The last example is more contemporary. There is recent attention on diagnostic classification models (DCMs), and book-length volumes have appeared in the literature (e.g., Rupp et al., 2010; von Davier & Lee, 2019). It is useful to review these models here because they highlight the possibilities afforded by explicitly constraining parameters in a measurement model, another important concept in modeling of data from educational assessments. DCM applications are more often confirmatory in nature than in item factor analysis, for instance. In contrast to the IRT model discussed earlier, where θ 's are continuous latent variables, standard DCMs assume the presence of discrete latent variables underlying the responses to items, often 0–1. They may represent mastery of skills or knowledge, presence of attributes, possession of misconceptions, etc.

Consider a $p \times 1$ vector of dichotomous (0–1) latent variables ξ . The relationship between items and latent attributes is captured by the so-called **Q**-matrix (Tatsuoka, 1983), which is a matrix of fixed 0's and 1's, just as a design matrix. The (i, q) th entry in the **Q**-matrix takes on a value of 1 if item i measures latent variable q . These values are typically informed by the blueprint and item development process. From the outset, a DCM resembles a MIRT model, which in turn extends a generalized linear model:

$$P(y_i = 1 | \xi) = \frac{1}{1 + \exp[-\eta_i]} = \frac{1}{1 + \exp[-\alpha_i - \beta_i' h(\mathbf{Q}, \xi)]}. \quad (12)$$

The $h(\mathbf{Q}, \xi)$ term in Equation 12 is a vector-valued function that defines how the latent variables in ξ should combine to create the linear predictor η_i . Henson et al. (2009) systematically placed constraints on the item parameters α_i and β_i and showed how different choices of $h(\mathbf{Q}, \xi)$ lead to a general model that contains several of the more commonly utilized diagnostic models as special cases (see also Choi et al., 2013; Rupp et al., 2010).

For instance, suppose that according to the **Q**-matrix, a mathematics test item measures two skills (attributes ξ_1 and ξ_2) and that successful solution of the item requires both skills. The linear predictor may take the well-known deterministic-input noisy “and” gate (DINA; Junker & Sijtsma, 2001) form, with an intercept and a single interaction term:

$$\eta_i = \alpha_i + \beta_i \xi_1 \xi_2. \quad (13)$$

In this case, $h(\mathbf{Q}, \xi) = \xi_1 \xi_2$ yields a second-order interaction only. Alternatively, perhaps the item only requires *either* Attribute 1 or Attribute 2. Then the deterministic-input noisy “or” gate (DINO; Templin & Henson, 2006) model may be appropriate,

with the slopes of the two main effects and the interaction constrained equal in absolute magnitude, albeit with the interaction having an opposite sign:

$$\eta_i = \alpha_i + \beta_i \xi_1 + \beta_i \xi_2 - \beta_i \xi_1 \xi_2. \quad (14)$$

One can easily verify that in terms of the log-odds, Equation 14 is indifferent as to which of the two attributes is present, and having both present provides no advantage in log-odds. Yet another possibility is reflected by the general diagnostic model (Hartz, 2002; von Davier, 2005), which is similar to factor analysis:

$$\eta_i = \alpha_i + \beta_{i1} \xi_1 + \beta_{i2} \xi_2. \quad (15)$$

The values of the latent attributes can be further modeled along the lines of higher order factor analysis (see, e.g., de la Torre & Douglas, 2004). The attributes essentially become hidden items, whose pattern of presence or absence can help identify their location relative to a second-order latent dimension (Cai, Choi, & Kuhfeld, 2016). For example, if there are $l=1, \dots, L$ attributes, the following one-parameter logistic (Rasch-type) model and a single higher order dimension ζ may be specified:

$$P(\xi_l = 1 | \zeta) = \frac{1}{1 + \exp[-(\tau_l + \zeta)]},$$

where τ_l is the intercept/location parameter for attribute l . Alternatively, the 2^L attribute profile probabilities may be represented as a multinomial with $2^L - 1$ free parameters. The economy in using the higher order formulation is clear; the model above accounts for the attribute profile with only $L + 1$ parameters. DCMs can also be further integrated with item factor analysis models to provide even more flexible modeling frameworks. These will be discussed further later in the chapter.

Conditional Independence

It is obvious that without knowing the value of the latent variable predictors in any of the models we have discussed, the measurement models are not directly estimable. After all, we only have access to the information contained in the observed variable, and all the previously presented equations contain more unknowns than available data. However, an aspect that we have not yet discussed is that most data in educational measurement are multivariate in nature, with assessments usually containing many items or tasks and each response possibly scored for different outcomes. Furthermore, the random variables in the multivariate data set usually present themselves to the statistician as correlated and patterned. This stands in contrast to, say, a traditional linear model, where the outcome variable y has a trivial covariance/correlation structure, or even a traditional hierarchical linear model (Raudenbush & Bryk, 2002), which may have several more variance or covariance components but retains the emphasis on modeling changes in expectations, as in regression analysis. The task of the statistician, therefore,

lies in the formulation of linear, generalized linear, or nonlinear multivariate statistical models that can represent the pattern of correlatedness in a meaningful way in terms of the underlying latent variables, ideally according to assessment design. When combined with the assumed distributional form of the latent variables, a joint distribution of the observed variables and latent variables naturally leads to the marginal distribution of the observed variables, which contains a host of information about the structural parameters. Finally, with Bayes' formula, we can find posterior distributions of the latent variables given the observed data and the model. Statistical summaries of the posterior, such as means and standard deviations, have important uses in the scoring and inference of educational assessments.

To accomplish the model building and statistical computation necessary in our kind of multivariate analysis for modeling educational assessment data, the most useful device at our disposal is arguably conditional independence, also known as residual independence and local independence in more restricted contexts. We illustrate it with two examples.

Exploratory (Unrestricted) Factor Analysis: Uncorrelated Residuals

First, recall that the linear factor analysis model in Equation 1 implies a conditionally normally distributed y , for a generic outcome variable (Equation 2). Let us assume that there exist n such variables, indexed as $y_1, \dots, y_i, \dots, y_n$, perhaps representing n measures. The vector of observations $\mathbf{y} = (y_1, \dots, y_i, \dots, y_n)$ can be represented in a multivariate regression model such as

$$\mathbf{y} = \begin{pmatrix} \lambda_{11} & \cdots & \lambda_{1p} \\ \vdots & \ddots & \vdots \\ \lambda_{n1} & \cdots & \lambda_{np} \end{pmatrix} \begin{pmatrix} \theta_1 \\ \vdots \\ \theta_p \end{pmatrix} + \begin{pmatrix} e_1 \\ \vdots \\ e_n \end{pmatrix} = \mathbf{\Lambda} \boldsymbol{\theta} + \mathbf{e},$$

where $\mathbf{\Lambda}$ is the $n \times p$ factor loading matrix, and $\mathbf{e} = (e_1, \dots, e_i, \dots, e_n)$ is the vector of unique factors, typically assumed to be multivariate normal with a zero mean vector and covariance matrix $\mathbf{\Psi}$, if, for example, maximum likelihood estimation and inference is desired. Consequently, the conditional distribution of $\mathbf{y}$ is multivariate normal:

$$\mathbf{y} | \boldsymbol{\theta} \sim \text{MVN}(\mathbf{\Lambda} \boldsymbol{\theta}, \mathbf{\Psi}). \quad (16)$$

We now introduce the crucial conditional independence assumption for exploratory factor analysis, which states that conditionally on $\boldsymbol{\theta}$, the variates in $\mathbf{y}$ become independent. In other words, if we could partial out/control for the influence of the latent variables, the observed variables should not be related at all. This affords a particular causal interpretation, that is, the observed associations are due *solely* to the influence of the hidden variables. Because of the normality assumption, uncorrelatedness is equivalent to independence. Thus, conditional independence in the

present context effectively becomes an assumption on the covariance structure of the unique factors: that $\mathbf{e}$ has a diagonal covariance matrix, that is, $\mathbf{\Psi} = \text{diag}(\sigma_i^2)$, with zero covariances.

The key insight is this: When the number of factors p is substantially fewer than the number of observed variables n , the factor analysis model equipped with conditional independence provides a much more parsimonious representation of the observed pattern of covariances/correlations, and the factor loadings can be identified from the observed covariance matrix, even though at first glance the exploratory factor model contains, paradoxically, more unknowns than there are available data. Together with other criteria such as Thurstone's simple structure and factorial invariance, the loading matrix provides a more meaningful explanation of the empirical data than the raw correlations alone.

Local Independence in IRT

The second example is also familiar to educational measurement researchers and helps set the stage for a discussion of likelihood, prior, marginal likelihood, and posterior. We begin with the 2PL-inspired MIRT model in Equation 6. For a single dimension θ , the model for a particular item i can be alternatively written, without loss of generality, as

$$P(y_i = 1 | \theta, \omega) = \frac{1}{1 + \exp[-(\alpha_i + \beta_i \theta)]} = T_i(\theta, \omega), \quad (17)$$

where the T_i notation pays homage to the term *traceline* coined by Lazarsfeld (1950). The parameters for this item are assumed to come from an overall parameter vector ω , to avoid notational clutter. This leads to a conditional Bernoulli distribution:

$$P(y_i | \theta, \omega) = [T_i(\theta, \omega)]^{y_i} [1 - T_i(\theta, \omega)]^{1 - y_i}, \quad (18)$$

where $y_i \in \{0, 1\}$, for example, an observed item response for a dichotomously scored test.

With n items, the local independence assumption in IRT states that for θ values sufficiently close to one another, that is, controlling for the latent variable, the collection of item responses should be independent. The IRT model, just as in factor analysis, tells a specific causal story about why the observed item responses are correlated. We realize that with conditional independence on θ , we can now write the conditional probability of the item response vector $\mathbf{y} = (y_1, \dots, y_i, \dots, y_n)$ in a fully factored form,

$$P(\mathbf{y} | \theta, \omega) = \prod_{i=1}^n [T_i(\theta, \omega)]^{y_i} [1 - T_i(\theta, \omega)]^{1 - y_i}, \quad (19)$$

which functions in the same way as the assumption of uncorrelated residuals in exploratory factor analysis that reduces the unique factor covariance matrix Ψ to a diagonal one, though without the help of multivariate normality that equates uncorrelatedness with independence. Evidence that suggests the lack of conditional or local independence (e.g., W. H. Chen & Thissen, 1997) causes concern in IRT applications because the resulting parameter estimates, as well as inferences based on those estimates, may be biased. In a similar vein, if the specification of the number of dimensions is incorrect in a factor analysis, the factor loadings will be biased. Thus, a large part of fit appraisal for latent variable models focuses on dimensionality specification.

Prior and Likelihood

In Equations 16 and 19, the conditional distributions of the observed variables on latent variables are specified. The model is still incomplete because the conditional distribution alone does not allow us to estimate the parameters and conduct inference about the latent variables. We must specify the prior distributions of the latent variables. In some texts, especially in IRT, they are also referred to as the population distributions. Regardless, the priors enable us to write down the joint probability of both observed and latent variables. Integrating over the latent variables leads to the marginal likelihood, which is free of latent variables.

Normal-Normal Factor Analysis Model

As an example, consider an exploratory factor analysis (Spearman, 1904). The initial factor extraction almost always assumes uncorrelated common factors; oblique factors are the result of rotation only. Thus, we can assume θ to be multivariate normal with zero means and an identity matrix as its covariance matrix. Combined with the conditional distribution in Equation 12, we arrive at the important marginal distribution of $\mathbf{y}$, free of any latent variables:

$$\mathbf{y} \sim \text{MVN}(\mathbf{0}, \mathbf{\Lambda}\mathbf{\Lambda}' + \mathbf{\Psi}), \quad (20)$$

which says that the covariance matrix of the observed variables is structured by the parameters of the model (its loadings and unique variances). The marginal distribution of $\mathbf{y}$ enables one to write down the marginal likelihood of the observed data, forming the basis of parameter estimation and model fit appraisal. Suppose we use Σ to represent the covariance matrix of $\mathbf{y}$. Per Equation 20, we have $\Sigma(\omega) = \mathbf{\Lambda}\mathbf{\Lambda}' + \mathbf{\Psi}$. In this case, we are using the parentheses to emphasize that in a similar manner as in Equation 13, we have a covariance structure model that depends on a set of structural parameters in ω , including the factor loadings and unique factor variances.

As an aside, to obtain Equation 20 we have taken advantage of our more modern knowledge of matrix algebra and multivariate normal distribution theory, which facilitates the derivation of the joint distribution of both $\mathbf{y}$ and θ . With joint normality, a

traditionally difficult task of integrating over the latent variable to arrive at the marginal distribution of $\mathbf{y}$ in Equation 20 can be accomplished with ease. This is not true in general.

Logistic-Normal IRT Model

The IRT model offers another, perhaps more direct, example. Continuing from Equation 19, if we assume the prior/population distribution of the latent variable θ is $h(\theta|\omega)$, typically normal with mean zero and unit variance (but can contain unknown structural parameters, if the data collection design requires their presence), the marginal probability of the observed item response vector is

$$P(\mathbf{y}|\omega) = \int P(\mathbf{y}|\theta, \omega) h(\theta|\omega) d\theta. \quad (21)$$

By a perversion of notation involving data and parameters, we see that Equation 21 provides the marginal likelihood of the item parameters ω , given observed data $\mathbf{y}$:

$$L(\omega|\mathbf{y}) = \int P(\mathbf{y}|\theta, \omega) h(\theta|\omega) d\theta. \quad (22)$$

Again, note that the marginal likelihood does not depend on the unobserved latent variable. Information about the item parameters and the prior distribution of the latent variable (i.e., the structural parameters) is contained in the marginal likelihood. Once more, the optimization of the marginal likelihood provides parameter estimates, standard errors, and model fit statistics.

Numerical Integration

There is, however, one wrinkle. Unlike the multivariate normal factor analysis model, Equation 22 is already in the most simplified form, because the combination of the logistic IRT model and normally distributed latent variable does not lead to a closed-form solution for the integral (the distributions being not conjugate, in Bayesian parlance). Indeed, few practically useful models possess marginal likelihoods that admit the kind of simplifications owing to conjugacy that leads to a closed form expression such as Equation 20. Starting from Bock and Lieberman (1970), likelihood-based item parameter estimation has become a recurring topic in psychometrics because of the numerical challenges of having to integrate over θ .

One popular approach involves numerical quadrature. The integral in Equation 22 may be directly approximated by a sum, where the integrand is evaluated at Q quadrature points X_q , with corresponding weights W_q :

$$\bar{L}(\omega|\mathbf{y}) = \sum_{q=1}^Q \prod_{i=1}^n [T_i(X_q, \omega)]^{y_i} [1 - T_i(X_q, \omega)]^{1-y_i} h(X_q|\omega) W_q. \quad (23)$$

More recent computational algorithms often involve stochastic sampling or alternatives such as variational Bayes (Cai, 2010b; Edwards, 2010; Jeon et al., 2017). We will be discussing these computational approaches in more detail later in this chapter.

Posterior Distribution and Information

Upon estimating the structural parameters from the marginal likelihood, the standard approach in applications of latent variable models for educational assessments is to conduct inferences about those latent variables based on what we have observed. Usually, an empirical Bayes approach is adopted, and the maximum marginal likelihood estimates of the structural parameters $\hat{\omega}$ that we are maximizing the log-posterior with respect to is plugged into the posterior distribution of the latent variables. The conditional independence assumption continues to play an important role in helping derive additional indices from the measurement models that produce numerical summaries of the educational assessment pertaining to its reliability, degree of error and consistency, etc. These topics are important in the practice of educational measurement and are represented in other chapters of this volume in more detail. Here, we rely on the IRT example to illustrate the use of posterior distribution and the derivation of the Fisher information function for a test made up of dichotomously scored items.

