 states, along with the U.S. Virgin Islands and the Bureau of Indian Education at the time this chapter was written) that administer common assessments to students in American public schools in Grades 3–8 and 11, near the end of each academic school year. We focus here on the Smarter Balanced assessment of English language arts (ELA), within which reading comprehension is identified as one of four “claims” about student abilities that scores on subsets of items on the test are intended to support. An overtly stated purpose of the test is to “accurately describe both student achievement (how much students know at the end of the year) and student growth (how much students have improved since the previous year) to inform program evaluation and school, district, and state accountability systems.”⁷ Even more generally, the test results are meant to be interpreted as an

**FIGURE 21.2**

Trends in National Assessment of Educational Progress Reading Comprehension for Grade 4 Students From 1998 to 2022

Note. Data are from the U.S. Department of Education, Institute of Education Sciences, National Center for Education Statistics, National Assessment of Educational Progress, 1998, 2000, 2002, 2003, 2005, 2007, 2009, 2011, 2013, 2015, 2017, 2019, 2022 Reading Assessments.

indication of student progress toward “college and career readiness” by the time they complete high school. Because the assessment is administered using a computerized adaptive test design, Smarter Balanced argues that its tests provide for “efficient and precise” measurement. Unlike NAEP, measurement results are reported for individual students, though they are also aggregated to examine trends across classrooms, schools, and school districts.

An example of a student-specific Smarter Balanced score report for ELA/Literacy tailored to the state of California is shown in Figure 21.3. Notice that reading comprehension measurement results are reported on an ordinal scale consisting of three discrete categories (*Below Standard*, *Near Standard*, and *Above Standard*). In contrast, the overall ELA/Literacy assessment results are reported, like NAEP, on two different scales, one of which is at least implied to have interval properties (with scores ranging from 2131 to 2663) and another resulting from a transformation of this scale into ordered levels.

Substantive Theory

How do people learn to read? Although reading itself has been around in some form since the dawn of human civilization, formal research and scholarship aimed at producing theories that explain how we learn to read is relatively new and still evolving. Although the lines that divide them are sometimes blurry, *learning theories* can be distinguished by the attention they place on behavioral, cognitive, social, and cultural factors involved in the process of developing knowledge and skill.

In general, *behavioral* learning theories focus attention on decomposing the act of reading comprehension into its constituent skills and then identifying the environmental conditions that can be plausibly manipulated to facilitate mastery of these skills

FIGURE 21.3
Mock Report of Student Results From Smarter Balanced English Language Arts/Literacy Assessment
Note. Data are from the California Department of Education website, retrieved June 25, 2020. <http://www.caaspp.org/rsc/pdfs/Smarter-Balanced-Grade-4-Sample-Student-Score-Report-English.2019-20.pdf>

(Alexander & Fox, 2004). A defining feature of the behaviorism predominant in the United States through the mid-20th century was a strong commitment to empirical observation and an avoidance of reference to nondirectly observable entities (such as the mind) and processes (such as cognition) wherever possible (e.g., Skinner, 1938; E. L. Thorndike, 1905; Watson, 1913). In contrast, *cognitive* theories of learning focus on the process of reading comprehension as it is believed to take place within the mind of an individual reader. Notable features of cognitive theories of learning are the focus on the development of knowledge and skill as a learner moves from “novice” to “expert” over

time and on the active role individuals play in constructing knowledge over the course of this development. Overlapping with cognitive theories, *sociocognitive* (and *sociocultural*) theories are premised on the idea that learning, especially in school settings, is an intrinsically social activity that takes place within a cultural context. Sociocognitive and sociocultural theories of learning focus on the roles of knowledgeable others (i.e., teachers and peers) in supporting a developing learner through the use of scaffolding (e.g., Vygotsky, 1978) and the value of drawing on resources from a student's community and cultural context to foster engagement and agency with learning (e.g., Lave & Wenger, 1991). For two important consensus overviews of modern theories of learning and their research base, see National Research Council (2000) and National Academies of Sciences, Engineering, and Medicine (2018).

In a report chapter commissioned by the National Academy of Education, Kendeou (2020, p. 72) described reading comprehension as

among the most complex of human activities. It involves processing words, connecting words using rules of syntax to understand sentences (Perfetti & Stafura, 2014), integrating meaning across sentences, drawing on relevant knowledge, generating inferences, identifying the structure of the text, and taking into consideration the authors' goals and motives (Graesser, 2015). The end product is a mental representation, what has been termed the "situation model" (Kintsch & van Dijk, 1978), which reflects the overall meaning of the text.

This conceptualization is consistent with an earlier and influential publication by the RAND Reading Study Group in 2002. The panel of reading scholars behind this report defined reading comprehension as the "process of simultaneously extracting and constructing meaning through interaction and involvement with written language (p. 11)." They further proposed that comprehension can be understood with respect to three elements: the reader who is comprehending, the text that is to be comprehended, and the activity for which comprehension is required, all of which are shaped by a larger sociocultural context. For a visual illustration of the key elements of the theory as taken up by a group of national experts asked to develop a new framework that would guide the design of the 2026 NAEP Reading tests, see Figure 21.4.

How does theory inform the measurement of reading comprehension? The 2026 NAEP Reading Framework, adopted by the National Assessment Governing Board (NAGB) in August 2021, incorporates the four central elements of a general sociocultural model of reading comprehension (readers, texts, activities, and sociocultural context) as follows (NAGB, 2021, p. 10):

Reading comprehension is making meaning with text, a complex process shaped by many factors, including readers' abilities to:

- engage with text in print and multimodal forms;
- employ personal resources including foundational reading skills, language, knowledge, and motivations; and
- extract, construct, integrate, critique, and apply meaning in activities across a range of social and cultural contexts.

**FIGURE 21.4**

Visual Representation of a Sociocultural Theory of Reading Comprehension From the Public Comment Draft of the Reading Framework for the 2026 National Assessment of Educational Progress

As illustrated in Figure 21.4, reading is to be understood as a purpose-driven activity in which comprehension depends on the genre, complexity, and discourse structure of the text, as well as the knowledge, affect, agency, and language skills of the reader. A key component of this sociocultural theory is the idea of reading comprehension as a sociohistorically contingent activity, which is greatly influenced by the “scaffolds” available to students at a given place and time (which for most U.S. students would now include the Internet, for example, and may increasingly include tools based on artificial intelligence). This highlights the role of students’ metacognitive attributes in reading comprehension to know when and how to make use of such scaffolds.

Instrumentation

Historically, instruments designed to help make inferences about students’ reading comprehension have come in the form of collections of passages of text to read and related questions administered either orally, on paper, or in a digital environment. The need for guidelines with respect to the design of such measuring instruments was

one of the motivations for both the publication of *Educational Measurement* and the formation of NCME. One of the major recent developments in this body of knowledge and practice is the shift from paper-and-pencil to digital administration (e.g., via a computer monitor or tablet). From its inception in 2015, Smarter Balanced has administered its tests via a digital interface; NAEP transitioned to a digital administration of reading tests in 2017. This has led to a proliferation of possible item formats that can be efficiently administered through so-called technology-enhanced items (e.g., a student can be asked to highlight the text in a passage that provides the best answer to a question). It also suggests new possibilities in making the interactions between students and test items more dynamic through the use of scenario-based tasks⁸ and potentially more attentive to the different elements involved in a sociocultural theory of reading (as summarized in the previous section).