From the conditional probability and marginal likelihood in Equations 19 and 22, we can see that the posterior distribution of the latent variable θ is

$$P(\theta | \mathbf{y}, \hat{\omega}) = \frac{\prod_{i=1}^n [T_i(\theta, \hat{\omega})]^{y_i} [1 - T_i(\theta, \hat{\omega})]^{1-y_i} h(\theta | \hat{\omega})}{L(\hat{\omega} | \mathbf{u})} \quad (24)$$

$$\propto \prod_{i=1}^n [T_i(\theta, \hat{\omega})]^{y_i} [1 - T_i(\theta, \hat{\omega})]^{1-y_i} h(\theta | \hat{\omega}),$$

where the second line follows from the fact that the marginal likelihood $L(\hat{\omega} | \mathbf{y})$ at the optimum is a fixed number upon plugging in the structural parameter estimates $\hat{\omega}$. Taking natural logarithms, we see that the log-posterior becomes a sum, due to the factored form of the posterior under conditional independence:

$$\log P(\theta | \mathbf{y}, \hat{\omega}) = \sum_{i=1}^n (y_i \log T_i(\theta, \hat{\omega}) + (1 - y_i) \log (1 - T_i(\theta, \hat{\omega}))) + \log h(\theta | \hat{\omega}). \quad (25)$$

Posterior Summaries

Maximizing the log-posterior in Equation 25 with respect to θ leads to the maximum a posteriori (MAP) scaled score estimator, well known in the practice of test scoring. More precisely, we can write

$$\hat{\theta}_{\text{MAP}} = \arg \max_{\theta} \log P(\theta | \mathbf{y}, \hat{\omega}) \quad (26)$$

to indicate that we are maximizing the log-posterior with respect to θ . Omitting the contribution from the population leads to the maximum likelihood estimator, which is

still widely used despite its numerical instability. For example, the maximum likelihood estimator has a tendency to generate extremely low or extremely high estimates of θ (accompanied by undefined standard errors) when the likelihood does not possess a mode. The issue is mitigated with the prior distribution present. The posterior in Equation 24 can also be approximated with quadrature, leading to the following approximating expression for the mean of the posterior distribution:

$$\begin{aligned}\hat{\theta}_{\text{EAP}} &= E(\theta | \mathbf{y}, \hat{\omega}) = \int \theta P(\theta | \mathbf{y}, \hat{\omega}) d\theta \\ &\approx \frac{\sum_{q=1}^Q X_q \prod_{i=1}^n [T_i(X_q, \hat{\omega})]^{y_i} [1 - T_i(X_q, \hat{\omega})]^{1-y_i} h(X_q | \hat{\omega})}{\bar{L}(\omega | \mathbf{u})}.\end{aligned}\quad (27)$$

This is the expected a posteriori (EAP) estimator in test scoring (see Thissen & Wainer, 2001). As an aside, Thissen and Wainer (2001) also extensively discussed the IRT-based characterization of the posterior distribution of θ based on observed summed scores instead of the raw item response patterns. See Cai (2015) and Huang and Cai (2021) for further references, as well as extensions of the approaches discussed in Thissen and Wainer (2001) to the case of multidimensional models.

Information

Fisher's information $F(\theta)$ is a measure of expected (averaged over samples) curvature of the log-likelihood or log-posterior. In other words, it is the expectation of the negative second derivative of Equation 25. Assuming that the population distribution is standard normal, its negative second derivative with respect to θ is 1. After some algebra, this leads to

$$\begin{aligned}F(\theta) &= -E\left(\frac{\partial^2 \log P(\theta | \mathbf{y}, \hat{\omega})}{\partial \theta^2}\right) = \sum_{i=1}^n \beta_i^2 T_i(\theta, \hat{\omega})(1 - T_i(\theta, \hat{\omega})) + 1 \\ &= \sum_{i=1}^n F_i(\theta) + 1,\end{aligned}\quad (28)$$

where $F_i(\theta) = \beta_i^2 T_i(\theta, \hat{\omega})(1 - T_i(\theta, \hat{\omega}))$ is often referred to as the item information function. In other words, we obtained the familiar result that the test's information function is equal to the sum of each item's information function, plus an additional contribution from the population distribution. One may evaluate the Fisher information function and take the square root of its reciprocal (or matrix inverse when θ becomes a vector) as the IRT-based definition of the standard error of measurement (SEM), i.e., $SEM(\theta) = \sqrt{1/F(\theta)}$. We can see that the SEM is a function of the latent variable in IRT. This implies that, to generate the most precise individual estimate, different items should be administered for individuals with different θ values to minimize SEM.

Computerized adaptive testing (e.g., Gibbons et al., 2008; Wainer et al., 2000) research prominently features the use of likelihoods, posteriors, and information functions in the development of optimal item selection algorithms.

The Appraisal of Model Fit

Before one can rely on model-based inference, one must assess the degree of model fit that is relevant to the primary inferential objective at hand. Statements about model fit should always be framed in terms of the sensitivity of model-based inference to the nature of lack of fit. For example, the declaration of adequate model fit for the purpose of dimensionality analysis should not be identical to the needed degree of model fit for the purpose of establishing the stability of anchoring items in a new test form. Neither should one always use the same quantitative measures to gauge model fit. We offer these comments as an antidote to the widespread practice, especially in structural equation modeling, of focusing (and reporting) exclusively on a set of fit measures irrespective of the intended purpose of model fitting.

While we will provide later a more in-depth and technical treatment of the topic of model evaluation, especially in the context of multivariate analysis of discrete/categorical variables frequently encountered in educational measurement, we begin here with a discussion of some general concepts that may be less familiar to educational assessment researchers. Again, it is easiest to use an example. Recall the factor analysis covariance structure model in Equation 20, where y 's covariance matrix is structured as $\Sigma(\omega) = \Lambda\Lambda' + \Psi$, which depends on the free parameters ω specified by a modeler with the parameter matrices (Λ and Ψ). When the number of free parameters in ω is less than the number of nonduplicated elements in Σ , we say that the model is not saturated and has positive degrees of freedom. Note that this patterned covariance structure is a model imposed on the true covariance matrix Σ_0 , which is presumed to exist (and is positive definite). However, there may not be a simple model that can reproduce Σ_0 completely.

Exact and Approximate Goodness of Fit

The first concept is the difference between exact (or absolute) and approximate goodness of fit (Cudeck & Henly, 1991). By goodness of fit, we mean the discrepancy between the model-implied covariance matrix $\Sigma(\omega)$ and the true covariance matrix Σ_0 . This discrepancy can be quantified with a discrepancy function, such as the one motivated by ordinary least squares,

$$F_{OLS}(\Sigma_0, \Sigma(\omega)) = \frac{1}{2} \text{tr}(\Sigma_0 - \Sigma(\omega))^2, \quad (29)$$

which measures the squared difference between the population/true covariance matrix and the model-implied covariance matrix. There are many alternative discrepancy functions (see, e.g., Bollen, 1989), and the one based on normal theory maximum likelihood

(Cudeck & Browne, 1992) is extremely popular in the practice of factor analysis or structural equation modeling:

$$F_{ML}(\Sigma_0, \Sigma(\omega)) = \log|\Sigma(\omega)| + \text{tr}(\Sigma_0 \Sigma(\omega)^{-1}) - \log|\Sigma_0| - n. \quad (30)$$

These discrepancy functions take on a value of 0 if and only if the two inputs Σ_0 and $\Sigma(\omega)$ are identical. Otherwise, they take on positive values that reflect the degree of lack of fit.

The discrepancy function values above are of theoretical interest but cannot be computed directly unless Σ_0 is known, such as in a Monte Carlo simulation. Conceptually, however, their importance cannot be overstated. They indicate that a researcher's model is at best an approximation—a *working model*, as called by MacCallum (2003)—that attempts to capture the unknown true state of affairs. When the working model fails to account for all the nuances of the true state of affairs, even after optimizing over the values of ω , we say that there exists *model error* (MacCallum & Tucker, 1991), which means that there does not exist any parameter value ω in its plausible space of existence that would allow the working model to completely reproduce Σ_0 . The existence of model error is a profound concept and describes what is always true when conducting empirical research, even though the true state of affairs as described by Σ_0 is not known.

The situation is not hopeless, however, because we could still learn a great deal about the unknown structure in Σ_0 by minimizing the discrepancy function. More formally, let

$$\omega_0 = \arg \min_{\omega} F(\Sigma_0, \Sigma(\omega))$$

be the minimizer of the discrepancy, for a given choice of F , the parameters ω_0 that minimize such error is perhaps best described as the *minimum ignorance* estimates along the lines of Akaike (1973) and White (1980, 1982), and M. W. Browne (1984).

The discrepancy function value at the minimizer $F_0 = F(\Sigma_0, \Sigma(\omega_0))$ is 0 if and only if there exists such a set of parameters ω_0 that can completely reproduce the true covariance matrix Σ_0 . In that case, we say the model fits *exactly*. If at the minimizer ω_0 , F_0 is nonzero but small, we say the model fits only *approximately*.

Unfortunately, we do not know the population covariance matrix Σ_0 in general, so F_0 is not directly computable. We do, however, have access to the sample covariance matrix $\mathbf{S}$, which provides (assuming the sampling is unbiased) a consistent estimate of the population covariance matrix. Therefore, we can choose to minimize the discrepancy between the sample covariance matrix and the model, that is,

$$\hat{\omega} = \arg \min_{\omega} F(\mathbf{S}, \Sigma(\omega)).$$

The discrepancy function value at the minimizer $\hat{F} = F(\mathbf{S}, \Sigma(\hat{\omega}))$ signifies both model error and sampling error because the sample size leading to $\mathbf{S}$ is not infinite. This minimized value $\hat{F}$ may be referred to as the *error of approximation*.

Fit Indices

Classical goodness-of-fit tests widely used in moment structure analysis (e.g., Bentler, 1983; M. W. Browne, 1984), and more recently in IRT (e.g., Cai et al., 2006; Maydeu-Olivares & Joe, 2005), are invariably functions of $\tilde{F}$ or of similar measures. Only when model error is absent may we use the standard large sample chi-square approximations to test the absolute fit of the model, with a null hypothesis that says the model fits exactly, that is, no model error. But as Box (1976) observed, “all models are wrong.” We must accept that the “no model error” null hypothesis will always be rejected in the practice of model fitting. It is a fundamentally uninteresting hypothesis because we do not expect (nor do we need) our models to be free of model error to have scientific value. The statistical significance test is therefore routinely a test of whether our sample size is large enough to lead to a rejection of the null hypothesis of exact fit. Hence, other fit measures are needed.

In structural equation modeling, researchers have developed many fit measures that attempt to take the influence of sample size into account or that attempt to quantify the magnitude of model error. Prominent indices include the Tucker–Lewis index (TLI), the root-mean-square error of approximation (RMSEA), and the standardized root-mean-square residual. Guidelines of assessing approximate model fit have been discussed extensively (e.g., Hu & Bentler, 1999; McNeish, & Wolf, 2023; Shi et al., 2019). In IRT, similar measures have been proposed and studied (e.g., Cai et al., 2021; Maydeu-Olivares et al., 2011).

Generalizability Trade-Offs

It is well known to the statistically inclined that a well-fitting model does not guarantee that the model will work as well in an independent replication data set. It has been known for decades (e.g., MacCallum et al., 1992) that seeking good fit alone could lead to models and/or parameters that fit idiosyncratic patterns of a particular data set, due to capitalization on chance. Independently, statisticians have advocated the use of information theory-based indices such as the Akaike information criterion (Akaike, 1973) or Bayesian information criterion (Schwartz, 1978) to penalize models with more parameters that may fit the data better, but potentially at the expense of overfitting. An overfitted model may not generalize (i.e., may not fit as well to new data sampled from the same population as the original). This is an issue that has attracted attention, particularly in the machine learning world (see, e.g., Hastie et al., 2009, Chapter 7). Strategies to mitigate overfitting and improve generalizability range from simple approaches such as cross-validating a model over independent replications (e.g., holding out a random batch of data to test whether the model fits adequately in the hold-out sample) to more formal approaches such as regularization (e.g., the *lasso*; Tibshirani, 1996). It is sufficient to say that even simple approaches such as keeping a random subset of holdout sample for replication, when used routinely in data analysis, can

help significantly improve the generalizability and validity of model-based inference in education.

The Representation of Research Design

An important but often overlooked modeling task in educational assessment is to connect the latent variables representing outcomes with predictor variables, while representing key features of the research design (e.g., randomization) in the model so that unbiased inferences can be drawn. This leads to a blurry boundary between strictly psychometrics-oriented modeling and the models employed in the broader educational statistics field, such as the hierarchical linear model (HLM; Raudenbush & Bryk, 2002). Sometimes the choices of models is clear, such as when group differences at the latent variable and item levels need to be disentangled using differential item functioning methods based on IRT, or when background covariates are entered into a latent regression model, as in NAEP data analysis. Sometimes the choices must be made on a case-by-case basis, such as in the context of using educational assessments to evaluate the efficacy of interventions and programs, when the assessment design itself manifests in increasingly complex dimensionality, or when the data collection design leads to multilevel data structures that make the specification of crossed or nested random effects (latent variables) necessary. In all these cases, it would be important for the modeler to tailor the statistical model to accommodate those aspects of the research design that are the most impactful to the goal of inference. It is helpful to review a prominent example to illustrate our point.

Large-scale educational surveys such as NAEP or Program for International Student Assessment (PISA) provide overall data about educational systems' performance. Multidimensional IRT-based plausible value (PV; Mislevy, 1991; von Davier et al., 2009) methodology is one of the key technical approaches behind these surveys (see also Braun & Kirsch, this volume, for further discussion of PVs in the context of international large-scale assessments). The PV methodology is based on Rubin's multiple imputation theory for missing data analysis (Little & Rubin, 2019; Rubin, 1987). Student achievement latent variables are considered unobserved/missing data. Responses to achievement assessment items and background variables (e.g., demographics, access to resources, motivation, peer context, and school characteristics) are the observed data. To provide efficient estimates of means, variances, and group contrasts at higher levels of aggregation than the individual student, the assessment design makes use of random sampling of items so that each student receives only a small fraction of items selected from the item pool. When individual fractions of missing information are high—and if simple averaging of individual point estimates is used—there is no guarantee that group-level inferences will be unbiased (Mislevy, 1991). The situation is akin to the problem of using single imputation versus multiple imputation in data analysis with missing values present in the data set. In PV methodology, instead of a single point estimate, multiple sets of PVs of student proficiency

variables are generated stochastically from a posterior distribution of the missing data conditional on the entirety of observed data, including background variables (Mislevy, 1991; Mislevy et al., 1992). The imputer's model that generated the PVs combine the background variables with the assessment item response data through a multivariate latent regression model. Therefore, researchers using the PVs to address their own hypotheses do not have to go back to the raw data sets, which are large and complex. Instead, the PVs may be used just as any other multiply imputed data in secondary data analysis.

Suppose NAEP item i assessing domain d has C_i categories, with observed response $c \in \{0, \dots, C_i - 1\}$ from individual j . Let $\mathbf{y}_{jd}$ be the observed student response data in domain d with typical element y_{ijd} denoting item response from individual j to item i in domain d . The individual response vector is $\mathbf{y}_j = (y_{j1}, \dots, y_{jD})$ and $\mathbf{Y} = (\mathbf{y}_1, \dots, \mathbf{y}_N)$ collects together all observed outcomes. Of interest to the assessment developers and users is estimating the unobserved student achievement in the D domains, and the vector containing these latent achievement variables for student j is represented by $\boldsymbol{\theta}'_j = (\theta_{j1}, \dots, \theta_{jd}, \dots, \theta_{jD})$. In NAEP, the domains are correlated. Finally, let $\mathbf{X} = (x_1, \dots, x_j, \dots, x_N)$ be the matrix of background variables, where $\mathbf{x}_j$ is the covariate vector for individual j , and let N denote the total sample size.