The design of instrumentation inevitably requires reference to substantive theory. For example, a liquid-in-glass thermometer instantiates a *transduction principle*, whereby variability in temperature causes variability in the expansion of a thermometric fluid, based on the laws of thermodynamics. Can we similarly argue that variability in the ability of, say, fourth-grade students to comprehend text can be transduced into variability in their item responses? A key question to be posed along these lines would be, On what basis would we hypothesize that items with a given set of features are effective transducers⁹ of reading comprehension? One attempt to answer this question seems to be implicit when professional item writers work with “task models” (Mislevy & Haertel, 2006) that connect prospective test items to unique content standards (e.g., describing the central ideas and key details of a written passage, defining word meanings). These task models can also provide a basis for hypotheses about items that should be easier or harder to answer correctly as a function of the complexity of the cognitive process involved. For example, after reading a passage, items that require students to locate and recall information might be predicted to be easier, on average, than items that require them to integrate and interpret information or to analyze and evaluate it. This becomes a theory with testable implications for explaining the variability in item difficulty estimates as a function of task model features (see, e.g., Gorin, 2006).

On the Smarter Balanced and NAEP Reading assessments, a connection between theory and instrumentation is most visible through the specification of *achievement-level descriptors*, which are designed to assist item writers in the task of writing items that would distinguish between “achievement levels.” To be more concrete, the task design factors that are posited to distinguish achievement levels on NAEP and Smarter Balanced come from two sources: differences in the complexity of the text that a test taker is given to read and differences in the complexity of the questions that are posed about the text after it has been read. Relative to the sociocultural theory of reading comprehension, what is reflected in the Smarter Balanced and NAEP achievement-level descriptors are implicit cognitive models pertaining to the interaction of a reader and text.

Scales and Units

The bodies of knowledge and practices here are specific to methods for ensuring that measurement results are interpretable by everyone relative to the same standard and comparable (i.e., invariant) irrespective of the occasion of measurement, the specific instrument used, and the person tested. In educational measurement, this encompasses methods that have been invented and developed to scale, link, and equate tests (for a variety of perspectives, cf. Angoff, 1971; Bond & Fox, 2015; Briggs, 2021a; Holland & Dorans, 2006; Kolen & Brennan, 2004). Many methods of scaling applied to educational tests are premised on a desire to “encourage accurate interpretations of test scores and discourage improper score interpretations” by “incorporating normative, score precision, or content information into the score scales” (Kolen, 2006, p. 156). However, there are other methods that are premised on a desire to place both students and items on a common scale with ratio or interval properties and a unit analogous to those found in the physical sciences (Briggs, 2019, 2021a, 2021b; Sijtsma, 2012; Rasch, 1980; Thurstone, 1925).

The reporting scales for reading comprehension on Smarter Balanced and NAEP are quite different (recall Figures 21.2 and 21.3). As previously noted, the Smarter Balanced scale for reading comprehension consists of three discrete categories. In contrast, the NAEP test results are presented on two different scales, one with a theoretical range from 0 to 500 in integer units and the other in terms of four discrete achievement levels. There is a direct relationship between the two NAEP scales because the thresholds for the discrete categories of achievement levels are defined by engaging stakeholders in one of many possible “standard-setting” procedures (see Hambleton & Pitoniak, 2006, Cizek & Bunch, 2007, and Ferrara et al., this volume for overviews; for an interesting design-based approach, see Lewis & Cook, 2020). A similar correspondence exists for the two scales provided for the Smarter Balanced ELA/Literacy test, for which reading comprehension represents a subdomain. On this test, student scores are reported on a common scale that ranges from a low of 2292 in Grade 3 to a high of 2678 in Grade 11 and also with respect to four achievement levels.

What are the properties of the scales used to report measurement results from the NAEP and Smarter Balanced tests? The reporting of results in terms of ordered discrete categories implies a scale with ordinal properties. The interpretation of the finer grained scales that Smarter Balanced and NAEP use to equate tests over time and grades seems more equivocal. Zwick (1992) argued that in the NAEP context, the finer grained scale should also only be given an ordinal interpretation, and as such, statistical comparisons of groups on the scale should be restricted to those that are invariant to all admissible monotonic scale transformations. However, both NAEP and Smarter Balanced scores are frequently used for statistical comparisons of means and variances that imply that the underlying scale has at least interval properties. And the technical documentation for each testing program does not address scale properties. We will return to this issue shortly in the context of the challenge inherent to evaluating magnitude, but for now we note that just as it is difficult to consider choices in regard to instrumentation without

regard to substantive theory about the construct, it can be problematic to separate the interpretation of scales and their units from commitments about theory, as well as from choices about instrumentation and the modeling of item responses.

Modeling

With a few notable exceptions, most large-scale educational assessments invoke the models of IRT (Lord & Novick, 1968; van der Linden, 2016; van der Linden & Hambleton, 1997). As described in earlier in our section on IRT, this can have several practical benefits, provided the model adequately fits the data. First, IRT models person and item parameters in terms of a common numeric continuum. Second, the estimates of these parameters will be invariant up to a linear transformation. Thus, within limits, the estimates will not be biased by the sample of persons or items used for their calibration. These features of IRT make it convenient as a tool for linking and equating different test forms within and across test administrations (as in NAEP) or within the context of a computer-adaptive test administration (as in Smarter Balanced). A third important benefit is the utility IRT provides to quantify uncertainty about measures through test information functions and their inverse, standard error of measurement functions. These functions can be used to help design test instruments that minimize at least some forms of measurement error at targeted locations on the modeled continuum.

This flexibility and generality of IRT modeling is especially important for NAEP. Student responses to NAEP test items are modeled using a combination of two fairly conventional IRT models first introduced in the 1960s, the 3PLM and the graded response model (Samejima, 2010). However, as noted earlier, the unit of analysis on NAEP tests is not the individual student, but a population and subpopulations defined by geographic, demographic, and socioeconomic considerations. As a result, the complete statistical model applied to NAEP tests nests a model for item responses within a model for the population from which a given individual student has been sampled. Although the mathematical details of how NAEP generates aggregate estimates of reading ability from this model through a combination of latent regression and the plausible values drawn from each test taker's posterior distribution is outside the scope of this chapter (for details, see Mislevy, 1984; Mislevy, Johnson, & Muraki, 1992; Mislevy, Beaton, et al., 1992; Oranje & Kolstad, 2019), these details arguably show off an educational measurement success story when it comes to the use of modeling (and probability theory) to solve numerous challenges related to instrumentation in a large-scale assessment program.

The modeling of Smarter Balanced ELA/Literacy tests makes for an interesting contrast. The selected response items on the Smarter Balanced test are modeled using the 2PLM (Birnbaum, 1968) instead of the 3PLM. Does this mean that selected response items on the Smarter Balanced test do not induce guessing? Or has the decision been made for more pragmatic reasons (e.g., guessing is thought to occur, but there is no sufficiently defensible method of modeling its effect on the probability of successfully responding to items)? Another key difference is that the Smarter Balanced tests involve a census rather than a sample of students taking the tests within participating states, and each student

spends much more time taking the test. So, there is not the same obvious need for a population model to accommodate sampling issues. The modeling of the Smarter Balanced tests arguably provides another example of an educational measurement success story when it comes to the interaction between instrumentation and modeling. Specifically, this is the ability to administer test items that are “adaptive” in the sense that the difficulty of a set of reading comprehension items a student receives depends on their performance on a previous set (e.g., Chang, 2015; Meijer & Nering, 1999).

CHALLENGES AND DEBATES IN EDUCATIONAL MEASUREMENT

In the previous section, we introduced the TISM framework and illustrated its four central components in the context of measuring temperature (physical science) and measuring reading comprehension (education). In both instances, the components interact. Advances in our theoretical understanding of a property or construct can change the approaches we take in the design of instrumentation and vice versa. Choices regarding instrumentation also depend on the results from the modeling efforts taken with an eye toward maximizing the consistency of results across replications of the procedure. The construction of a scale for reporting measurement results can depend on the identification of one or more invariant reference standards, and the choice of unit may interact with the approach taken to quantify the amount of chance error to be expected anytime a measurement is taken.

There are unique challenges involved in the measurement of educational (and psychological) constructs, challenges that collectively can make the interpretation of educational measures far more equivocal than the interpretation of most physical measures. In what follows, we describe these challenges, and we turn to the TISM framework to help clarify their nature.

What’s Validity Got to Do With It?

Discussions about the quality and trustworthiness of educational tests and psychological measures often invoke the concept of validity, described by the *Standards for Educational and Psychological Testing* (American Educational Research Association [AERA] et al., 2014, p. 11) as “the most fundamental consideration in developing and evaluating tests” in the human sciences. Although a complete treatment of either the history or the philosophical underpinnings of validity is well beyond the scope of this chapter (for recent comprehensive treatments, see, e.g., Markus & Borsboom, 2013; Newton & Shaw, 2012; Slaney, 2017) and Lane and Marion (this volume) aim to give a contemporary perspective, there is one question we think is worth addressing here: How, exactly, does the concept of validity relate to that of measurement? When we talk about the authority of measurement results, as we do in this chapter, are we really just discussing validity?

Part of the difficulty in addressing this issue is that, as with measurement, there is no universally accepted definition of validity, despite wide agreement regarding its

importance. A starting point might be to say that a measuring instrument's validity is simply the extent to which it measures what it claims to measure: This is arguably the oldest formal definition of validity and may still be the most common understanding of the term across the social sciences in general (see, e.g., Newton & Shaw, 2012). However, at least in the context of educational testing in North America, most commonly encountered definitions of validity are broadly consistent with a perspective often credited to Samuel Messick (1989) and codified by the aforementioned *Standards* (AERA et al., 2014), that is, that validity is "the degree to which evidence and theory support the interpretations of test scores for proposed uses of tests" (p. 11). This perspective is largely consistent with an "argument-based" approach to validation developed by scholars such as Cronbach (1971), Kane (1992, 2006, 2013), and Mislevy (2018). This approach shifts the focus of validation efforts away from demonstrations of measurement per se and instead toward pragmatic, context-specific arguments for the utility of tests, tailored for specific audiences and circumstances. According to this perspective, the activity of validation is seen as open-ended, with any given test regarded as, at most, provisionally valid insofar as the available argumentation and evidence are found to be convincing by a relevant community of observers and in reference to a specific, socio-historically embedded set of interpretations and uses.

As has been observed elsewhere (e.g., Borsboom et al., 2009; Maul, 2013; Michell, 2009; Slaney, 2017), the gradual shift in focus away from the question of whether a test measures what it claims to measure and toward context-specific argumentation for the adequacy and appropriateness of tests for particular goals has had the result that it is often not obvious how, or even if, contemporary perspectives on validity and validation relate to the concept of measurement. Within the mainstream literature on validity, one would be hard-pressed to find serious engagement with the topic of measurement, even in authoritative sources such as the *Standards* (in which the term *measurement* is frequently used but never defined). At least in part, this disconnect may simply be a function of the fact that the literature on validation—and in particular, each of the editions of the *Standards*, dating back to 1966—has largely focused on the roles that tests play in education (including both large-scale standardized achievement tests and smaller scale tests such as those designed primarily for pedagogical purposes) and, to some extent, in other domains in which tests are regularly used to make decisions about individuals and groups, such as in industrial/organizational settings and counseling and clinical psychology. This is contrasted with settings in which tests are intended more explicitly as scientific measures, such as psychophysics and other areas of basic research. Further, while the contemporary literature on validation provides broad guidance on the aims and structure of the relevant arguments and the kinds of evidence that might be considered relevant (e.g., the five categories of evidence for validity discussed in the *Standards*, AERA et al., 2014), for the most part it does not aim to provide concrete guidance on what specific forms of evidence would be necessary to defend specific kinds of interpretations and uses, instead leaving such decisions to the relevant communities of stakeholders. That is, the emphasis on contextualized argumentation in support of specific, here-and-now decision-making and on the criterion of success

being not truth but the collective judgment of a relevant community arguably renders this conception of validity essentially legalistic rather than scientific (Borsboom, 2012). In contrast, other recent scholarship on validity, largely coming from outside education (and also outside North America) has argued in favor of understanding the semantics of validity in terms of measurement. Borsboom and colleagues have developed an account of validity that could be regarded as an extension of the earliest understanding of the term (i.e., a test is valid if it measures what it claims to measure): specifically, “a test is a valid measure of an attribute if (a) the attribute exists and (b) variation in the attribute causes variation in the outcomes of the test” (Borsboom et al., 2004, p. 1061). This perspective emphasizes that whether or not a test is valid as a measure of an attribute (or property) is a claim about the actual state of affairs in the world and is thus independent of the evidence available at any given time, or the extent to which that evidence is found to be persuasive by any given community of observers (see also Borsboom et al., 2009; Cizek, 2020). Stated alternatively, in apparent contrast to the Messickian perspective, it is possible to be mistaken about the validity of an instrument—a group of stakeholders may make an integrated and evaluative judgment that a given test is adequate and appropriate for the purpose of measuring a particular attribute, but may simply be wrong, just as it is possible to be wrong about any other belief formed about the state of affairs in the world.

From this perspective, the critical issue of validity—at least as it pertains to measurement—is the causal relationship between (inter- and/or intrapersonal) variation in the target construct and variation in the outcomes of the testing procedure that serves as the measuring instrument. In the vocabulary of the TISM framework for measurement described in this chapter, this could be seen as a focus on the transduction between (variation in) the construct and (variation in) the results of the application of an instrument, and thus on the theory and instrumentation components of the TISM framework. A possible point of contention seems to arise from the fact that this is a theory of validity and not of validation—that is, Borsboom and colleagues’ body of work on validity does not aim to offer explicit advice on how to go about establishing validity, but instead focuses just on clarifying the semantics of validity claims—but a fairly obvious corollary of this perspective is an emphasis on the importance of articulating and ultimately testing strong cognitive theories explaining the way in which instruments instantiate relationships between the constructs they intend to measure and the test scores or other results of their application. In this way, the emphasis of Borsboom and colleagues’ perspective is broadly consistent with what we perceive to be a trend in at least some major recent works on assessment design, such as the influential report *Knowing What Students Know* (National Research Council, 2001), which foregrounded the alignment of cognitive theory and assessment design and, in turn, influenced frameworks for the construction of instruments such as the Berkeley Evaluation and Assessment Research Assessment System (e.g., Wilson, 2023) and evidence-centered design (ECD; e.g., Mislevy, & Haertel, 2006). Additionally, it could also be argued that similar or overlapping concerns have motivated a good deal of recent work in psychometric theory, which has emphasized the need for a connection between statistical models with cognitive theory and test design

(e.g., De Boeck & Wilson, 2004; Embretson, 2010; Embretson & Gorin, 2001; Leighton & Gierl, 2007; Mislevy, 2018; Sijtsma & van der Ark, 2020). Using the language of the TISM framework, these trends may indicate a greater interest in the interaction between the modeling component with both the theory and the instrumentation components than has been found in previous decades.