Next, in the conditioned latent regression model that produces the PVs, the latent proficiency vector $\boldsymbol{\theta}_j$, is regressed on $\mathbf{x}_j$

$$\boldsymbol{\theta}_j = \boldsymbol{\Gamma} \mathbf{x}_j + \boldsymbol{\varepsilon}_j,$$

where the disturbance term $\boldsymbol{\varepsilon}_j$ follows a D -variate normal distribution with zero means and an unstructured covariance matrix $\boldsymbol{\Sigma}$. The multivariate regression model implies that $\boldsymbol{\theta}_j$ is D -variate normally distributed with conditional mean vector $\boldsymbol{\Gamma} \mathbf{x}_j$ and covariance matrix $\boldsymbol{\Sigma}$, where $\boldsymbol{\Gamma}$ represents a matrix of unknown regression coefficients (see Thomas & Gan, 1997). The background covariates contribute to the explanation of the individual-specific outcomes by giving each student potentially different conditional means. Let $f(\boldsymbol{\theta}_j; \boldsymbol{\Gamma} \mathbf{x}_j, \boldsymbol{\Sigma})$ represent a multivariate normal density function with mean $\boldsymbol{\Gamma} \mathbf{x}_j$ and covariance matrix $\boldsymbol{\Sigma}$.

We now need the conditional independence assumption. Suppose that the items in each of the proficiency domains are independent once the latent proficiency θ_{jd} is accounted for and that each item belongs to only one domain, that is, the independent cluster pattern in factor analysis. The posterior distribution of the latent proficiencies $\boldsymbol{\Theta} = (\boldsymbol{\theta}_1, \dots, \boldsymbol{\theta}_N)$ is then proportional to the following joint likelihood:

$$f(\boldsymbol{\Theta} | \mathbf{X}, \mathbf{Y}) \propto \prod_{j=1}^N f(\boldsymbol{\theta}_j; \boldsymbol{\Gamma} \mathbf{x}_j, \boldsymbol{\Sigma}) \prod_{d=1}^D f_d(\mathbf{y}_{jd} | \theta_{jd}), \quad (31)$$

from which sets of PVs of $\boldsymbol{\Theta}$ can be drawn. The main lesson here is that the model described in Equation 31 is custom built to encode core features of the assessment design, which should be a desirable goal in modeling of educational assessment data.

A GENERAL FRAMEWORK

Given the foregoing discussions, we present a general multivariate statistical framework that combines elements of factor analysis, multidimensional, multilevel (including cross-classified relations), diagnostic classification IRT models, with conditioning covariates and predictors. The model may be constrained to obtain existing, known factor analysis or IRT models, as Table 10.1 illustrates. From this framework, one can obtain more specialized models that are fit for particular research designs or inferential purposes akin to the practice of model building in the field of structural equation modeling.

Measurement Models

The Nested Case

To begin, let us consider the case of fully nested relationship in our data collection design, using the language of HLM. Suppose the observed data are from a Level 1 unit j nested within independent sampling unit (Level 2 unit) k , for example, a student nested within a school. For a generic item/observed variable i , we may denote the linear combination of latent variables as

$$\eta_{ijk} = \beta'_{i1} \begin{pmatrix} h_{i1}(\mathbf{Q}_1, \boldsymbol{\xi}_{jk}) \\ \boldsymbol{\theta}_{jk} \end{pmatrix} + \beta'_{i2} \begin{pmatrix} h_{i2}(\mathbf{Q}_2, \boldsymbol{\xi}_k) \\ \boldsymbol{\theta}_k \end{pmatrix}, \quad (32)$$

where β_{i1} and β_{i2} are the item slope parameters, with $\mathbf{Q}_1$ and $\mathbf{Q}_2$ the $\mathbf{Q}$ matrices at Levels 1 and 2, respectively. The subscripts on $\boldsymbol{\xi}$ and $\boldsymbol{\theta}$ indicate whether the latent variables vary over Level 1 units (j and k) or over Level 2 units (k only). The dimensions of the slope vectors are dependent on both the number of continuous latent dimensions (factors) in $\boldsymbol{\theta}$ and the number of terms, such as interaction effects, generated by the h functions and $\mathbf{Q}$ matrices at each level for the diagnostic attributes in $\boldsymbol{\xi}$. We will assume that there are K Level 2 units in total, and each Level 2 unit consists of N_k Level 1 units. The total number of Level 1 units is $N = \sum_k N_k$.

The Cross-Classified Case

In educational research, we also frequently encounter cases in which the lowest unit of data collection design belongs to two or more nonnested higher level units simultaneously. This yields a cross-classified data structure (e.g., Beretvas, 2011; W. J. Browne et al., 2001; Fielding & Goldstein, 2006; Goldstein, 1994; Huang, 2021; Jeon et al., 2017; Raudenbush & Bryk, 2002). When assessment instruments made up of multiple items are employed to measure unobserved variables, we have multivariate categorical outcome variables with a cross-classified data structure. An example is the ubiquitous use of student surveys for evaluation of instruction in higher education. In educational assessment, the person-by-item response matrix may be perceived of as a form of cross-classification as well. This leads directly to the explanatory and random item models (see de Boeck & Wilson, 2004) that promise to significantly expand the scope of the linear variance components approach (Searle et al., 2006)

that remains to this day foundational in generalizability theory (G theory; Shavelson & Webb, 1991). These random-item models also influenced new developments in models for network psychometrics (e.g., Jin & Jeon, 2019).

With model building in mind, let us consider adaptations to the linear combination in Equation 32. For item i that is within a cell jk defined by a two-way cross-classification, the linear combination of latent variables can take the following form:

$$\eta_{ijk} = \beta'_{i1} \begin{pmatrix} h_{i1}(\mathbf{Q}_1, \boldsymbol{\xi}_j) \\ \boldsymbol{\theta}_j \end{pmatrix} + \beta'_{i2} \begin{pmatrix} h_{i2}(\mathbf{Q}_2, \boldsymbol{\xi}_k) \\ \boldsymbol{\theta}_k \end{pmatrix}, \quad (33)$$

where the $\boldsymbol{\xi}_j$ and $\boldsymbol{\theta}_j$ vary over the first facet of the cross-classification, and $\boldsymbol{\xi}_k$ and $\boldsymbol{\theta}_k$ vary over the second facet. They may be aptly termed the row side and the column side in an imaginary two-way table wherein each cell contains multivariate outcomes that are influenced by the latent variables. For example, the rows may represent students and the columns the courses they took—or perhaps the rows are essays and the columns are the raters. We assume that there are J rows and K columns, with the total number of cells equal to $N = J \times K$.

Link Functions and Conditional Distributions

Substituting the linear combination in Equations 32 or 33 into, for example, the 2PL model, results in the item's conditional response probability, for example,

$$T_i(1 | \eta_{ijk}) = \frac{1}{1 + \exp[-(\alpha_i + \eta_{ijk})]}, \quad (34)$$

with an additional item intercept parameter α_i . For an item with multiple categorical responses $c \in \{0, \dots, C_i - 1\}$, the conditional probability of observing response y_{ijk} is a multinomial with trial size 1 in C_i categories:

$$f_{\omega}(y_{ijk} | \eta_{ijk}) = \prod_{c=0}^{C_i-1} T_i(c | \eta_{ijk})^{\chi_c(y_{ijk})}, \quad (35)$$

where the indicator function $\chi_c(y_{ijk})$ takes a value of 1 if and only if $y_{ijk} = c$ and is zero otherwise. We use the subscript ω to emphasize that the conditional distribution depends on a set of structural parameters contained in this vector.

The conditional probability $T_i(c | \eta_{ijk})$ may take on a variety of forms. The 2PL, 3PL, and GPC models presented earlier are popular candidates. Samejima's (1969) graded response model with cumulative logits is another practical choice. Its item conditional probability is usually written as

$$T_i(c | \eta_{ijk}) = \frac{1}{1 + \exp[-(\alpha_{i,c} + \eta_{ijk})]} - \frac{1}{1 + \exp[-(\alpha_{i,c+1} + \eta_{ijk})]}, \quad (36)$$

to indicate that the category probability is the difference between adjacent cumulative probabilities, which are themselves modeled after the 2PL model. The two boundary cases are defined as

$$T_i(0|\eta_{ijk}) = 1 - \frac{1}{1 + \exp[-(\alpha_{i,1} + \eta_{ijk})]},$$

and

$$T_i(C_i - 1|\eta_{ijk}) = \frac{1}{1 + \exp[-(\alpha_{i,C_i-1} + \eta_{ijk})]} - 0,$$

for the obvious reasons that the cumulative probability of the response falling in category 0 or above is equal to 1.0 and that there is simply no probability for a response coded as C_i beyond the highest response of $C_i - 1$. The graded model subsumes the 2PL as a special case (i.e., when $C_i = 2$).

As an aside, we can handle the linear factor analysis (continuous outcome) case easily by assuming that the conditional distribution of the outcome variable is normal,

$$f_{\omega}(y_{ijk}|\eta_{ijk}) \sim N(\alpha_i + \eta_{ijk}, \sigma_i^2),$$

where α_i is the usual measurement intercept parameter. If the outcome is a count variable, we can implement a log-linear model with a Poisson conditional distribution,

$$f_{\omega}(y_{ijk}|\eta_{ijk}) \sim \text{Pois}(\alpha_i + \eta_{ijk}).$$

Other link functions and conditional distributions may be assumed if warranted, such as log-normal distributions for response time data (van der Linden, 2007). One simply has to follow standard theory in generalized linear mixed modeling (e.g., McCulloch et al., 2008) and in generalized latent variable modeling (e.g., Bartholomew et al., 2011; Cai, 2008; Skrondal & Rabe-Hesketh, 2004).

Conditioning on Predictors

To build the model further, we invoke the conditional independence assumption, so that the conditional response pattern probability for the response vector $\mathbf{y}_{jk} = (y_{1jk}, \dots, y_{njk})$ containing n observations is expressed as a product of individual item response probabilities. For the nested case, we have

$$f_{\omega}(\mathbf{y}_{jk}|\boldsymbol{\xi}_{jk}, \boldsymbol{\xi}_k, \boldsymbol{\eta}_{jk}, \boldsymbol{\eta}_k) = \prod_{i=1}^n f_{\omega}(y_{ijk}|\boldsymbol{\xi}_{jk}, \boldsymbol{\xi}_k, \boldsymbol{\eta}_{jk}, \boldsymbol{\eta}_k). \quad (37)$$

For the cross-classified case, we have

$$f_{\omega}(\mathbf{y}_{jk}|\boldsymbol{\xi}_j, \boldsymbol{\xi}_k, \boldsymbol{\eta}_j, \boldsymbol{\eta}_k) = \prod_{i=1}^n f_{\omega}(y_{ijk}|\boldsymbol{\xi}_j, \boldsymbol{\xi}_k, \boldsymbol{\eta}_j, \boldsymbol{\eta}_k). \quad (38)$$

The presence of both types of latent variables (continuous and discrete) at both levels allows the model to be more flexible than standard multidimensional or multilevel IRT models, as well as DCMs. The remaining task involves the conditioning of the $\boldsymbol{\eta}$ and $\boldsymbol{\zeta}$ variables by regressing them on covariates or predictors.

In general, the conditioning regression model is a multivariate linear model that takes the following form:

$$\boldsymbol{\eta} = \boldsymbol{\Gamma}\mathbf{x} + \boldsymbol{\varepsilon},$$

where the equation disturbance term $\boldsymbol{\varepsilon}$ is typically assumed to be multivariate normal with zero means and an error covariance matrix that may contain estimable parameters.

Consider the latent regression for the nested case, where $\mathbf{x}_{jk}$ indicates a vector of background covariates or predictors that varies over Level 1 units and, if applicable, $\mathbf{x}_k$ is a vector of Level 2 predictors. There are two simultaneous regression equations:

$$\begin{pmatrix} \boldsymbol{\eta}_{jk} \\ \boldsymbol{\eta}_k \end{pmatrix} = \begin{pmatrix} \boldsymbol{\Gamma}_{11} & \boldsymbol{\Gamma}_{12} \\ \mathbf{0} & \boldsymbol{\Gamma}_{22} \end{pmatrix} \begin{pmatrix} \mathbf{x}_{jk} \\ \mathbf{x}_k \end{pmatrix} + \begin{pmatrix} \boldsymbol{\varepsilon}_{jk} \\ \boldsymbol{\varepsilon}_k \end{pmatrix}, \quad (39)$$

where the lower left block of the regression coefficient matrix is zero because Level 2 latent variables should not be regressed on Level 1 predictors. A set of similar, and simpler, equations can be specified for the cross-classified case:

$$\begin{pmatrix} \boldsymbol{\eta}_j \\ \boldsymbol{\eta}_k \end{pmatrix} = \begin{pmatrix} \boldsymbol{\Gamma}_{11} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Gamma}_{22} \end{pmatrix} \begin{pmatrix} \mathbf{x}_j \\ \mathbf{x}_k \end{pmatrix} + \begin{pmatrix} \boldsymbol{\varepsilon}_j \\ \boldsymbol{\varepsilon}_k \end{pmatrix}, \quad (40)$$

where the predictors vary along the same facets of the latent variables, that is, row-side latent variables are regressed on row-side predictors and the same for the column side. In both nested and cross-classified cases, the predictor vectors may contain a constant term so that the regression intercept parameters may be estimated.

Likelihoods

Combining various parts reviewed earlier, and following standard modeling practices, the latent variables can now be integrated out of the joint likelihood. Suppose $\boldsymbol{\omega}$ is the $d \times 1$ vector that collects together all free parameters in the model. These include parameters from all the items (the α 's, β 's, and γ 's), parameters for the latent variables, the regression coefficients, and covariance matrices of the error terms.

The Nested Case

For the nested case, the integration is done sequentially. In the first step, the Level 1 discrete latent attributes are integrated out:

$$f_{\omega}(\mathbf{y}_{jk} | \boldsymbol{\xi}_k, \boldsymbol{\eta}_{jk}, \boldsymbol{\eta}_k) = \int f_{\omega}(\mathbf{y}_{jk} | \boldsymbol{\xi}_{jk}, \boldsymbol{\xi}_k, \boldsymbol{\eta}_{jk}, \boldsymbol{\eta}_k) f_{\omega}(\boldsymbol{\xi}_{jk}) d\boldsymbol{\xi}_{jk}, \quad (41)$$

where $f_{\omega}(\boldsymbol{\xi}_{jk})$ is the prior distribution on the Level 1 attributes. Second, the Level 1 continuous latent variables are integrated out, bringing along the conditioning covariates as well:

$$f_{\omega}(\mathbf{y}_{jk} | \boldsymbol{\xi}_k, \boldsymbol{\eta}_k, \mathbf{x}_{jk}, \mathbf{x}_k) = \int f_{\omega}(\mathbf{y}_{jk} | \boldsymbol{\xi}_k, \boldsymbol{\eta}_{jk}, \boldsymbol{\eta}_k) f_{\omega}(\boldsymbol{\eta}_{jk} | \mathbf{x}_{jk}, \mathbf{x}_k) d\boldsymbol{\eta}_{jk}, \quad (42)$$

where $f_{\omega}(\eta_{jk} | \mathbf{x}_{jk}, \mathbf{x}_k)$ follows from the first term of the matrix equations in Equation 39. In the next step, one requires the assumption of conditional independence again, this time of the independence of N_k Level 1 response vectors nested within Level 2 unit k , conditionally on all the Level 2 latent variables:

$$\begin{aligned} f_{\omega}(\{\mathbf{y}_{jk}\}_{j=1}^{N_k} | \{\mathbf{x}_{jk}\}_{j=1}^{N_k}, \mathbf{x}_k) \\ = \int \int \prod_{j=1}^{N_k} f_{\omega}(\mathbf{y}_{jk} | \xi_k, \eta_k, \mathbf{x}_{jk}, \mathbf{x}_k) f_{\omega}(\xi_k) f_{\omega}(\eta_k | \mathbf{x}_k) d\xi_k d\eta_k, \end{aligned} \quad (43)$$

where $f_{\omega}(\xi_k)$ is the prior distribution on the Level 2 attributes and $f_{\omega}(\eta_k | \mathbf{x}_k)$ follows from the second row of the matrix equation in Equation 39. The parenthetical notation $\{\mathbf{y}_{jk}\}_{j=1}^{N_k}$ and $\{\mathbf{x}_{jk}\}_{j=1}^{N_k}$ collects all the Level 1 outcome and covariate observations within Level 2 unit k . Suffice it to say that Equation 43 contains the marginal likelihood function of all parameters of the model. In both the nested and the cross-classified cases, we shall collect all the outcome variables into $\mathbf{Y}$ and all predictors into $\mathbf{X}$.