Another measurement-focused perspective on validity has been offered by Joel Michell (e.g., 2009), who argued that a great deal of the literature on validity and validation seems to be premised on a misunderstanding of measurement and, as a result, fails to test the most critical relevant hypotheses, with the conclusion being that many or perhaps even all claims to measurement in education and the human sciences are at best premature. This sobering conclusion is based on a decades-long exploration of the history and philosophy of measurement (to name just a few key sources, see Michell, 1997, 1999, 2005, 2008); while any attempt to succinctly summarize this body of work will obviously miss much of its nuance and depth, the basic premise of Michell's argument (as briefly introduced in the section "Measurement in the Physical Sciences") is that measurement, like scientific inquiry in general, is an activity aimed at discovery of facts about the true state of affairs in the world (as opposed to an act of pure construction, numerical assignment, etc.). More specifically, Michell argued that measurement is historically understood in scientific contexts as being aimed at the discovery of ratios of quantities of a property, usually relative to a unit of that property. (A statement like "Derek is 50 years old" can be understood as "the ratio of Derek's age to the unit of a year is 50.") Michell's perspective thus aligns with that of Borsboom and colleagues in its emphasis that whether a measurement claim is valid is a function of the state of affairs in the world rather than the judgment of any particular group of stakeholders, and it adds an additional specification regarding the output taking the form of estimated ratios of quantities. One corollary of this premise is that processes that lead to results reported on what Stevens (1946) referred to as nominal or ordinal scales of measurement could not be considered actual instances of measurement (just as thermoscopes are not measuring instruments, but thermometers at least potentially are). Another corollary of this premise is that a key task facing anyone interested in measuring an educational construct is to figure out whether the construct is, in fact, quantitatively structured—that is, whether differences in magnitudes of the construct meaningfully admit of ratio-level comparisons—which is an empirical question, to which the answer might in fact be "No," in which case it is not possible even in principle to measure it (though other modes of assessment of the construct may still be possible, such as purely qualitative assessment, or classification, or seriation). If an instrument is constructed to measure a given construct without the due diligence of checking whether it is quantitative (which further presupposes that the property has been defined with a sufficient degree of clarity and precision to allow such a question to be meaningfully asked of it), and if results from the application of this instrument are presented in quantitative terms, presupposing the meaningfulness of units—for example, "This student's reading comprehension ability is 550 units, which is 150

more than last year and 1.5 times the average year-to-year-change”—such results may simply not be credible, and presenting them as results of genuine measurement processes could be considered duplicitous.

It seems fair to say that, for the most part, Michell's line of critique has not led to a significant re-evaluation of mainstream practices in educational measurement. We might speculate as to some of the contributing factors: First, the critique is nuanced and may be challenging to understand without substantial background in the history and philosophy of science, which is likely not a point of emphasis in the training of many testing professionals and social scientists; second, for the most part, the critique has not been developed in a way that makes it clear exactly what consequences it has for mainstream practice, particularly in educational testing (though see, e.g., Briggs, 2013; Briggs & Domingue, 2013). Third, even if one were to take the critique seriously, there is arguably still no consensus on exactly how one should go about testing the quantity hypothesis. Michell's own proposals are largely based on testing axioms of additive conjoint measurement (see, e.g., Michell, 1990), but examples of the successful use of such approaches are still largely absent from the literature (for commentary about why this is the case, see, e.g., Borsboom, 2005, 2006; Cliff, 1992). Some scholars have proposed that the Rasch model can be interpreted as a probabilistic instantiation of the theory of additive conjoint measurement (e.g., Kyngdon, 2008; Perline et al., 1979) and as such can at least indirectly test the quantity hypothesis (Briggs, 2013; Domingue, 2014; Maul et al., 2019), though there remains controversy both regarding whether this is a reasonable proposal in principle (Michell, 2004) and to what extent the Rasch model is actually used this way in practice (e.g., McGrane & Maul, 2020). Other scholars have proposed alternative paths to establishing the meaningfulness of quantitative measurement results, such as Sherry (2011), who argued that such claims can be evaluated on pragmatic grounds by investigating their usefulness over weaker (i.e., nonquantitative) claims, though again, clear applications of such approaches in the human sciences seem to remain rare.

Returning to the concept of validity, Borsboom and Michell's perspectives (along with others not discussed at length here; e.g., Hughes, 2018; Maraun, 1996, 2012; Sijtsma, 2012; Trendler, 2009) could be seen as not necessarily incompatible with the argument-based perspective, but as focused on the precise nature of the evidence and argumentation that would be necessary to defend one particular type of interpretation of test scores. That is, it could be noted that interpreting test scores as measures of a construct is only one among many possible interpretations, and tests are routinely put to uses that, strictly speaking, do not appear to require that any measurement take place at all (as when, for example, the mere existence of a test inspires a student to study). That said, interpretations of test scores as measurement results do seem to be quite common, insofar as test scores or assessment results are often presented and interpreted in quantitative terms, and the perspectives of Borsboom and Michell call attention to the need to take these claims as being in need of rigorous evaluation in their own right.

From our perspective, this is where the contribution of the present chapter comes in. The TISM framework aims to help clarify the elements that secure the objectivity and trustworthiness of measurement results—that is, their validity, by another name. Again, we see this not as incompatible with the argument-based perspective on validation, but as complementary: If the argument for the adequacy of a test for a given purpose involves a claim about measurement, careful attention to and documentation of each of the TISM components and their interplay can provide backing for that argument. Conversely, failing to attend to all four elements of the framework could result in an argument that is incomplete at best or deceptive at worst.

Reliability, Measurement Error, and Uncertainty

If there is one procedure that any psychometrician working with test data knows how to complete, it is how to compute a *reliability coefficient* (usually Cronbach's alpha) and convert it into a standard error of measurement (SEM). In the context of tests that have been modeled with IRT, conditional SEMs can be examined through the inversion of a test information function. The SEMs associated with educational test scores are usually substantial, even when reliability coefficients are near .90. For example, on the Smarter Balanced ELA/Literacy tests taken by students in California, the marginal reliability coefficients for each grade are between .86 and .88, yet the average SEM ranges from a low of 35.0 in Grade 3 to a high of 36.6 in Grade 8. To put this magnitude in perspective, recall the mock Smarter Balanced ELA/Literacy score report for the Grade 5 student depicted in Figure 21.3. The hypothetical student on that report has a scale score value of 2421. Assuming that measurement error is normally distributed, if a single SEM of 36 is added and subtracted, the range of possible scores ranges from 2385 to 2457, which encompasses two of the four possible achievement levels (Levels 1 and 2); if two SEMs are added and subtracted, the range would be 2349 to 2493, encompassing three of the four possible levels (Levels 1, 2, and 3). Notably, representation of this uncertainty is missing from the mock score report in Figure 21.3. Although “Sophia’s” test score places her in Level 2 (“Standard nearly met”), she may well have ELA/Literacy knowledge and skills consistent with Level 3 (“Standard met”) or Level 1 (“Standard not met”). In short, there is considerable uncertainty associated with Sophia’s measured value of ELA/Literacy ability, and this uncertainty seems to be substantially larger than is typically associated with physical measuring instruments such as thermometers.