Summing across the (assumed) independent Level 2 units, the overall marginal log-likelihood function is

$$\log L(\omega | \mathbf{Y}, \mathbf{X}) = \sum_{k=1}^K \log f_{\omega}(\{\mathbf{y}_{jk}\}_{j=1}^{N_k} | \{\mathbf{x}_{jk}\}_{j=1}^{N_k}, \mathbf{x}_k). \quad (44)$$

The Cross-Classified Case

For the cross-classified case, the integration is iterated over all rows and columns in the two-way cross-classification to arrive at the marginal likelihood function:

$$\begin{aligned} L(\omega | \mathbf{Y}, \mathbf{X}) = \prod_{k=1}^K \int \int \prod_{j=1}^J \int \int f_{\omega}(\mathbf{y}_{jk} | \xi_j, \eta_j, \xi_k, \eta_k) f_{\omega}(\xi_j) \\ f_{\omega}(\eta_j | \mathbf{x}_j) d\xi_j d\eta_j f_{\omega}(\xi_k) f_{\omega}(\eta_k | \mathbf{x}_k) d\xi_k d\eta_k. \end{aligned} \quad (45)$$

We begin by conditioning on a particular row j 's latent variables. We realize that if we further condition on the column-side latent variables, all columns become conditionally independent within this row. Next, with the regression equation in Equation 40, we can integrate out the continuous latent variables and bring the predictors into the conditioning set. The marginal log-likelihood is the logarithm of Equation 45. Software such as flexMIRT (Houts & Cai, 2022) implements nearly all of the features of the generalized modeling framework presented previously and estimates the structural parameters with maximum marginal likelihood. Alternatives such as fully Bayesian approaches may also be adopted.

ESTIMATION METHODS

At this point, with the marginal likelihoods fully specified, the task in front of the statistical modeler is that of the estimation of the structural parameters of the model in ω and the appraisal of model fit, before inferences about the latent variables are drawn using the empirical Bayes approach already discussed (see, e.g., Equation 20), which

is about test scoring in the practice of educational measurement with comprehensive discussions appearing elsewhere (e.g., Thissen & Wainer, 2001).

The optimization of the marginal log-likelihoods in Equations 44 or 47 typically requires advanced iterative numerical methods because closed-form solutions are unavailable. Various computational approaches may be used, including the venerable expectation–maximization (EM) algorithm with fixed quadrature (see Equation 19) due to Bock and Aitkin (1981), or the more recent Metropolis–Hastings Robbins–Monro algorithm (MH-RM; Cai, 2008, 2010b, 2010c) based on stochastic approximation. Alternatively, one may also adopt fully Bayesian estimation using Markov chain Monte Carlo (MCMC) sampling methods (Hastings, 1970; Metropolis et al., 1953) for maximal flexibility in model specification and estimation. See Edwards (2010) for a review in the context of IRT or borrow an optimization toolkit from machine learning (Urban & Bauer, 2021). For a recent review, please see Y. Chen et al. (2022).

Despite the algorithmic advances now at the fingertips of modelers of educational assessment data, it is important to review some computational concepts so that modelers may be equipped with the knowledge to diagnose computational troubles that may frustrate any data analyses involving iterative optimization of models and parameters. We begin with the missing data formulation present in Dempster et al.’s (1977) classic paper that coined the term expectation–maximization algorithm.

For now, let us return to the basic case of a unidimensional IRT model as in Equation 13 with a standard normal prior/population distribution. Let $\mathbf{Y}$ be a matrix of all observed item responses, and $\mathbf{y}_j$ is the $n \times 1$ vector of responses from individual j . The marginal likelihood function for all the structural parameters in ω can be expressed as

$$\begin{aligned} L(\omega | \mathbf{Y}) &= \prod_{j=1}^N \int \prod_{i=1}^n [T_i(\theta, \omega)]^{y_{ij}} [1 - T_i(\theta, \omega)]^{1-y_{ij}} h(\theta) d\theta \\ &= \prod_{j=1}^N \log L(\omega | \mathbf{y}_j). \end{aligned} \quad (46)$$

Because the marginal likelihood does not depend on the unobserved θ values, it may also be referred to as the *observed* data likelihood. Implicit in the “observed data” reference is a realization that the latent variables are the missing values. Suppose θ is a vector that collects together all N latent variable scores and $\mathbf{y}_i$ is the $N \times 1$ vector of responses to item i . If we were able to observe the latent variables, then the “complete data” likelihood function of item parameters takes on a factored form, again by virtue of the conditional independence assumption of item responses and the independence of individuals. We can express it as

$$\begin{aligned} L(\omega | \mathbf{Y}, \theta) &= \left[\prod_{j=1}^N h(\theta_j) \right] \left[\prod_{j=1}^N \prod_{i=1}^n [T_i(\theta, \omega)]^{y_{ij}} [1 - T_i(\theta, \omega)]^{1-y_{ij}} \right] \\ &\propto \prod_{j=1}^N L(\omega | \mathbf{y}_j, \theta_j) = \prod_{i=1}^n L(\omega | \mathbf{y}_i, \theta), \end{aligned} \quad (47)$$

where

$$L(\omega | \mathbf{y}_j, \theta_j) = \prod_{i=1}^n [T_i(\theta, \omega)]^{y_{ij}} [1 - T_i(\theta, \omega)]^{1-y_{ij}}$$

is the complete data likelihood for individual j , and

$$L(\omega | \mathbf{y}_i, \theta) = \prod_{j=1}^N \prod_{i=1}^n [T_i(\theta, \omega)]^{y_{ij}} [1 - T_i(\theta, \omega)]^{1-y_{ij}}$$

is the complete data likelihood for item i . The proportionality on the second line of Equation 47 holds because $h(\theta_j)$ is assumed to be standard normal and becomes a constant if the θ 's were known. Equation 47 makes it clear that the complete data likelihood is a constant multiple of the product of n item-specific complete data likelihoods or N individual-specific complete data likelihoods.

Of course, we do not observe the latent variable θ values. But the posterior distribution of the latent variables given the observed item responses provides the basis of a principled way to fill in (impute) the missing data. For an individual, recall the posterior is defined as the following (Equation 20):

$$P(\theta | \mathbf{y}_j, \omega) = \frac{\prod_{i=1}^n [T_i(\theta, \omega)]^{y_{ij}} [1 - T_i(\theta, \omega)]^{1-y_{ij}} h(\theta | \omega)}{\int \prod_{i=1}^n [T_i(\theta, \omega)]^{y_{ij}} [1 - T_i(\theta, \omega)]^{1-y_{ij}} h(\theta | \omega) d\theta}. \quad (48)$$

The distribution function itself is analytically intractable, but the posterior is proportional to the joint distribution in the numerator, which implies that with MCMC, the posterior can be sampled, for example, with Patz and Junker's (1999) algorithm. But even more important, we can verify that the following equality holds under mild regularity conditions:

$$\frac{\partial \log L(\omega | \mathbf{y}_j)}{\partial \omega} = \int \frac{\partial \log L(\omega | \mathbf{y}_j, \theta_j)}{\partial \omega} P(\theta_j | \mathbf{y}_j, \omega) d\theta_j. \quad (49)$$

Equation 49 is known as Fisher's identity (Fisher, 1925). This is arguably the second most important computational concept in latent variable modeling, after the missing data formulation. Fisher's identity states that the gradient of the observed data log-likelihood $\log L(\omega | \mathbf{y}_j)$ is equal to the conditional expectation of the gradient of the complete data log-likelihood $\log L(\omega | \mathbf{y}_j, \theta_j)$. The expectation is taken over the posterior distribution of the latent variables given the observed variables. This powerful insight suggests that instead of trying to maximize the observed data likelihood, which is direct but often more difficult, one should consider iteratively maximizing the conditional expected complete data likelihood (i.e., the right-hand side of Equation 19), which is indirect but more tractable. It lies behind Bock and Aitkin's (1981) EM algorithm and motivated many modern variants, including the MH-RM algorithm.

Bock–Aitkin EM Algorithm

From Equation 19, we see that the marginal likelihood can be approximated to arbitrary precision by replacing the integration with a summation over a set of Q quadrature points X_q spread over θ , with quadrature weights W_q . Bock and Aitkin (1981) saw that the height of the posterior at quadrature point X_q can be approximated to arbitrary precision as well:

$$P(X_q | \mathbf{y}_j, \omega) \approx \frac{[T_i(X_q, \omega)]^{y_{ij}} [1 - T_i(X_q, \omega)]^{1-y_{ij}} W_q}{\sum_{q=1}^Q \prod_{i=1}^n [T_i(X_q, \omega)]^{y_{ij}} [1 - T_i(X_q, \omega)]^{1-y_{ij}} h(X_q) W_q}. \quad (50)$$

Ignoring constants and taking the logarithm of Equation 47, the complete data log-likelihood is

$$\begin{aligned} \log L(\omega | \mathbf{Y}, \theta) &= \sum_{j=1}^N \sum_{i=1}^n y_{ij} \log T_i(\theta_j, \omega) \\ &\quad + \sum_{j=1}^N \sum_{i=1}^n (1 - y_{ij}) \log(1 - T_i(\theta_j, \omega)). \end{aligned} \quad (51)$$

Following Fisher's identity, the conditional expected complete data likelihood given provisional item parameter values ω^* can also be approximated by quadrature,

$$\begin{aligned} M(\omega | \mathbf{Y}, \omega^*) &\approx \sum_{j=1}^N \sum_{q=1}^Q \sum_{i=1}^n y_{ij} \log T_i(X_q, \omega) P(X_q | \mathbf{y}_j, \omega^*) \\ &\quad + \sum_{j=1}^N \sum_{q=1}^Q \sum_{i=1}^n (1 - y_{ij}) \log(1 - T_i(X_q, \omega)) P(X_q | \mathbf{y}_j, \omega^*) \end{aligned} \quad (52)$$

By interchanging the order of summation, Bock and Aitkin (1981) realized that the posterior probabilities can be accumulated over individuals first:

$$\begin{aligned} M(\omega | \mathbf{Y}, \omega^*) &\approx \sum_{i=1}^n \sum_{q=1}^Q \log T_i(X_q, \omega) \left(\sum_{j=1}^N y_{ij} P(X_q | \mathbf{y}_j; \omega^*) \right) \\ &\quad + \sum_{i=1}^n \sum_{q=1}^Q \log(1 - T_i(X_q, \omega)) \left(\sum_{j=1}^N (1 - y_{ij}) P(X_q | \mathbf{y}_j; \omega^*) \right) \\ &= \sum_{i=1}^n \sum_{q=1}^Q r_{iq} \log T_i(X_q, \omega) + \sum_{i=1}^n \sum_{q=1}^Q \bar{r}_{iq} \log(1 - T_i(X_q, \omega)), \end{aligned} \quad (53)$$

where $r_{iq} = \sum_{j=1}^N y_{ij} P(X_q | \mathbf{y}_j; \omega^*)$ can be understood as the expected number of positive/correct/endorsement responses to item i at quadrature point X_q , and

$\bar{r}_{iq} = \sum_{j=1}^J (1 - y_{ij}) P(X_q | \mathbf{y}_j; \boldsymbol{\omega}^*)$ is its counterpart for the negative/incorrect/disagreement responses. Taken together, let $n_{iq} = r_{iq} + \bar{r}_{iq} = \sum_{j=1}^J P(X_q | \mathbf{y}_j; \boldsymbol{\omega}^*)$ be the expected number of individuals at quadrature point X_q . We then have

$$M(\boldsymbol{\omega} | \mathbf{Y}, \boldsymbol{\omega}^*) \approx \sum_{i=1}^n \sum_{q=1}^Q r_{iq} \log T_i(X_q, \boldsymbol{\omega}) + (n_{iq} - r_{iq}) \log(1 - T_i(X_q, \boldsymbol{\omega})). \quad (54)$$

Equation 54 implies that the conditional expected complete data log-likelihood is a set of n parallel logistic regression log-likelihoods for “grouped” data, with the quadrature points X_q serving as the predictor values and weights given by n_{iq} and r_{iq} . Optimizing $M(\boldsymbol{\omega} | \mathbf{Y}, \boldsymbol{\omega}^*)$ leads to new and improved item parameter estimates, which can be used to update the posterior probabilities, and consequently the weights n_{iq} and r_{iq} .

In general, Bock–Aitkin EM (or any EM algorithm) alternates between the following two steps from a set of initial parameter estimates, say $\boldsymbol{\omega}^{(0)}$, and it generates a sequence of parameter estimates $\boldsymbol{\omega}^{(0)}, \dots, \boldsymbol{\omega}^{(k)}$ that converges under some very general conditions to the maximum marginal likelihood estimate of $\boldsymbol{\omega}$ as the number of cycles k tends to infinity (Wu, 1983).

E-Step

Given $\boldsymbol{\omega}^{(k)}$, evaluate the conditional expected complete data log-likelihood $M(\boldsymbol{\omega} | \mathbf{Y}; \boldsymbol{\omega}^{(k)})$, which is taken as a function of $\boldsymbol{\omega}$.

M-Step

Maximize $M(\boldsymbol{\omega} | \mathbf{Y}; \boldsymbol{\omega}^{(k)})$ to yield updated parameter estimates $\boldsymbol{\omega}^{(k+1)}$. Go back to E-step and repeat until estimates from adjacent cycles stabilize (i.e., convergence).

MH-RM Algorithm

Although Bock–Aitkin EM is highly efficient for unidimensional IRT parameter estimation, it does not generalize well to the case of multidimensional IRT because of the inherent limitation of numerical quadrature. The likelihoods and posteriors are evaluated over grids of quadrature points, leading to exponentially increasing computational burden as the number of latent variables increases. This is called the *curse of dimensionality* in the literature. As educational assessments become more complex, alternative estimation approaches are needed.

Cai (2008, 2010a, 2010b) reasoned that if one can randomly draw plausible values or imputations of θ from the posterior $P(\theta | \mathbf{y}_j, \boldsymbol{\omega}^*)$, with provisional parameter estimates $\boldsymbol{\omega}^*$, the left-hand side of Equation 49 can be approximated by Monte Carlo integration, that is,

$$\frac{\partial \log L(\boldsymbol{\omega} | \mathbf{y}_j)}{\partial \boldsymbol{\omega}} \approx \frac{1}{V} \sum_{v=1}^V \frac{\partial \log L(\boldsymbol{\omega} | \mathbf{y}_j, \theta_{jv})}{\partial \boldsymbol{\omega}}, \quad (55)$$

where θ_{jv} are random draws from $P(\theta \mid \mathbf{y}_j, \boldsymbol{\omega}^*)$. Stated differently, the Monte Carlo average of the gradients of the complete data log-likelihood contain (approximately) the same ascent direction as the observed data log-likelihood gradients. These random samples can be easily produced with the help of an MCMC sampling method, such as the Metropolis–Hastings algorithm. At this point, Cai (2008) drew an analogy to the engineering applications of Robbins and Monro's (1951) classical stochastic approximation method. The approximate ascent directions are corrupted by random sampling noise, but it can be gradually filtered out in the Robbins–Monro (RM) recursions with the use of a sequence of decreasing gain constants to achieve a point-wise convergent algorithm (see Cai, 2010a, for a proof) that resembles the EM algorithm. Thus, the number of random samples V can be a fixed and small number (as low as 1) throughout all the iterations of the algorithm.

In general, starting from $k = 0$ (initial values), cycle $k + 1$ of the MH-RM algorithm consists of three steps:

Imputation

Given provisional parameter estimates $\boldsymbol{\omega}^{(k)}$, V sets of random samples of the latent variables $\boldsymbol{\theta}_v^{(k+1)}$ are drawn. For each individual, the draws may come from a Metropolis–Hastings sampler that has, as its unique invariant (target) distribution, the posterior distribution $P(\theta_j \mid \mathbf{y}_j, \boldsymbol{\omega}^{(k)})$ of the missing data given the observed data and provisional parameter values. Form complete data sets as $\{\mathbf{Y}, \boldsymbol{\theta}_v^{(k+1)}\}_{v=1}^V$.

Approximation

In the second step, based on the imputed data, the complete data log-likelihood and its derivatives are evaluated so that the ascent directions for parameters can be determined. The complete data gradient (score function) is approximated as

$$\mathbf{s}_{k+1} = \frac{1}{V} \sum_{v=1}^V \frac{\partial \log L(\boldsymbol{\omega}^{(k)} \mid \mathbf{Y}, \boldsymbol{\theta}_v^{(k+1)})}{\partial \boldsymbol{\omega}}. \quad (56)$$

At the same time, to improve stability and speed, we also evaluate a Monte Carlo approximation to the conditional expected complete data information matrix:

$$\mathbf{I}_{k+1} = -\frac{1}{V} \sum_{v=1}^V \frac{\partial^2 \log L(\boldsymbol{\omega}^{(k)} \mid \mathbf{Y}, \boldsymbol{\theta}_v^{(k+1)})}{\partial \boldsymbol{\gamma} \partial \boldsymbol{\gamma}'}. \quad (57)$$

Because of conditional independence, the complete data information matrix is often block diagonal, vastly reducing the number of elements that must be computed.

Robbins–Monro Update

In the third step, Robbins–Monro stochastic approximation filters are applied when updating the estimates of item parameters. First, the Robbins–Monro filter is applied

to obtain a recursive stochastic approximation of the conditional expectation of the complete data information matrix

$$\mathbf{I}_{k+1} = \mathbf{I}_k + g_k (\mathbf{I}_{k+1} - \mathbf{I}_k), \quad (58)$$

where g_k is a sequence of nonnegative *gain constants* such that $g_k \in (0, 1]$, $\sum_{k=0}^{\infty} g_k = \infty$, $\sum_{k=0}^{\infty} g_k^2 < \infty$. Next, we use the Robbins–Monro filter again when updating the parameters:

$$\boldsymbol{\omega}^{(k+1)} = \boldsymbol{\omega}^{(k)} + g_k (\mathbf{I}_{k+1})^{-1} \mathbf{s}_{k+1}. \quad (59)$$

The iterations are started from some initial parameter values $\boldsymbol{\omega}^{(0)}$ and terminated when the estimates stabilize. Cai (2008, 2010a) showed that the sequence of parameters converges with probability 1 to a local maximum of the marginal/observed data likelihood function $L(\boldsymbol{\omega} | \mathbf{Y})$. Typically, the sequence of gain constants are taken to be $g_k = 1/(k+1)$, in which case the initial choice of $\mathbf{I}_0$ becomes arbitrary. Cai (2010a) provided formulas for recursively approximating the parameter error covariance matrix, as well as further discussions about convergence checking. The Metropolis-Hastings samplers can be tuned for optimal efficiency using the theory and approach developed by Robert & Rosenthal (2001).

THEORY AND METHODS FOR MODEL FIT EVALUATION

After obtaining estimates of the structural parameters and uncertainty estimates such as standard errors, the immediate task is to evaluate the fit of the model. In the context of factor analysis and structural equation modeling, this topic has been thoroughly discussed and is part of the standard practice. In the application of statistical modeling of educational assessment data, however, discussions of a coherent theory and methods of model fit evaluation have been scarce because discrete multivariate analysis is not a widely introduced topic. In this section, we will review some important concepts particularly relevant to the applications of models for discrete outcome variables (e.g., IRT and DCM).

The Multinomial Formulation

Let there be n items in a test. Suppose we use the model in Equation 6. The IRT model specifies the marginal probability of the item response pattern as the following integral:

$$P(\mathbf{y} | \boldsymbol{\omega}) = \int P(\mathbf{y} | \boldsymbol{\theta}, \boldsymbol{\omega}) h(\boldsymbol{\theta} | \boldsymbol{\omega}) d\boldsymbol{\theta} = \pi_{\mathbf{y}}(\boldsymbol{\omega}). \quad (60)$$

The parenthetical notation $\pi_{\mathbf{y}}(\boldsymbol{\omega})$ in Equation 60 is used to emphasize the fact that it is the model. The marginal probability depends on the response pattern $\mathbf{y}$, the $d \times 1$ vector of structural parameters $\boldsymbol{\omega}$, the conditional probability $P(\mathbf{y} | \boldsymbol{\theta}, \boldsymbol{\omega})$, and the latent variable distribution $h(\boldsymbol{\theta} | \boldsymbol{\omega})$.

Recall that C_i is the number of categories for item i . The total number of possible item response patterns is $C = \prod_{i=1}^n C_i$. This can be arranged (grouped) in the form of a contingency table under multinomial sampling. Based on a sample of N respondents, let the observed proportion associated with pattern $\mathbf{y}$ be denoted p_y . The sampling model for this contingency table is a multinomial distribution with C cells and N trials. The log-likelihood for the item parameters ω is proportional to

$$\log L(\omega) \propto N \sum_y p_y \log \pi_y(\omega), \quad (61)$$

where the summation runs over all C possible response patterns if all p_y are positive. Otherwise, the summation can be assumed to run over the observed response patterns when some observed p_y values are zero. Maximization of the log-likelihood leads to the maximum marginal likelihood estimator $\hat{\omega}$.

Upon finding $\hat{\omega}$, the model generates model-implied probabilities for each response pattern $\pi_y(\hat{\omega}) = \hat{\pi}_y$. Suppose the model-implied response pattern probabilities $\hat{\pi}_y$ are collected into a $C \times 1$ vector $\hat{\pi}$ of all model-implied response pattern probabilities. By analogy, let a $C \times 1$ vector π contain the true response pattern probabilities. The observed proportions p_y can be collected into a $C \times 1$ vector $\mathbf{p}$ as well. For example, for three dichotomously items, there are $2^3 = 8$ item response patterns, and the response pattern probabilities and observed proportions are

$$\pi = \begin{pmatrix} \pi_{000} \\ \pi_{001} \\ \pi_{010} \\ \pi_{011} \\ \pi_{100} \\ \pi_{101} \\ \pi_{110} \\ \pi_{111} \end{pmatrix}, \quad \hat{\pi} = \begin{pmatrix} \hat{\pi}_{000} \\ \hat{\pi}_{001} \\ \hat{\pi}_{010} \\ \hat{\pi}_{011} \\ \hat{\pi}_{100} \\ \hat{\pi}_{101} \\ \hat{\pi}_{110} \\ \hat{\pi}_{111} \end{pmatrix} = \begin{pmatrix} \pi_{000}(\hat{\omega}) \\ \pi_{001}(\hat{\omega}) \\ \pi_{010}(\hat{\omega}) \\ \pi_{011}(\hat{\omega}) \\ \pi_{100}(\hat{\omega}) \\ \pi_{101}(\hat{\omega}) \\ \pi_{110}(\hat{\omega}) \\ \pi_{111}(\hat{\omega}) \end{pmatrix}, \quad \mathbf{p} = \begin{pmatrix} p_{000} \\ p_{001} \\ p_{010} \\ p_{011} \\ p_{100} \\ p_{101} \\ p_{110} \\ p_{111} \end{pmatrix}. \quad (62)$$

Distribution of Residuals

Based on standard results from discrete multivariate analysis (Bishop et al., 1975), the maximum likelihood estimator $\hat{\omega}$ is consistent, asymptotically d -variate normal, and asymptotically efficient, which can be summarized as follows:

$$\sqrt{N}(\hat{\omega} - \omega) \xrightarrow{D} \text{MVN}(0, \mathcal{F}^{-1}), \quad (63)$$

where the notation $\xrightarrow{D}$ denotes convergence in distribution and $\mathcal{F} = \Delta [\text{diag}(\pi)]^{-1} \Delta$ is the $d \times d$ Fisher information matrix, with the Jacobian

matrix Δ defined as the $C \times d$ matrix of all first-order partial derivatives of the response patterns probabilities with respect to the item parameters, where d is the size of ω :

$$\Delta = \frac{\partial \pi(\omega)}{\partial \omega'}. \quad (64)$$

Given Equation 63, it can be shown that the asymptotic distribution of $(\mathbf{p} - \boldsymbol{\pi})$ is C-variate normal:

$$\sqrt{N}(\mathbf{p} - \boldsymbol{\pi}) \xrightarrow{D} MVN(\mathbf{0}, \Xi), \quad (65)$$

where $\Xi = \text{diag}(\boldsymbol{\pi}) - \boldsymbol{\pi}\boldsymbol{\pi}'$ is the multinomial covariance matrix associated with the multinomial distribution (Equation 61). Applying asymptotic distribution theory once again (see, e.g., Cai et al., 2006), the multinomial residual vector $(\mathbf{p} - \hat{\boldsymbol{\pi}})$ is asymptotically C-variate normal:

$$\sqrt{N}(\mathbf{p} - \hat{\boldsymbol{\pi}}) \xrightarrow{D} MVN\left(\mathbf{0}, \Xi - \Delta \mathcal{F}^{-1} \Delta'\right). \quad (66)$$

Lower Order Marginal Probabilities and Reduction Operators

From Equation 66, one of the key insights is that the multinomial residuals themselves may be combined with linear reduction operator matrices to obtain model-implied marginal (or other reduced) probability summaries that can be tailored to address specific model fit evaluation questions in educational assessment research. We will explain these reduction operators with several examples.

Consider the three-item example from Equation 62. There are three first-order marginal probabilities $\dot{\pi}_i$ ($i = 1, \dots, 3$), one per item. There are also three second-order marginal probabilities $\ddot{\pi}_{ij}$ for the unique item pairs ($1 \leq j < i \leq 3$). In general, these probabilities correspond to the n univariate and $n(n-1)/2$ bivariate margins that can be obtained from the full C-dimensional contingency table using a reduction operator matrix (see, e.g., Maydeu-Olivares & Joe, 2005). An example is given here:

$$\hat{\boldsymbol{\pi}}_2 = \begin{pmatrix} \dot{\pi}_1 \\ \dot{\pi}_2 \\ \dot{\pi}_3 \\ \ddot{\pi}_{21} \\ \ddot{\pi}_{31} \\ \ddot{\pi}_{32} \end{pmatrix} = \mathbf{L} \hat{\boldsymbol{\pi}} = \begin{pmatrix} 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \hat{\pi}_{000} \\ \hat{\pi}_{001} \\ \hat{\pi}_{010} \\ \hat{\pi}_{011} \\ \hat{\pi}_{100} \\ \hat{\pi}_{101} \\ \hat{\pi}_{110} \\ \hat{\pi}_{111} \end{pmatrix}, \quad (67)$$

where $\mathbf{L}$ is a fixed operator matrix of 0's and 1's that reduces the response pattern probabilities and proportions into marginal probabilities and proportions up to order 2. $\hat{\pi}_2$ is the vector of first- and second-order marginal probabilities. Correspondingly, $\mathbf{p}_2 = \mathbf{L}\mathbf{p}$ is the vector of first- and second-order observed marginal proportions.

The choice of focusing on the lower order margins is not accidental. As the number of observed variables increases, the number of response patterns increases exponentially. For more than a dozen or so dichotomous variables, the contingency table on which the multinomial is defined becomes sparse for any realistic N . This is known as the sparseness problem in discrete multivariate analysis (see, e.g., Bartholomew & Tzamourani, 1999). Compared with the full multinomial, the lower order margins are significantly better filled under moderate sample size and realistically long educational assessments. Test statistics using marginal probabilities can be significantly more powerful (Cai & Hansen, 2013). Estimation of key parameters in popular models such as IRT models also draw information primarily from the first- and second-order margins. In addition, the second-order marginal residuals contain information about conditional independence, which is critical to model building, as discussed earlier.

More general versions of the reduction operator matrices for models with multiple categorical discrete outcomes can be derived similarly (see, e.g., Cai & Hansen, 2013; Maydeu-Olivares & Joe, 2006). Note that $\mathbf{L}$ has full row rank. It implies that the marginal residual vector $(\mathbf{p}_2 - \hat{\pi}_2) = \mathbf{L}(\mathbf{p} - \hat{\pi})$ is a full-rank linear transformation of the multinomial residual vector $(\mathbf{p} - \hat{\pi})$. Therefore, the marginal residual vector $(\mathbf{p}_2 - \hat{\pi}_2)$ is asymptotically normal:

$$\sqrt{N}(\mathbf{p}_2 - \hat{\pi}_2) = \sqrt{N}\mathbf{L}(\mathbf{p} - \hat{\pi}) \xrightarrow{D} MVN(0, \Xi_2 - \Delta_2 \mathcal{F}^{-1} \Delta_2'), \quad (68)$$

where $\Xi_2 = \mathbf{L}\Xi\mathbf{L}'$, and $\Delta_2 = \mathbf{L}\Delta$ is the Jacobian for the marginal probabilities up to order 2. The dimensionality of the normal random variable is equal to the number of first- and second-order marginal residuals. For example, in the case of dichotomous items, the number is $n(n+1)/2$.

Equation 68 has led to a number of mathematically rigorous model fit indices with known distributional properties. These include limited-information test statistics and additional derived indices for item factor models, hierarchical model, and DCMs (e.g., Hansen et al., 2016; Monroe & Cai, 2015), covering a large segment of the models presented in Table 10.1. Rigorous distribution theory for stepdown tests such as W. H. Chen and Thissen's (1997) local dependence (LD) X^2 that focus on diagnosing the sources of model misfit have also been developed (e.g., Edwards et al., 2018; Liu & Maydeu-Olivares, 2013).