In metrology, the concept of uncertainty is somewhat more encompassing compared to what is referred to as *measurement error* in psychometric contexts. In metrology, it is common to see total “uncertainty budgets” composed of several distinct forms of uncertainty, such as uncertainty associated with the way in which the property is defined (*definitional uncertainty*), the physical limitations of the measuring instrument (*instrumental uncertainty*), and the ways in which scales are defined with respect to a common unit or standard (*calibration uncertainty*; see, e.g., Mari et al., 2023). Of these, what psychometricians refer to as measurement error most closely resembles instrumental

uncertainty; even more specifically, instrumental *repeatability* is associated with the independent replication of the same measurement procedure across occasions. In educational measurement, where independent replications across occasions are difficult to realize, the concept is often understood with respect to variation in the items that have been selected to comprise the test instrument. Disentangling uncertainty due to other facets associated with an instrument's repeatability (specific to, for example, choices of test occasion, mode of presentation, linking items), would require a more complex experimental test design and mathematical model (for examples, see the many-faceted Rasch model, Linacre, 1989; generalizability theory, Brennan, 2003; or the variance decomposition approaches used for NAEP, Oranje & Kolstad, 2019).

The TISM framework calls attention to the fact that there are several forms of potential uncertainty associated with any given set of measurement results, and some of these might be difficult to quantify. With respect to theory, there might be substantial *definitional uncertainty*: unlike temperature, which is understood to be an invariant feature of the world and of which we now have a fairly stable and detailed understanding, both our conception of and the actual nature of reading comprehension continue to evolve. Even if we were to limit ourselves to a definition of reading ability as primarily a function of text complexity, there is heated debate among reading experts about the proper way to define text complexity (cf., Graesser et al., 2004; Sheehan, 2013; Stenner et al., 1983). If different definitions of text complexity chosen by test developers lead to different choices in the construction of reading passages and test questions, it may not be obvious how or even whether results can be compared across different tests, which is a well-known problem with operationalism in general (see, e.g., Bickhard, 2001; Borsboom, 2005, chap. 2; Markus & Borsboom, 2013, chap. 2; Mari et al., 2023, chap. 4). Even if the measurement results could be considered comparable in principle, these choices could change the ordering of item difficulty, which could change the location of achievement-level thresholds as part of a standard-setting procedure.

There is also ample room for disagreement when explicating a broader sociocultural theory of reading comprehension: Does it include reading speed? Are orthographic fluency and morphemic awareness subcomponents of reading comprehension or causes of it? Does reading comprehension include metacognitive abilities like critical analysis of textual information, or should the latter be regarded as a distinct but related construct? And so on. It is rare to find that a testing program has taken a clear stance on these substantive issues. In short, the theoretical and definitional uncertainty in attempting to characterize a construct such as reading comprehension can be considerable, and because theories and definitions of educational constructs are rarely specified with respect to an explicit mathematical model, it will usually only be possible to express this uncertainty in qualitative terms. As a result, what is referred to as measurement error in psychometric contexts may relate to only a small portion of the total uncertainty that should be attributed to results of an educational measurement.

Scales, Units, and the Evaluation of Magnitude

One of the most fundamental differences between measuring scales in the physical sciences and the “score scales” on which test performance is expressed in educational contexts is in the interpretation that can be afforded to the units of measurement. In the physical sciences, although the specific choice for a unit is sometimes arbitrary (e.g., Celsius vs. Fahrenheit), the ability to connect that unit to theory such that it can be realized experimentally is not, and instruments are carefully calibrated to ensure that the meaning of a unit is the same across different replications of the same instrument. Most well-known measuring scales in the physical sciences have ratio or interval properties. The properties of educational measurement scales are far more uncertain. In general, they are presumed to have at least ordinal properties, but are frequently interpreted and used in statistical analyses in ways that imply interval properties. To illustrate this, Figure 21.5 provides an example of how the results from the 2022 NAEP Reading Assessment were publicly disseminated for Grade 4 students.

The graphic in Figure 21.5 emphasizes the comparison of the average scale score to three other time points, most notably 2019 (a year before the onset of the COVID-19 pandemic), 2003 (about 20 years earlier), and 1992 (the first score available in the trend, about 30 years earlier). Given the widespread disruptions to schooling and learning experiences between 2020 and the time during which students were tested for NAEP in January 2022, it is not surprising to see that average scores have declined.

But how should we evaluate the *magnitude* of a 3-point decline? In Figure 21.5, it is only apparent that a 3-point decline is “big” by comparing it to all other score changes over a 2- to 4-year interval. Without seeing this, how should we evaluate the magnitude of 3 scale score units? One way to attempt to answer this question would rely on achievement-level thresholds (i.e., *cut scores*) on the NAEP score scale to serve as de facto reference standards. Specifically, a score of 208 is the threshold for achievement

Trend in fourth-grade reading average scores

that is considered *Basic* (as opposed to *Below Basic*), a score of 238 is the threshold for achievement that is considered *Proficient* (as opposed to *Basic*), and a score of 268 is the threshold for achievement that is considered *Advanced* (as opposed to *Proficient*). From this, we can infer that the national average for reading comprehension has landed between the demarcations for the *Basic* and *Proficient* achievement levels since 1992. We can also notice that the distance between the *Basic* and *Proficient* demarcations is 30 points, which puts into perspective that a change of 3 points is 10% of the distance between two particular locations along the score scale that have been designated as qualitatively meaningful. Interestingly, the distance between the *Proficient* and *Advanced* thresholds happens to also be 30 points. This gives the impression that the difference in reading comprehension necessary to move from a *Basic* to a *Proficient* level is equivalent to the amount needed to move from a *Proficient* to an *Advanced* level.

Figure 21.6 contrasts with Figure 21.5 in that it depicts the trend in reading ability only with respect to the (inferred) percentage of fourth-grade students with a score above the demarcation for the *Proficient* achievement level. In effect, each student's test score is reduced to a binary variable that takes a value of 1 if the score is 238 or higher and a value of 0 otherwise. From this, we can see that a 3-point decrease on the NAEP scale from 2019 to 2022 translates into a 2 percentage point decrease in the number of students with test performance that would place them in one of the top two NAEP achievement levels.

Now, strictly speaking, if the NAEP scale has interval properties, both Figures 21.5 and 21.6 would represent equally defensible ways to convey information about educational progress (or lack thereof) over time; the choice between them simply depends on what information one wishes to emphasize. This is because one can always choose to “go backward” from a scale that falls along Stevens's taxonomy (turning an interval scale into an ordinal scale). However, if the NAEP scale only has ordinal properties, then a representation such as the one shown in Figure 21.6 might be more defensible because it places a focus on changes in a categorical frequency distribution instead of a change in means. When a scale is ordinal, then any monotonic (i.e., order-preserving) transformation to it is admissible, and depending on the nature of the transformation, a comparison between two individuals or groups on the untransformed and transformed scales using means and variance can lead to contradictory conclusions (see, for example, Michell, 1986). Therefore, if the NAEP scale is only ordinal, it could be transformed in a way that led to the conclusion that the mean scores had decreased by more than 3 points during the pandemic—or that the mean had stayed the same, or even increased—without any loss of information about order. This means that the answers to questions about magnitude (i.e., practical significance) that are based on a comparison between mean scores on an ordinal scale lack generalizability, and this is why questions about scale properties are fundamental to scientific research in education.

Although the question of whether a scale has interval as opposed to ordinal properties is important, a superficial focus on this question can obscure important theoretical

assumptions being made about the construct of measurement. That is, to focus solely on methods that can be used to generate a numeric scale (i.e., the I, S, M ellipses of the TISM framework) is to ignore the interactions of these methods with substantive theory. For example, in a discussion about NAEP scale score properties, Zwick (1992, p. 209) wrote that “when the characteristic to be measured cannot be directly observed, claims of equal-interval properties with respect to that characteristic are not testable and are therefore meaningless” and, further, that the “interval property has no particular implications for the relation between the units of the scale and the attributes the scale purports to measure or predict”—in other words, claims about interval properties are untestable, meaningless, and without consequence. Now, if the construct of measurement is hypothesized to be a quantity, this is a curious position to take. After all, if a scale

is claimed to have interval properties, there are clear implications for the relationship between differences in the construct and differences on the scale. For instance, if *Basic*, *Proficient*, and *Advanced* represent qualitatively ordered levels of a reading comprehension construct, then if an interval scale indicates that *Proficient* is 30 units from *Basic*, and *Advanced* is 30 units from *Proficient*, this would mean that the *difference* in reading comprehension between these levels is the same. One source of confusion here is with the idea that the interval properties of a scale can only be established when a one-to-one correspondence can be “directly observed” between the units of the measuring scale and a decomposition or recomposition of the construct of interest. Yet there is no way to directly compare the intervals on a Celsius thermometer to changes in temperature, nor is it possible to directly compare the seconds on a watch to changes in time. Still, we accept these instruments as producing measures of quantitative properties on an interval or ratio scale because of a theoretical understanding about the relationship between thermodynamic energy, liquids, and volume in the case of temperature and because we have engineered an invariant meaning for the second from the vibrations of a cesium atom. Moreover, there is a substantial body of literature on how scale properties can be (indirectly) tested, as briefly discussed in our section on the Rasch Model. It therefore goes too far to suggest that a construct such as reading comprehension cannot possibly be expressed on an interval scale because the latter is not “directly observable.”

However, the conclusion that forming an interval scale for an educational construct is *possible* does not imply that it is *plausible* (e.g., see Michell, 2014). In educational contexts there is seldom any formal hypothesis in place about the structure of a construct like reading comprehension. Even when learning theories are most consistent with a model of the construct that posits ordinal levels with heterogeneous differences in terms of the cognitive processes involved, the construct posited as underlying the responses to an educational test is typically treated “as if” it was a continuous quantity (Lord & Novick, 1968; Mislevy, 2018). This may be done to take advantage of the putative affordances from IRT models for activities such as adaptive test design and equating test forms composed of different sets of items (the I-by-M interaction of the TISM framework). But the potential incoherence of the model with substantive theory (the T-by-M interaction of the TISM framework) is one reason why reading scholars may be skeptical of claims that reading comprehension has been accurately measured by a single number of a reporting scale.

In much of the educational scaling literature, either the issue of how one would distinguish ordinal from interval scales is not taken up at all (e.g., Kolen & Brennan, 2004) or the advice provided seems fairly ambiguous. For example, Lord and Novick (1968, pp. 21–22) suggested that any test score scale can be treated as if it were on an interval scale so long as it can be shown to be a good predictor of some behavioral criterion. But this simply pushes the question back to the choice of behavioral criterion and the evidence needed to establish “goodness” of prediction. If the prediction involved were to be evaluated based on, say, the value of a Pearson correlation coefficient, this would appear to presume from the outset that the test and criterion variables are on at least interval scales. Moreover, the interpretation of the result is equivocal: Should a weak correlation

be taken as evidence that the scale of the test score (and/or the criterion score) does not have interval properties? Or should it be taken as evidence of invalidity—that the test does not have the expected relationship with a criterion it was expected to predict? A problem with the pragmatic advice from Lord and Novick is that any substantive theory one might have about the construct does not appear to have any falsifiable implications for the scale and unit in which measurements are to be reported.

Another matter of debate in the field has to do with the relationship between desired scale properties and the choice of mathematical model applied to test responses (the S-by-M interaction of the TISM framework). In one tradition, consistent with Lord and Novick's approach, choice of scale is considered independent of model selection (for details, see Briggs, 2021a). This is not the case in the Rasch measurement tradition, where adequate fit to the Rasch model is taken as a necessary condition for a scale with interval properties.

To the extent that IRT can serve as a tool for establishing a measuring scale with a designated and invariant reference interval, the Rasch model does in fact come with clear advantages relative to models such as the 2PLM and 3PLM (used for Smarter Balanced and NAEP tests, respectively). Under the Rasch model, the comparison of any two individuals is invariant to the choice of item that serves as a frame of reference, and by extension, the comparison is invariant to the choice of any distance between two items. When applying the Rasch model to construct a scale, any distance between two items (or between groups of items) can be used as an interval to compare distances between individuals.¹⁰ But this is contingent on having items on a test instrument that maintain the same order of response probabilities at any location on the scale. In short, the item characteristic curves cannot cross. If they do, as can be the case under the 2PLM and 3PLM, then the interpretation of differences between individuals will be sensitive to the choice of a reference interval, and it will be challenging, if not impossible, to articulate the meaning of a unit across the full range of the resulting scale. This is not to say that the Rasch model can perform alchemy. It imposes strong conditions on item design that can be extremely challenging to satisfy in practice, especially in the absence of a theory that can be used to manipulate factors that predict item difficulty. In the absence of such theory, fitting the Rasch model in isolation will be insufficient to establish an *interpretable* and *replicable* unit of measurement (see, e.g., Briggs, 2019).

One example of an approach that relies on a theoretically motivated application of the Rasch model is the Lexile scale for reading comprehension (Stenner et al., 2013; Stenner et al., 1983). The Lexile scale was explicitly developed to be analogous in at least some respects to the measurement of temperature. As described previously, the intervals for the Celsius scale are identified relative to anchor points (i.e., reference standards) that correspond to discernible thermodynamic phenomena associated with the freezing and boiling points of water, with a unit then defined relative to these standards (e.g., a degree Celsius is 1/100th of the distance between these two reference standards). The Lexile scale attempts to mimic this approach first by modeling reading ability and item difficulty in terms of two central factors that make texts more or less complex: average sentence length in a reading passage and average familiarity of the

words in the passage. These factors are used to connect the difficulty of items calibrated to a Rasch model directly to the text complexity of reading materials associated with different levels of schooling. A Lexile unit is then defined as 1/1,000th of the distance between the text complexity a student should be expected to comprehend in the first grade of schooling and the text complexity of passages found in an electronic encyclopedia, typical of the midpoint of reading materials found in workplace text (also typical of text found in grade 10 reading passages).

Note that the two reference locations on the Lexile scale are more equivocal than the reference locations for a thermometer because they depend on societal judgments about what children should be able to read at different ages, and this is likely to change over time. Beyond this, the extent to which the instrumentation used to establish the Lexile scale fits the Rasch model and/or adequately satisfies the axioms of additive conjoint measurement remains an open question (cf., Domingue, 2014; Kyngdon, 2011). But the general approach in which a scale and its units are being motivated by an interaction between theory and modeling (a T-by-S-by-M interaction in the TISM framework) represents a valuable proof of concept.