In addition to these statistics, other reduction operator matrices may lead to further refined procedures that target latent variable distribution assumptions (e.g., Li & Cai, 2018) and item-level fit (Orlando & Thissen, 2000). Consider a test with n items and C_i categories for item i . There are $S = 1 + \sum_{i=1}^n (C_i - 1)$ summed scores ranging from 0 to $S - 1$. Suppose the observed summed probabilities based on a sample of size N are equal

to $\bar{p}_s$ for $s = 0, \dots, S-1$. Under maximum likelihood estimation of item parameters, the corresponding model-implied summed score probabilities are formally defined as

$$\bar{\pi}_s = \sum_y 1_s(\|\mathbf{y}\|) \hat{\pi}_y, \quad (69)$$

where $\|\mathbf{y}\| = \sum_{i=1}^n y_i$ is the summed score associated with response pattern $\mathbf{y}$ and the indicator function takes a value of 1 if and only if $s = \|\mathbf{y}\|$, that is,

$$1_s(\|\mathbf{y}\|) = \begin{cases} 1, & \text{if } s = \|\mathbf{y}\| \\ 0, & \text{otherwise} \end{cases}. \quad (70)$$

Equation 70 shows that the model-implied probability for summed score s is a sum over all such response pattern probabilities leading to summed score s ; in other words, it may also be obtained by a reduction operator matrix.

Let $\mathbf{S}$ be this reduction operator matrix. It is a matrix of 0's and 1's such that the premultiplication of $\boldsymbol{\pi}$ by $\mathbf{S}$ yields the summed score probabilities. Each row of $\mathbf{S}$ can be understood as a set of binary logical relations. An element in row j of $\mathbf{S}$ is equal to 1 if and only if the corresponding response pattern in $\boldsymbol{\pi}$ leads to summed score $j-1$. In particular, $\mathbf{S}$ has full row rank and the rows of $\mathbf{S}$ are mutually orthogonal.

Let us return to the three-item example mentioned previously. There are four summed scores in this case: 0, 1, 2, and 3. The 4×8 matrix $\mathbf{S}$ (below) relates the summed score probabilities to the original multinomial probabilities:

$$\bar{\boldsymbol{\pi}} = \begin{pmatrix} \bar{\pi}_0 \\ \bar{\pi}_1 \\ \bar{\pi}_2 \\ \bar{\pi}_3 \end{pmatrix} = \mathbf{S} \boldsymbol{\pi} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \pi_{000} \\ \pi_{001} \\ \pi_{010} \\ \pi_{011} \\ \pi_{100} \\ \pi_{101} \\ \pi_{110} \\ \pi_{111} \end{pmatrix}, \quad \hat{\boldsymbol{\pi}} = \begin{pmatrix} \hat{\pi}_0 \\ \hat{\pi}_1 \\ \hat{\pi}_2 \\ \hat{\pi}_3 \end{pmatrix} = \mathbf{S} \hat{\boldsymbol{\pi}}. \quad (71)$$

The observed summed score proportions can be obtained in a similar way by multiplying the reduction operator with the vector of observed proportions for each response pattern:

$$\bar{\mathbf{p}} = \begin{pmatrix} \bar{p}_0 \\ \bar{p}_1 \\ \bar{p}_2 \\ \bar{p}_3 \end{pmatrix} = \mathbf{S} \mathbf{p} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} p_{000} \\ p_{001} \\ p_{010} \\ p_{011} \\ p_{100} \\ p_{101} \\ p_{110} \\ p_{111} \end{pmatrix}. \quad (72)$$

The summed score residual vector $\bar{\mathbf{p}} - \hat{\bar{\boldsymbol{\pi}}}$ is asymptotically S-variate normally distributed, assuming maximum likelihood estimation of the parameters in the model:

$$\sqrt{N}(\bar{\mathbf{p}} - \hat{\bar{\boldsymbol{\pi}}}) = \sqrt{N}\mathbf{S}(\mathbf{p} - \hat{\boldsymbol{\pi}}) \xrightarrow{D} MVN(0, \bar{\boldsymbol{\Xi}} - \bar{\Delta}\mathcal{F}^{-1}\bar{\Delta}'), \quad (73)$$

where $\bar{\boldsymbol{\Xi}} = \mathbf{S}\boldsymbol{\Xi}\mathbf{S}' = \mathbf{S}(\text{diag}(\boldsymbol{\pi}) - \boldsymbol{\pi}\boldsymbol{\pi}')\mathbf{S}' = \text{diag}(\bar{\boldsymbol{\pi}}) - \bar{\boldsymbol{\pi}}\bar{\boldsymbol{\pi}}'$, and $\bar{\Delta} = \mathbf{S}\Delta$ can be understood as the Jacobian for the summed score probability vector. Pragmatically, the Lord-Wingersky (Lord & Wingersky, 1984) algorithm, already popular in IRT analysis and test scoring, could be used to compute the model-implied summed score probabilities (see Thissen & Wainer, 2001) or any further decompositions to target item-specific model fit (see Orlando & Thissen, 2000).

Overall Fit Measures

The foregoing technical discussion highlights the fact that the multinomial residual vector and its linearly reduced variants have well-defined distributional properties. Therefore, they can inform the development of overall fit measures that differ from the traditional approach in the analysis of categorical data such as likelihood ratio G^2 and Pearson's X^2 . On the one hand, these traditional statistics, often called full-information statistics, use residuals based on the full response pattern cross-classifications to test the specified model against the general multinomial alternative:

$$G^2 = 2N \sum_y p_y \log \frac{p_y}{\hat{\pi}_y}, \quad X^2 = N \sum_y \frac{(p_y - \hat{\pi}_y)^2}{\hat{\pi}_y}. \quad (74)$$

Under the null hypothesis that the model fits exactly, these two statistics have the same asymptotic reference distribution, which is a central chi-square with degrees of freedom equal to $C - 1 - d$ (Bishop et al., 1975), when N is large relative to C , which is almost never true in the applications of these models to educational assessment data (Bartholomew & Tzamourani, 1999).

On the other hand, limited-information model fit statistics (e.g., Maydeu-Olivares & Joe, 2005) have become arguably one of the most thoroughly discussed and theoretically understood development in model fit evaluation for discrete multivariate data. As the name suggests, limited-information statistics rely on the linear reduction operators discussed earlier to reduce the multinomial containing full information into distinct summary probabilities.

One class of limited-information fit statistics use residuals based on lower order (e.g., first- and second-order) margins of the contingency table (Cai et al., 2006; Joe & Maydeu-Olivares, 2010). The most prominent member is M_2 . Under the assumption that the number of first- and second-order margins is larger than the number of free parameters d and that Δ_2 has full column rank (local identification), M_2 can be written as

$$M_2 = N(\mathbf{p}_2 - \hat{\boldsymbol{\pi}}_2)' \tilde{\Delta}_2 [\tilde{\Delta}_2' \boldsymbol{\Xi}_2 \tilde{\Delta}_2]^{-1} \tilde{\Delta}_2' (\mathbf{p}_2 - \hat{\boldsymbol{\pi}}_2), \quad (75)$$

where $\tilde{\Delta}_2$ is an orthogonal complement of Δ_2 such that $\tilde{\Delta}_2' \Delta_2 = \mathbf{0}$. From Equation 68, $(\mathbf{p}_2 - \hat{\boldsymbol{\pi}}_2)$ is asymptotically normal with zero means and covariance matrix $\boldsymbol{\Xi}_2 - \Delta_2 \mathcal{F}^{-1} \Delta_2'$, which implies that the covariance matrix of $\tilde{\Delta}_2' (\mathbf{p}_2 - \hat{\boldsymbol{\pi}}_2)$ is $\tilde{\Delta}_2' \boldsymbol{\Xi}_2 \tilde{\Delta}_2$. Thus, M_2 (for dichotomous data) is asymptotically chi-square distributed with degrees of freedom equal to $n(n+1)/2 - d$. Polytomous versions of the statistic have also been proposed (see, e.g., Cai & Hansen, 2013). The well-established distribution theory of M_2 has also facilitated the derivation of the sample size-independent RMSEA (Maydeu-Olivares & Joe, 2014). Other M_2 -inspired fit indices include the TLI for IRT (Cai et al., 2021).

Beyond Frequentist Model Evaluation in Models for Discrete Data

The new overall model fit statistics described above are technically superior to traditional ones in terms of better decision error rates and statistical power. But perhaps the most intriguing prospect that they offer is the possibility of using our now significantly more refined understanding of the relative sensitivity of each of the pieces to modeling assumption violations, (e.g., first-order margins, second-order margins, summed scores, item-specific summed scores) to help construct statistics that can incorporate principles of model evaluation that are not classical frequency based.

Bayesian Posterior Predictive Checks

In educational measurement, Bayesian posterior predictive model checking (Gelman et al., 1996) is a relatively well-understood tool now thanks to important earlier contributions that examined a number of indices (several based on margins and summed scores) that could serve as the so-called discrepancy measures or test quantities (Levy et al., 2009; Sinharay et al., 2006). In Bayesian posterior predictive model checking, one would need to be able to characterize the entire posterior distribution of all the parameters, for example, with random samples drawn from the posterior. For each random parameter value, we apply the discrepancy measure to the observed data set, yielding the “realized” discrepancies. For each random parameter value, a replicate (plausible) data set can also be produced from the likelihood function. A discrepancy measure may be computed on this replicate data set—the “predictive” discrepancy. The process is typically repeated hundreds, if not thousands, of times in a Monte Carlo simulation, after fitting the model. Plots or numerical summaries of the bivariate distribution of the realized versus predictive discrepancy measures can lead to graphical model fit diagnosis or a Bayesian p value that can help guide model choice.

As an example, Levy et al. (2009) studied a number of discrepancy measures for dimensionality analysis in IRT modeling. These discrepancy measures use information

contained in the item-by-item bivariate distribution to help diagnose the lack of conditional independence. If we were interested in other aspects of model fit, we could choose a different set of discrepancy measures. This point highlights the practically most important aspect of the posterior predictive model-checking procedure. Namely, it can be entirely driven by the needs of the researcher in a particular situation, and there is also no requirement to derive a distribution theory for the discrepancy measures involved. The major contingency is that the model must be estimated with Bayesian parameter estimation approaches. More recently, Lee et al. (2016) proposed approximate procedures inspired by Bayesian posterior predictive model checking but used with standard maximum marginal likelihood estimation. They proposed to replace the samples from the posterior with samples from approximations to the posterior. Kuhfeld (2019) showed that the procedure appears to have performance that is comparable to the original Bayesian procedure while offering additional flexibility.

Information Theory–Based Fitting Propensity Analysis

As a further move beyond frequentist and Bayesian model evaluation techniques, we should address the issue of a model's inherent tendency to fit well to a large number of possible data patterns. This is prominent in the critique against standard goodness-of-fit testing (see S. Roberts & Pashler, 2000, 2002). If the researcher's model is able to fit many possible data patterns well, its excellent fit to a particular data set perhaps offers little evidence in support of substantive theory that led to the model in the first place. Preacher (2006) called this phenomenon the *fitting propensity* (FP) of a model. He also demonstrated that FP not only is a function of the number of parameters (as is customarily intuited), but also is directly related to a model's functional form (i.e., how the parameters are configured in the model's equations). Thus, two models with the same number of free parameters may exhibit wildly different FP.

In earlier literature, FP was also called model *complexity*. Myung and Pitt (1997) defined complexity as "the flexibility inherent in a model that enables it to fit diverse patterns of data" (p. 80). This concept is best captured in the information-theoretic discussions around the minimum description length (Grünwald, 2007; Rissanen, 2007) principle. In the sense of information theory, a statistical model encodes the data as its input. Different models encode data differently. Hence, even for models having an identical number of parameters, if the functional forms of the models are different, the models' FP (or complexity) will be different. Importantly, this is not due to the features of a sample; the difference is attributable to the features of the models under consideration.

To investigate complexity, Bonifay and Cai (2017) fitted a series of latent variable models with an identical number of parameters (but different functional forms in terms of the item-level model involved, nature of latent variables, and constraints on parameters) to randomly generated data uniformly distributed over the space of all possible data sets that can be fit by those models. Replicating Preacher's (2006) results for linear covariance structure models, they found that certain models, such as item exploratory factor analysis and item bifactor models, tend to fit random data sets far better than others.

The concept of model complexity is philosophically and practically important for the statistical modelers and should be considered in conjunction with model fit. When a model fits the data set well, and when the model replicates in other independent holdout samples, it could very well be the case that it is because the model is more complex. That is, such a model naturally fits a large portion of possible data sets. In the language of Popperian philosophy of science, models are mathematical embodiments of theories. On the one hand, a less complex model can make a specific prediction that is more likely falsified in the empirical setting. A more complex model, on the other hand, while doing a good job explaining the observed variations, is less likely to be falsified. As per Occam's razor, one should generally prefer the more falsifiable model.

Concluding Thoughts on Model Fit

Since the publication of the last edition of *Educational Measurement*, substantial progress has been made on the topic of model fit evaluation. We now have access to more accurate limited-information model fit statistics, useful and practical fit indices such as RMSEA and TLI that borrow from concepts developed out of structural equation modeling, and Bayesian posterior predictive model fit checking procedures. We also know, through FP analyses reported in the literature, that some models may have inherently better FP than other models, all else being equal. This suggests that in empirical data analysis measurement researchers should hopefully use a range of possible fit measures that can provide information about different aspects of model fit. The purpose of the analysis and the use of the model's output should be factored into the choices of models. Whenever possible, researchers should not rely on a single model because alternative models may offer additional explanations.

EMPIRICAL EXAMPLE 1

In the first empirical example, we analyze a data set collected from a large-scale randomized, controlled, multisite trial of a math intervention with pre and post measures to illustrate issues around model building, model selection, and fit appraisal. We begin with simpler methods, such as sum scoring and descriptive statistics, followed by applications of more modern methods that make effective use of item-level data and its structure. The goal of our analyses is to illustrate the modeling options and approaches we discussed earlier. We also hope that by providing a more detailed report of our model-building process than typical, the readers could appreciate the decisions involved in statistical modeling of assessment data with realistic degrees of design complexity.

Data Source

The data come from a multisite trial containing item responses collected from 1,664 individuals in 31 treatment classrooms and 29 control classrooms in 23 schools, along with information on school membership and random assignment status (Chung et al., 2014). The original intent was to determine each classroom's assignment (treatment vs. control) randomly within each school. This was complicated by a lack of

consistent implementation or compliance across sites. Some schools would prefer all the classrooms to be in the treatment condition. Many schools have only a single pair of treatment and control classrooms. As such, classroom-level differences are not the main focus of this analysis. Instead, we see the design offering a substantial amount of information regarding treatment effect variations across sites, in addition to the overall statement of the average treatment effect. The control and treatment conditions have 813 and 851 individuals, respectively. The item responses are based on 10 dichotomously scored (0 or 1) items targeting concepts of fractions, such as identifying fractions in the context of a number line and adding fractions. All items are administered at both pretest and posttest. Of the 10 items, 1 is a multiple-choice item with four response options, and the other 9 are fill-in-the-blank items. Figure 10.1 shows 7 of the 10 items used.

Item description	Example(s)
Adding two fractions (the fraction does not need to be simplified)	$\frac{2}{7} + \frac{1}{7} = \frac{\boxed{}}{\boxed{}}$ $\frac{2}{5} + \frac{3}{10} = \frac{\boxed{}}{\boxed{}}$
At what number is the “?” located?	 
	How far is the puppet from its home? 
Fractional parts of a whole unit	The shaded part of the block below shows $\frac{1}{3}$ of a whole unit. Mark where $\frac{1}{6}$ of a whole unit is. 
	What does the bottom number (4) tell you in $\frac{3}{4}$?
Understand the denominator	a. It tells you there are four fourths in this fraction b. It tells you the whole unit is broken into four pieces c. It tells you there are four whole units in this fraction d. It tells you to add 3 four times

FIGURE 10.1
Example Items Used in Analyses

Summed Score Approach

Summed scoring is the most widely used method for scoring outcome measures, given its simplicity and connection to the classical summed score–based test theory in the social and behavioral sciences (Bauer & Curran, 2015; Curran et al., 2008). Albeit a straightforward method, summed scoring has several limitations when used in randomized multisite studies. The summed score disregards differences in item characteristics (e.g., item difficulty and discrimination), as if each item has the same relationship to the construct being measured. Multiple summed scores become less comparable when the number of items differs between tests or time points because of the study design or missing responses. Past research has also noted other issues and nuances of sum scoring with respect to scoring and scale validity (McNeish & Wolf, 2020) and the multidimensional nature of longitudinal item response data (Cai, 2010a; Cai, Choi, et al., 2016).