As we have seen, both the Smarter Balanced and the NAEP scales also have reference standards that have been defined through the process of writing achievement-level descriptors in concert with item analysis. However, these demarcations have no bearing on the way the unit of each measuring scale is defined. For example, the unit of the 0 to 500 NAEP score scale was originally chosen so that a value within this range could be interpreted as the number of items the average student would answer correctly on a hypothetical test with 500 items (Beaton & Johnson, 1992). The unit of the Smarter Balanced ELA/Literacy scale was defined by transforming the logit estimates from a calibration of the underlying item response model such that a change of one base unit (1 logit) is the equivalent of a change on the operational scale of 79.3 points. However, no rationale for this transformation is available in published materials, nor is any attempt made to provide an interpretation for the new unit that this transformation implies.

One promising approach that has been used to enhance the interpretability of the NAEP reporting scale is known as item mapping,¹¹ in which exemplar items are used to illustrate the kinds of questions that students would be expected to answer correctly at a given location of the scale. As implemented for NAEP, this approach makes no commitment to the scale having interval or even ordinal properties, and indeed because the locations of items on the scale correspond to a fixed response probability for the 3PLM, if a different response probability were selected to characterize item difficulty, many of the items might change their order (another instance of an S-by-M interaction in the TISM framework).

The need to make inferences about growth and development has always been a primary motivation for educational measurement (Rasch, 1980; E. L. Thorndike, 1918). But without careful attention to scales and units, such inferences will be highly equivocal. For example, meta-analysis is a method invented to permit generalizations about

the magnitude of experimental treatments, which in education research could include a wide range of programs and curriculum intended to have positive effects on student learning. When test scores serve as outcome measures, they are ostensibly placed on a common scale by expressing each difference in means with respect to a test's standard deviation (i.e., *effect size units*). But if a collection of experimental studies come from tests that convey only ordinal information, a variety of admissible monotonic transformations to the scales could inflate or deflate these standard deviations, which would in turn influence effect size estimates and thereby distort conclusions about the average size of the effects inferred from the meta-analysis.

Almost all educational measurement procedures use instrumentation to convert observable information about order into a location on a measuring scale according to a designated unit or into a scale in which a categorization is made relative to one or more reference standards. In educational testing, the score given to a student's test item response provides information about order, and a full test provides information about patterns of order in some vector of item responses. What can be left unsaid is whether and how evidence of order, via some mathematical model, is intended to provide falsifiable implications about a measurement construct. Attention to the TISM framework can bring these sorts of issues and conceptual tensions to the surface.

LOOKING FORWARD

We hope that this chapter has provided an entry point for those who appreciate—or are coming to appreciate—the complexity of measurement as both a concept and a process. Educational measurement is not just a concept, but also an established field of research and practice. If the field is to evolve and thrive, we would argue that it is important for professionals within this community to continue to grapple with its core concepts. Outside a rather small niche of scientists and scholars, educational measurement is most commonly described in a manner that paraphrases Stevens's claim that measurement is a process of assigning numbers to objects according to a specified procedure. Historically and into the present day, considerable emphasis has been placed on the design and administration of educational tests (i.e., *instrumentation*) and the *statistical modeling* of the scores that result. Thus, when a student takes a test, it does indeed produce a numeric value that gets assigned back to the student or some aggregate of students. It is little wonder in this sense that testing and measurement are viewed as one and the same thing. We hope that after reading our chapter the reader can appreciate why this conflation of terms is problematic.

We take a more encompassing view of the process of measurement as one that

- provides information about a property of an object or event in the world;
- uses instrumentation designed to be sensitive to differences in this property; and

- produces information in the form of values of that construct related to a scale or unit, which is, in turn, qualified by information about uncertainty.

Each of the elements in this process has a direct connection with one of the four components of the TISM framework we have introduced in this chapter. In this framework, we locate the practice of measurement in the interacting bodies of knowledge and practice that pertain to substantive theory, instrumentation, scales and units, and modeling. Many prominent perspectives on measurement in the human sciences call attention to one or more of these components, but leave others in the background, which can lead to incomplete or erroneous justifications for measurement claims. By “zooming out” to a structural understanding of measurement like the one we propose here, we gain a greater understanding of and appreciation for what is at stake with respect to the measurement debates and the conditions that would need to be met for claims of measurement to be fully justified. In an educational context, tests have the potential to play a critical role as the instrumentation of a measurement process, but in the absence of interactions with substantive theory, scales and units, and models, a test is just a series of questions, and there is no compelling reason to dress it up with the prestige that the term measurement is often intended to confer.

It has been over 50 years since the chapter “The Nature of Measurement” by Lyle Jones appeared in the second edition of *Educational Measurement*. At this time, Jones defined measurement as

a purposive acquisition of information about the object, organism, or event measured by the person doing the measuring. It is a determination of the magnitude of a specified attribute of the object, organism, or event in terms of a unit of measurement. The result of the measurement is expressed by a numeral. The classification of attributes, either qualitative or quantitative, is distinguished from the measurement of attributes, which must be quantitative. (Jones, 1971, pp. 336–337)

The reader will notice that Jones explicitly distinguished measurement from classification. In this chapter, we have not taken a firm stance on what is and is not an instance of measurement or, for example, whether the administration of a test for the purpose of classifying subjects according to discrete attributes (i.e., data that are typically modeled using latent class methods) is justifiably characterized as measurement. One reason for this is that although we agree in the broad sense expressed by the TISM framework on the necessary conditions for measurement, we would each likely give different answers about the sufficient ones. Another reason is that a broadened conceptualization of measurement, one generally in accord with Stevens’s definition, has long since become entrenched in public and professional discourse. Even within metrology, a field devoted to the scientific study of measurement and its applications in the physical sciences, an orderable property is also referred to as a quantity, and it is considered sensible to speak of measuring it (see Joint Committee for Guides in Metrology, 2012, pp. 2–3). There is

little point in attempting to police the usage of measurement terminology as it is applied to educational testing. The cat is out of the bag.

There is, however, great value in the recognition that measurement is a complex endeavor that goes beyond clever instrumentation and sophisticated statistical models. Although the terms *test*, *assessment*, and *measurement* may be used synonymously in public discourse, it is important for a professional community involved in educational measurement (e.g., NCME) to be able to articulate the salient differences. A test is just a set of questions that are subject to evaluation. An assessment is the evaluation or estimation of the nature, quality, or ability of someone or something. All measurement requires assessment, but not all assessment requires measurement. In classroom and informal educational settings, assessments are made all the time; in our view, it takes a more concerted effort to convert an assessment into a measurement.

Measurement has earned its social capital largely because of its highly successful history in the physical sciences and engineering. When educators and other human scientists make claims to measurement, they are at least implicitly laying claim to this capital, in particular, to the claim that measurement produces trustworthy information about a measured construct in the form of values of that construct. However, given the many differences between measurement in the physical and human sciences, it is not obvious that this trustworthiness has the same warrant. Indeed, an exploration of the methods and activities that have been described as measurement in educational and psychological contexts would be incomplete without an acknowledgment of the way that premature and ill-founded claims related to the measurement of intelligence provided a scientific veneer to racist, sexist, and xenophobic policies and practices in the early 20th century (see Briggs, 2021b; Gould, 1981; Stein, 2016). A lesson from this historical episode comes in the danger of reifying the name given to a test, that is, conflating it with the construct (or constructs) the test was designed to measure. More generally, when it comes to measurement, a great deal of humility is in order, especially when a theoretical understanding of the construct is nascent or lacking altogether. It is worth reiterating that although the evolution of our ability to measure temperature represents an accomplishment worthy of emulation, it is one that required hundreds of years of study and development. Something analogous in education may seem unlikely for many reasons, an obvious one being that unlike thermal energy, the constructs at play are socially constructed and likely to change over time. But without an ongoing commitment to a theoretical understanding of constructs we choose to value and the methods we employ to measure them, measurement will never be more than an operational activity. We argue it is better to appreciate measurement as an aspirational activity, one that is cyclical and iterative, even if (or when) it is being undertaken for pragmatic rather than scientific purposes.