Despite these problems, we begin with summed scoring as a baseline for pedagogical purposes. Table 10.2 shows the means and standard deviations of the summed scores of the outcome measure by treatment assignment conditions and occasion (pretest or posttest). The treatment groups are similar at pretest, in terms of both the group means and their standard deviations. There is also a noticeable difference in the change from the pretest to posttest means across conditions. Also as expected, we notice that the variability of the outcome measure increased slightly from pretest to posttest, perhaps more so for the treatment condition.

To break things down further, we can visualize the means and standard deviations of pretest and posttest summed scores by schools and conditions (Figure 10.2). For schools with both control and treatment conditions, most had between-condition differences at pretest falling within one point. There was also variability across schools in mean scores and pre–post changes.

To account for such variations across schools, one approach is to employ the traditional HLM (Raudenbush & Bryk, 2002), which is widely used to estimate the treatment effect in multisite evaluation studies. With a standard two-level model, we specify the Level 1 (within-site) and Level 2 (between-site) equations as follows:

$$y_{ij} = \beta_{0j} + \beta_{1j} * Trt_{ij} + \beta_{2j} * Pre_{ij} + \varepsilon_{ij}, \varepsilon_{ij} \sim N(0, \sigma^2)$$

Table 10.2 Descriptive Statistics of Sum Scores of Pretest and Posttest by Condition

Condition	Time	<i>M</i>	<i>SD</i>
Control (<i>n</i> = 813)	Pretest	4.36	2.73
	Posttest	4.42	2.96
Treatment (<i>n</i> = 851)	Pretest	4.39	2.74
	Posttest	5.02	3.13

Note. Minimum possible value is 0; maximum possible value is 10.

**FIGURE 10.2****Descriptive Statistics of Pretest and Posttest Sum Scores by Schools and Conditions**

Note. The points indicate means and the lines cover the interval of [mean—standard deviation, mean + standard deviation]

$$\begin{aligned}\beta_{0j} &= \gamma_{00} + u_{0j}, u_{0j} \sim N(0, \tau_{00}) \\ \beta_{1j} &= \gamma_{10} + u_{1j}, u_{1j} \sim N(0, \tau_{11}) \\ \beta_{2j} &= \gamma_{20} + u_{2j}, u_{2j} \sim N(0, \tau_{22})\end{aligned}$$

Here, y_{ij} denotes the outcome variable, that is, the observed posttest summed score from individual i in school j . The pretest summed score Pre_{ij} is school-mean centered and included as a covariate. The treatment indicator variable Trt_{ij} takes a value of -0.5 for the control condition or 0.5 for the treatment condition within each school j . This coding scheme allows β_{0j} to represent the mean posttest summed score for school j and β_{1j} to represent the expected difference in posttest summed score between the two conditions in school j after holding pretest constant.

Table 10.3 presents the HLM results. After controlling for pretest differences, the overall treatment impact ($\hat{\gamma}_{10}$) is 0.59 ($SE = 0.24$). Given that the pooled standard deviation of posttest is roughly 3.08 , we can convert the unstandardized regression coefficient into a standardized estimated effect size (Cohen's $d = 0.59/3.08 = 0.19$) to facilitate comparisons with later analyses.

Item Analysis With Pretest Items

We now turn to item analysis, an important step leading up to the analysis of outcome measures with more refined methods. One key purpose of item analysis is to identify the structure of the item response data—that is, dimensionality evaluation—through which we also address issues of model building, model selection, and fit appraisal. For example, we may want to know whether a set of items represents a single construct or multiple nontrivial ones. In the context of an IRT analysis, we may be concerned with

Table 10.3 Hierarchical Linear Model Results Based on Test Sum Scores

	Model 1: Unconditional			Model 2: Pretest as Covariate		
Fixed Effects	Estimate	SE	p	Estimate	SE	p
Intercept (γ_{00})	4.63	0.24	< .001	4.68	0.23	< .001
Treatment (γ_{10})	0.70	0.33	.036	0.59	0.24	.013
Pretest (γ_{20})				0.70	0.03	< .001
Variance components						
σ^2	2.85			2.21		
τ_{00}	1.05			1.10		
τ_{11}	1.52			0.77		
τ_{22}				0.01		
Log-likelihood	−4142.17			−3722.85		
Akaike information criterion	8296.34			7465.69		
Bayesian information criterion	8328.84			7519.86		

Note. All fixed regression coefficients and the variance components are estimated directly using maximum likelihood.

whether a unidimensional IRT model provides acceptable fit to the item data or if a MIRT model should be used instead. In addition to dimensionality assessment, item analysis provides information on the quality and performance of test items and adds validity evidence to score interpretations.

In what follows, we conduct item analysis on the students' responses to 10 items at pretest with progressively more complex methods discussed in earlier sections, ranging from classical summed score-based statistics, to IRT models, to bifactor models, to DCMs. We use the pretest item responses to show key components of the item analysis before addressing the longitudinal aspects of the example. As shown in Figure 10.1, items used in this example appear to address multiple subskills or concepts within the broader concept of fractions knowledge. However, we will start with unidimensional approaches to underscore the consequences of overlooking design insights and dimensionality and to explore methods for evaluating dimensionality. All models demonstrated for item analysis are estimated in flexMIRT 3.65 (Cai, 2022) using the Bock–Aikin EM algorithm with standard errors (SEs) estimated via the Richardson extrapolation method (e.g., Jamshidian & Jennrich, 2000).

Classical Item Statistics

Table 10.4 presents the classical item statistics—means and standard deviations of item score, correlations between item score and total score, and coefficient

Table 10.4 Classical Item Statistics

Item	Item Score		Item-Total Correlation	Alpha if Deleted
	<i>M</i>	<i>SD</i>		
1	.84	.36	.33	.78
2	.50	.50	.63	.74
3	.48	.50	.61	.74
4	.26	.44	.50	.76
5	.29	.45	.33	.78
6	.24	.42	.48	.76
7	.56	.50	.56	.75
8	.19	.39	.41	.77
9	.66	.47	.43	.77
10	.58	.49	.26	.79

Note. The overall coefficient alpha is .78.

alphas—computed for the listwise-complete data ($n = 1,473$). In general, it is useful to conduct and document these summaries. They often reveal features of the data that should be considered in more complex modeling that is to follow. Because all items are dichotomously scored, the mean value (M) is the proportion of individuals that correctly answered the item and hence is tied to the difficulty of the item. In this case, the hardest and the easiest items appear to be Item 8 ($M = 0.19$) and Item 1 ($M = 0.84$), respectively. The point-biserial item-total correlation compares an item score to the total score from an individual. The size of an item-total correlation provides information on how well an item differentiates between high-performing and low-performing individuals. For example, Item 2 has the highest correlation (.63), while Item 10 has the lowest correlation (.26). Together with the estimates of difficulty, the summaries suggest that the items have a reasonable chance of surviving further scrutiny under more complex models such as IRT.

Unidimensional IRT Model

Moving to the IRT paradigm, we start with a unidimensional IRT model that assumes conditional independence of the items on a single latent factor. Note that fitting a unidimensional model to multidimensional data ignores the dependencies among items forming clusters and will result in distorted estimates of factor loadings, or equivalently, item discrimination parameters (Reise et al., 2007; Steinberg & Thissen, 1996). We may also find signs of misfit based on item fit and model fit statistics.

Of the 10 items, the first 9 were modeled using the 2PL model (Equation 7), in which items varied in their intercept and slope (or discrimination). The last item, a multiple-choice item with four response options, was modeled using the 3PL model (Equation 10) with the lower asymptote parameter (or, equivalently, the pseudo-guessing

parameter) to account for the possibility of guessing. A normal prior distribution $N(-1.1, 0.5)$ was imposed on the *logit* of this parameter. The prior mean of -1.1 yields a prior mode around 0.25 for the $(0-1)$ pseudo-guessing probability. The standard deviation of 0.5 allows for a sufficiently diffuse prior, permitting the estimated pseudo-guessing parameter to move away from the prior mean as needed (e.g., Houts & Cai, 2022, p. 21). Last, the mean of the latent factor was fixed at 0 and its variance was fixed at 1. With this specification, there were $9 \times 2 = 18$ item parameters associated with the 2PL model, $1 \times 3 = 3$ item parameters associated with the 3PL model, and a total of $18 + 3 = 21$ model parameters to be estimated.

Table 10.5 presents the item intercept and slope estimates, as well as the converted factor loading parameters for the 10 pretest items using formulae under Equation 6. Table 10.5 shows a clear variation in the estimated item slopes and factor loadings. In particular, the first 4 items, highlighted in gray, had much higher loadings than the remaining 6 items, thereby potentially “stealing” or pulling the latent factor toward the cluster defined by these 4 items, leaving the underlying latent factor a significantly less important predictor of student performance on the remaining 6 items. Examining the content of the items, the first 4 items and the remaining items indeed appear to form two distinct clusters. In such a situation, it may be inappropriate to assume that the assessment data are unidimensional, making results using summed score-based or unidimensional IRT less desirable or informative.

Hopefully by now it is clear why the analyst’s choices should be informed by the design of assessments. Items presented in Figure 10.1 suggest that the items were designed with multiple subskills or concepts in mind. Items 1–4 targeted the concept of adding fractions, Items 5–9 targeted the concept of identifying fractions in the context of a number line, and Item 10 targeted the concept of understanding the meaning of the

Table 10.5 Unidimensional Item Response Theory Model Item Parameters

Item	Intercept (SE)	Slope (SE)	Loading (SE)
1	2.57 (0.19)	1.83 (0.20)	0.73 (0.06)
2	−0.15 (0.28)	8.70 (1.38)	0.98 (0.01)
3	−0.50 (0.20)	5.77 (0.56)	0.96 (0.01)
4	−2.07 (0.19)	2.69 (0.27)	0.84 (0.04)
5	−1.01 (0.07)	0.73 (0.08)	0.39 (0.06)
6	−1.54 (0.09)	1.27 (0.11)	0.60 (0.06)
7	0.29 (0.08)	1.30 (0.11)	0.61 (0.05)
8	−1.82 (0.10)	1.16 (0.11)	0.56 (0.06)
9	0.83 (0.08)	1.03 (0.10)	0.52 (0.06)
10	−0.11 (0.24)	0.66 (0.12)	0.36 (0.10)

Note. SE = standard error.

denominator. Had the item developers designed the items with only one type of skill in mind, such as adding two fractions with equal denominators, dimensionality issues might not be as dramatic as what we observed.

As further illustrations of their potential value, model fit indices also shed light on the presence of item clusters and data multidimensionality. Table 10.6 shows the item-specific marginal chi-square statistics based on the observed versus expected first-order margins and the LD X^2 indices of W. H. Chen and Thissen (1997) that provide pairwise diagnostic information on possible LD and its directionality. Notice that all of these values are based on the reduction operations introduced earlier (see Equation 67 and surrounding definitions). The LD X^2 values have been standardized with the expected chi-square mean and standard deviation for the ease of interpretation. Each of the first-order marginal chi-square values may be tested against a chi-square variable with one degree of freedom to examine item fit at the level of univariate margins. For each item pair, as suggested by Houts and Cai (2022), the standardized LD X^2 indices can be checked against a threshold (e.g., 3.0) for potential LD. The letter “p” is a convenience that standard IRT software tools now routinely offer. It indicates positive LD, where the observed pairwise association is higher than the model-implied association. The letter “n” indicates negative LD, where the observed association is lower than the model-implied association. As seen in Table 10.5, Items 5–10 showed an unusually high amount of LD in the positive direction. This is consistent with our earlier observation: that the current single latent factor cannot explain all the item-by-item associations among Items 5–10.

Before moving on to another model, we used the limited-information fit statistics M_2 to gauge overall fit: $M_2(34) = 1070.94(p < .001)$, $RMSEA = 0.14$. Recall that M_2 statistic (Equation 36) is computed using univariate and bivariate marginal residuals and is asymptotically chi-square distributed under the null hypothesis of exact model fit (Maydeu-Olivares & Joe, 2005). As noted earlier, on the one hand, exact fit may be

Table 10.6 Unidimensional Item Response Theory Model: Marginal X^2 and Standardized Local Dependence X^2 Statistics

Item	Marginal Chi-Square	1	2	3	4	5	6	7	8	9
1	0.0									
2	0.3	5.5p								
3	0.2	6.4p	2.7p							
4	0.0	2.6p	4.1p	−0.1p						
5	0.0	2.3n	0.9n	4.9n	1.8n					
6	0.0	2.3n	5.6n	7.9n	−0.3n	26.4p				
7	0.0	5.8n	9.2n	5.3n	2.0n	20.8p	38.7p			
8	0.0	4.9n	4.2n	4.5n	2.1n	20.6p	31.7p	31.9p		
9	0.0	5.3n	6.0n	3.9n	0.6n	5.4p	15.7p	137.7p	14.4p	
10	0.0	−0.4n	1.1n	2.5n	−0.7n	12.3p	12.4p	12.6p	4.3p	−0.4p

implausibly strict, and under a large sample such as the situation here, the chi-square will be significant even for very small amount of model error. RMSEA, on the other hand, is a fit measure that takes the influence of sample size into account. We rejected the unidimensional model on an absolute basis, and RMSEA also signals poor fit based on findings reported by Monroe and Cai (2015).

The empirical evidence so far does not support the use of a unidimensional IRT model. We now consider the following information prior to applying a MIRT model to address the lack of conditional independence: (a) all items are developed to measure a board common construct, the knowledge of fractions; and (b) Items 5–9 include number lines in their prompts, although their formats and specific knowledge specifications slightly differ. In this case, a bifactor IRT model could provide an appropriate representation of the item response structure. We now proceed to test that hypothesis.

Bifactor Model

Typically, a bifactor model has one *primary factor* representing the target construct and one or more conditionally orthogonal *specific factors*. These specific factors may represent (a) residual dependence not accounted for by the primary factor or (b) subdomains formed by item specifications (e.g., content, format). All items may load on a primary factor and at most one group/specific factor. When some items load only on the primary factor, some authors call the model an incomplete bifactor model (F. F. Chen et al., 2006). As mentioned earlier, Wainer et al.'s (2007) testlet model is formally nested within the bifactor model. This model adds only as many new parameters to the unidimensional model as there are group/specific factors, making it highly compact and more parsimonious than the general bifactor model. These group/specific factor variance components can also be interpreted as random intercepts for the specific items involved.

Recall that Items 1–4 and Items 5–10 form two clusters that might be distinct from each other. With this in mind, we set up an incomplete bifactor model with Items 1–4 loading on one extra factor specific to these 4 items and Items 5–10 loading on the primary factor only. This allows the general dimension to be defined by all the items, while permitting a group/specific factor to absorb residual dependence above and beyond the general factor. For computational stability, because there are only two clusters, the incomplete model can be substantially more stable than a model that has two group/specific factors. There are only two available clusters, so the choice of which specific cluster of items receives the influence of the group factor is a matter of indifference if one considers the variance decomposition of general versus group/specific factors. However, choosing to use the first 4 items to define a specific factor versus using Items 5–10 does make a difference in terms of the meaning of the general factor. In our case, we are removing any effect unique to Items 1–4 from the general dimension.