A limitation to the TISM framework we have introduced here is that it may give the impression that measurement procedures can be isolated from social, cultural, historical, and political contexts. This is clearly not the case. Consider the notion of objectivity, which has long been taken to be a hallmark of scientific measurement. Even when measurement instrumentation may appear to be objective, whether in the physical sciences

or in education, the choices of what to measure, who to measure, and the purpose for measuring are often highly subjective and value laden, and how this is negotiated can be political and contentious.

A recent example can be found in the process that culminated in a revision to the NAEP Framework for Reading in 2021. All subject domains tested on NAEP come with a framework that serves as the basis for item design. The process of revising a framework is overseen by NAGB, which consists of 26 members who are appointed by the U.S. Secretary of Education to set policy for NAEP. An initial framework is drafted by the members of a development panel, convened through nomination to be representative of subject matter experts, practitioners, administrators, researchers, business representatives, and members of the general public. This draft framework is then made available for comment and feedback from both NAGB and the general public. The feedback is used to revise the framework, and a final version must be approved by NAGB before it can go into effect.

The original version of the reading framework that was submitted for public comment foregrounded a concern about equity in education and the importance of design following from a sociocultural theory of learning as two new emphases for the 2026 NAEP Reading tests. These foci, among other features of the draft framework, evoked a controversial reception during public commentary. Questions were raised about what it meant for a measuring instrument to be “equitable by design” and whether this was consistent with the purpose of NAEP. Public officials from conservative states took issue with the term *sociocultural*, worrying that NAEP was becoming a vehicle for progressive social values. This influenced subsequent revision of the framework. Table 21.1 compares the definitions of reading comprehension provided in the original and revised reports.

Table 21.1 The Politics of the National Assessment of Educational Progress (NAEP) Reading Framework Revision	
Definition of Reading Comprehension Submitted to NAGB by Reading Specialists on the NAEP Framework Development Panel (June 2020)	Definition of Reading Comprehension Approved by NAGB (September 2021)
Reading comprehension is a sociocultural process in which individuals use language, knowledge, and foundational skills to extract, construct, integrate, and critique meaning as they engage with a wide range of texts for purposes shaped by home, community, and school experiences.	Reading comprehension is making meaning with text, a complex process shaped by many factors, including readers’ abilities to: • engage with text in print and multimodal forms; • employ personal resources that include foundational reading skills, language, knowledge, and motivations; and • extract, construct, integrate, critique, and apply meaning in activities across a range of social and cultural contexts.

To be clear, the definition of reading comprehension that was ultimately approved by NAGB is not inconsistent with a sociocultural theory of reading, but there are subtle and substantive differences in wording that reading and literacy scholars would notice, even if the lay public would not. In short, the substantive theory that is made publicly visible as a basis for test design on NAEP (the T of our TISM framework) is one that is mediated by both values and political power in ways that can be difficult to predict. There are similar stories to be told any time a test is administered on behalf of a public entity to monitor and evaluate trends in educational achievement.

What does the future hold for educational measurement? In the first half of the 20th century, the technological innovation of the group-administered standardized test gave birth to an educational testing industry, and modeling innovations followed to solve the problems that arose in the practice of testing students on an unprecedented scale. In the first half of the 21st century, we are in the midst of new technological innovations that could have dramatic ramifications for educational measurement: computers, the Internet, social media, and, most recently, artificial intelligence. As individuals increasingly experience assessment activities in digital environments, there will be both more and different kinds of data amenable to empirical analysis (e.g., big data and computational psychometrics; see, for example, von Davier et al., 2021). Whether this will lead to improvements in educational measurement is another question (see Briggs, 2022). The ability to make trustworthy inferences on the basis of test results depends on the quality of stimuli that comprise the test. More and different kinds of data may not provide any novel insights about student learning, especially when they are not integrated coherently with theories of learning. Will big data, digital learning environments, and artificial intelligence lead to better educational measurement? This will be an interesting and open question. What we can be most confident about is that there will always be a need to evaluate the methods, practices, and approaches to teaching and learning. It is hard to imagine a world in which a comprehensive evaluation could be done without an attempt at educational measurement. To do this will continue to require a reckoning with the four central components of measurement: theory, instrumentation, scales and units, and modeling.

ACKNOWLEDGMENTS

We would like to thank Robert Brennan, Neil Dorans, Mark Wilson, and the editors for the constructive comments provided on preceding drafts of this chapter.

NOTES

1. In this chapter, we occasionally use the term *construct* instead of *property* when referring to educational and psychosocial measurement, simply for consistency with the vocabulary in these fields. In the present context we treat these terms as synonyms, though with the awareness that they may not always be used synonymously in general (see, e.g., Slaney & Racine, 2013).
2. Some of the territory we cover in this chapter touches on ideas and terminology from the philosophy of science. For a reader looking to gain a greater entry point into these ideas and terminology, we recommend Godfrey-Smith (2003), Maul et al. (2016), Rosenberg and McIntyre (2020), Torres Iribarra (2021), and related entries (e.g., behaviorism, operationalism, realism, pragmatism) that can be found online at the *Stanford Encyclopedia of Philosophy* (<https://plato.stanford.edu/>).
3. A revealing example of the shift from discussion of tests as producing educational measurements to tests as instruments of educational measurement can be found in the name of the organization that is sponsoring this volume, the NCME. NCME was originally founded in 1938 by a group of college professors who were teaching courses on the design and analysis of mental tests. As such, its original name was the National Association of Teachers of Educational Measurements. In 1942, the name was changed to the National Council on Measurements Used in Education. Finally, in 1962, the name was changed to its present form with an emphasis on measurement (i.e., the process), as opposed to measurements (i.e., the products).
4. Here, we are using the term pragmatic in a way that can be viewed as more or less the same as one would use the term instrumentalist.
5. For good introductions, see chapter 2 of Michell (1990) and the first chapter of Krantz et al. (1971). For a retrospective account of representational measurement theory by two of its originators, see Luce and Suppes (2002).

6. Although we have gone through the process of naming each of the two- and three-way interactions depicted in the Venn diagram and identifying the measurement activity that each represents, we do not include it here to keep the discussion at a more general level.
7. <https://www.smarterbalanced.org/assessments/>, retrieved June 25, 2020.
8. See, for example, NAEP's Technology and Engineering Literacy assessment, <https://nces.ed.gov/nationsreportcard/tel/> and <https://nces.ed.gov/nationsreportcard/dba/>.
9. Note that if the "amount" of reading comprehension possessed by a student is only operationally defined by some admissible population of items, the concept of transduction we borrow from thermometry becomes circular since there is no distinction to be made between variability of an attribute and variability of a test score.
10. A red herring argument against the possibility of an interval scale in an IRT context is that the same monotonic transformations of person and item parameters in the 3PLM will leave response probabilities unchanged (Lord, 1980). This is true, but it is irrelevant to the argument that it is the trade-off relationship among persons and items that allows for an interval interpretation.