A 2PL item-level model was used for Items 1–9 (18 estimated item parameters), and a 3PL item-level model was used for Item 10 (3 estimated item parameters). We further placed testlet response theory-inspired constraints on the 2 item slopes for each of Items 1–4, making them equal within the item. For both the primary factor and one specific

factor, the means were fixed at 0. The variance of the primary factor was fixed at 1, while the variance of the specific factor was freely estimated. In total, there were $18 + 3 + 1 = 22$ freely estimated model parameters, one more than the unidimensional model.

With this constrained bifactor model, most of the factor loadings on the primary factor decreased relative to the factor loadings obtained from the unidimensional model. This was especially true for Items 1–4, of which the loadings ranged between 0.44 and 0.54 (cf. loading sizes of 0.73–0.98 in the unidimensional model). The variance of the specific factor was 2.19 ($SE = 0.29$), more than twice the fixed primary dimension variance of 1.0, indicating very strong excess correlation above and beyond the general factor.

Examining the model fit statistics in Table 10.7, -2 times the log-likelihood at convergence differed by hundreds as we transitioned from a unidimensional model to a constrained incomplete bifactor model, estimating one additional parameter (and losing a single degree of freedom). Other model fit statistics (RMSEA, TLI, Akaike information criterion/Bayesian information criterion) also improved in the same direction, strongly indicating the preference of the incomplete bifactor model over the unidimensional model. For example, the TLI is an incremental fit index based on the M_2 limited-information model fit statistics, with higher values generally indicative of better model fit. Cai et al. (2021) tentatively suggested that values above .96 indicate adequate model fit. The observed value is .99. Though not reported here, the standardized LD X^2 statistics also improve tremendously, and they no longer show any pattern of high LD.

Multilevel Bifactor Model

The multisite study data have a nested structure with individuals nested within sites (schools). Building on the results from bifactor models, we can apply a two-level bifactor model to the pretest item data, where a Level 2 random intercept latent factor is added to

Table 10.7 Model Fit Statistics: Unidimensional Item Response Theory Model Versus Bifactor Model

Statistics	Unidimensional IRT Model	Bifactor Model With One Specific Factor
No. parameters	21	22
$-2 \times \text{Log-likelihood}$	16,005.81	15,291.10
Akaike information criterion	16,047.81	15,335.10
Bayesian information criterion	16,161.56	15,454.27
M_2	1,070.94	83.81
Root-mean-square error approximation	0.14	0.03
Tucker–Lewis index	0.79	0.99

Note. Tucker–Lewis (nonnormed) fit index based on M_2 with the zero-factor null model.

account for any potential variation across schools. A total of 23 model parameters were estimated, including those outlined in the single-level bifactor model with one specific factor, and one additional parameter: 21 item parameters (held equal across levels), the variance of the specific factor, and the variance of the Level 2 factor. Results showed that the estimated variance of the Level 2 factor was 0.26. With the Level 1 (within-school) variance set to 1.00, the intraclass correlation is $0.26 / (1.00 + 0.26) = 0.21$, which suggests a nonnegligible amount of between-school variation. Model fit statistics on this two-level model are shown in Table 10.8. Comparing to those obtained from the incomplete bifactor model, the two-level bifactor model offers a further improvement in fit. It is also more consistent with the design of the overall study. We are, however, also aware that Bonifay and Cai (2017) suggested that the bifactor model may have a high degree of fitting propensity. Thus, the enthusiasm generated by the excellent model fit should perhaps be tempered because alternatives may also fit well.

Diagnostic Classification Model

We examine such an alternative model here. We consider a higher order DCM with discrete latent variables, specifically the DINA model. A core component of DCMs is the Q-matrix. If an item i requires a particular attribute k , the (i,k) th entry in the Q-matrix is 1, and 0 otherwise. In our case, there are 10 items and 5 attributes. The Q-matrix in Table 10.9 is specified based on the knowledge specifications (KS) that link each item with one or more of the five specifications listed here. These specifications were created prior to the actual writing of test items, based on an analysis of the content standards around fractions.

- KS1: Identical (common) units can be added to create a single numerical sum.
- KS2: Each whole unit or part of a whole unit (fractions) can be further broken into smaller, identical parts, if necessary.
- KS3: Positive nonintegers are represented by fractional parts of the interval between whole numbers.

Table 10.8 Model Fit Statistics: Single-Level Bifactor Model Versus Two-Level Bifactor Model

Statistics	Bifactor Model With One Specific Factor	Two-Level Bifactor Model
No. parameters	22	23
–2 Log-likelihood	15,290.05	15,149.81
Akaike information criterion	15,334.05	15,195.81
Bayesian information criterion	15,453.22	15,320.40

Note. Both models use the same bifactor representation with one primary factor and one specific factor; the difference lies in whether the model includes a Level 2 (between-school) latent variable.

Table 10.9 Q-Matrix Specified for Diagnostic Classification Models

Item	KS1	KS2	KS3	KS4	KS5
1	1	0	0	0	0
2	1	1	0	0	0
3	1	1	0	0	0
4	0	1	0	0	0
5	0	0	1	0	0
6	0	0	1	0	1
7	0	0	1	1	0
8	0	0	0	1	0
9	0	0	0	1	0
10	0	0	0	0	1

Note. KS = knowledge specification. Entries with 1 indicate that an item is linked to a given attribute.

- KS4: The size of a rational number is relative to how one whole unit is defined.
- KS5: The denominator of a fraction represents the number of identical parts in one whole unit. That is, if we break the one whole unit into “x” pieces, each piece will be “1/x” of the one whole unit.

One feature of DCMs is the classification of individuals’ attribute, knowledge, or skill mastery at a given time. Given five knowledge specifications, there are five latent attributes and $2^5 = 32$ possible mastery versus nonmastery patterns, termed *attribute profiles*. In using a DINA model, we are assuming that individuals must master all the attributes required by an item to answer that item correctly (the “and” gate). This is accomplished by setting the main effects to zero and estimating only the highest—in this case, second-order—attribute interaction terms for the items targeting more than one attribute, resulting in a total of eight possible inputs in the model: five main effects (KS1 to KS5) and three interaction terms (KS1–KS2, KS3–KS4, and KS3–KS5).

In Table 10.10, we present a subset of the estimated proportions of attribute profiles by conditions. Because we fitted the model on the pretest item data, differences in the estimated proportions between conditions would provide us another layer of assurance regarding the success of random assignment. For example, the percentages of individuals mastering all five attributes (Profile 11111) were 16.0% and 15.7% in the control and treatment conditions, respectively. Similarly, the percentages of individuals mastering none of the attributes (Profile 00000) were 4.7% and 6.1% in control and treatment conditions, respectively. Across all profiles, the mean absolute difference in the estimated proportions between the control and treatment conditions was approximately 0.02, which is quite small.

Model fit statistics of this DCM model, however, indicate worse fit than the bifactor model presented above: $M_2(29) = 227.63 (p < .001)$, RMSEA = 0.06. Inspection of item fit statistics showed higher LD between certain pairs of items, particularly for

Table 10.10 Top Five Estimated Proportions of Attribute Profiles in Diagnostic Classification Models

Condition	KS1	KS2	KS3	KS4	KS5	Proportion (Percentage)
Control	0	0	0	0	0	4.7
	1	0	0	0	0	10.2
	1	1	1	0	0	5.0
	1	1	1	1	0	3.3
	1	1	1	1	1	16.0
Treatment	0	0	0	0	0	6.1
	1	0	0	0	0	10.3
	1	0	1	1	0	4.0
	1	1	1	0	0	3.5
	1	1	1	1	1	15.7

Note. KS = knowledge specification. Only profiles that occur at least once are included. 1 = mastered, 0 = not mastered.

those involving Item 8. Based on research by Bonifay and Cai (2017), we know that DCMs have lower fitting propensity than typical multidimensional IRT models. In other words, a good model fit from a DCM gives us stronger evidence in support of the DCM than a similarly good fit would do to the evidentiary argument in support of, say, a bifactor model. But the degradation of model fit is far too substantial to ignore in this case, despite having four more parameters than the incomplete bifactor model. We chose not to explore the DCM option further.

Longitudinal Latent Variable Models

The prior work on item analysis informs us of the proper latent structure to use and allows us to focus on the changes in latent variables and treatment impact on the changes. We discuss applications of three multilevel item factor models with pre–post latent change parametrization. The first two are two-level models differing in how the treatment assignment status is represented in the data set. The third model is a cross-classified IRT model treating individuals and items as the two crossed factors and school-level influence conditioned out directly using school fixed effects. We realize that the third model is perhaps not ideal for the design that could be exploited to examine treatment effect heterogeneity. Our decision to include it here is pedagogical. Regression modeling with fixed effects is quite popular in evaluation studies, and many analyses only focus on the average treatment effect. We hope to show that econometrics-oriented fixed effects modeling could also be grafted onto complex psychometric-oriented cross-classified IRT models. All three models are estimated in flexMIRT

3.65 (Cai, 2022) using the MH–RM algorithm (Cai, 2010b, 2010c) with SEs estimated recursively (e.g., Cai, 2010b). We discuss applications of three multilevel item factor models with pre–post latent change parametrization, akin to historic models described in Bock & Bargmann (1966) as well as Embretson (1991) and McArdle (2009).

Two-Level IRT Growth Model With Treatment and Control Groups in Separate Data Columns

In the first two-level model, we explicitly represented individuals' treatment assignment status by restructuring the data from the conventional “wide” format to a “block-diagonal” format (Table 10.11). In each school, for individuals assigned to the treatment condition, their item responses occupied a block with $2 \times 10 = 20$ columns because there were 10 respective items for pretest and posttest. Similarly, for individuals assigned to the control condition, their item responses occupied another block with 20 columns. Because each row still represented an individual, the two blocks needed to be placed diagonally.

To model pre–post latent changes, we specified four within-school primary factors to represent the pretest and posttest statuses of the treatment and control groups. This is analogous to conditioning the latent outcome variable on the treatment assignment indicator because it allows the means and variances of latent variables to differ between the two experimental conditions. Because the multisite data have a nested structure

Note. Con = control condition; Pre = pretest; Pst = posttest; Trt = treatment condition. Variable Indv ID denotes the individual ID. Variable Sch ID denotes the school ID. Missing values are coded as –9.

with schools as the Level 2 units, we also specified two between-school primary factors to represent school-level variations in initial status and latent deviation from the initial status. Last, we established cross-factor constraints and freed the means and variances of the latent variables of interest. Table 10.12 presents the factor pattern matrix for such a model. The size of the full factor pattern matrix is 40 (10 items $\times$ 2 time points $\times$ 2 experimental conditions) by 26 (2 between-school primary factors, 4 within-school primary factors, and 20 within-school residual dependence dimensions).¹

Using conventional path diagrams, Figures 10.3 and 10.4 depict the core structures of this model at the between-site and within-site levels. The model is fitted to all 10 items at pretest and posttest, but only four pairs of items are shown because of space constraints. The rectangles represent items, and circles represent latent variables. The items load on two between-school (Level 2) primary dimensions, two within-school

FIGURE 10.4
A Path Diagram Depicting the Level 1 (Individual-Level) Model

(Level 1) primary dimensions, and 10 group-specific (Level 1) residual dependence dimensions in each condition.

Table 10.13 presents descriptive statistics of latent pretest scores and latent change scores by conditions. The means of latent pretest score were -0.02 and -0.46 for the control and treatment conditions, respectively, and their standard deviations were close to 1. The means of latent change scores for the control and treatment conditions were 0.09 and 0.39 , respectively, yielding a difference of 0.30 . The latent change factor could be seen as a difference between the latent pretest factor and the latent posttest factor. Based on variance algebra, because it results from subtraction, the latent change factor typically had a smaller variance or standard deviation relative to the latent pretest factor. This observation holds true for both experimental conditions in this case.

Two-Level IRT Growth Model With Treatment Assignment Indicator as a Predictor

An alternative way to represent the treatment/control conditions in a two-level IRT growth model is to include the treatment assignment indicator as a predictor. In this situation, the data set has the conventional “wide” format, where each row contains the condition indicator, as well as pretest and posttest item responses (Table 10.14).

For this model, we specified one between-school primary factor, to account for variability across schools, and two within-school primary factors to represent the individual-level initial status (pretest) and change. The individual-level pretest latent variable also represents individuals’ deviations from the school random intercept; the latter represents schools’ pretest deviations from the grand mean across all schools (Cai & Houts, 2021). To obtain the estimated treatment effect, we regressed the Level 1 latent variables on the condition indicator.

Table 10.13 Descriptive Statistics of Latent Pretest Score and Latent Change Score by Condition

Condition	Latent Variable	<i>M</i>	<i>SD</i>	Min.	Max.
Control (<i>n</i> = 813)	Pretest	−0.02	0.91	−2.07	2.42
	Change	0.09	0.40	−1.04	1.57
Treatment (<i>n</i> = 851)	Pretest	−0.46	0.99	−2.55	2.20
	Change	0.39	0.52	−0.98	2.04

Table 10.14 Two-Level Item Response Theory Growth Model With Condition Indicator as a Predictor: Data Structure

Individual ID	School ID	Condition	Pre 1	...	Pre 10	Pst 1	...	Pst 10
1	1	1	0	...	0	0	...	1
2	1	1	0	...	0	1	...	1
...	...	...	...	...	...	...	...	...
24	1	1	0	...	0	1	...	1
25	1	1	1	...	1	1	...	1
26	1	0	1	...	1	1	...	1
27	1	0	0	...	1	0	...	1
...	...	...	...	...	...	...	...	...
49	1	0	1	...	0	1	...	0
50	1	0	0	...	0	0	...	1

Note. For the Condition indicator, 1 represents the treatment condition and 0 represents the control condition.
Pre = pretest; Pst = posttest.

Table 10.15 presents key parameter estimates for the primary factors. Results suggested that, on average, the control and treatment groups did not differ significantly at pretest ($\hat{\gamma} = 0.04$, $SE = 0.04$). Also, there was statistically significant variability of pretest across schools (variance of the between-school primary factor = 0.30, $SE = 0.09$). With the individual-level pretest variance constrained to 1, we can compute the intraclass correlation: $0.30 / (0.30 + 1) = 0.23$. Moreover, there was a significant pre-post improvement in the control condition (latent change $M = 0.17$, $SE = 0.02$), reflecting ongoing learning, along with a significant treatment effect ($\hat{\gamma} = 0.31$, $SE = 0.03$) that is the regression coefficient associated with the within-school latent change variable. One may view this model as a refined HLM analysis, replacing summed scores with latent change as the outcome. Relative to the variability of the change dimension ($SD = \sqrt{0.38} = 0.62$), the magnitude of the treatment effect is roughly half a standard deviation.

Cross-Classified IRT Model With Individuals and Items as Crossed Factors

The last model is a cross-classified IRT model that treats the characteristics of items, such as their difficulty, as random parameters, and models individuals and items as two crossed factors. For this model, our data set is structured by converting item responses from each individual into a diagonal matrix, where each row corresponds to an individual-item combination. Table 10.16 presents the example data structure for two individuals belonging to two schools. We again include the condition indicator as a predictor. Because individuals are nested within schools, the school membership is denoted by a set of dummy indicators that take on a value of 1 if the corresponding individual is in the school denoted by the dummy and 0 otherwise. In this situation, school effects are estimated as fixed effects. With this particular data structure, individuals and items are the two crossed Level 2 factors. The Level 1 units are the specific item responses.

Table 10.15 Two-Level Item Response Theory Growth Model With Condition Indicator as a Predictor: Key Results

Parameter	Between-School	Within-School Initial Status (Pretest)	Within-School Change
Latent mean (SE)	0.00 (—)	0.00 (—)	0.17 (0.02)
Regression coefficient (SE)		0.04 (0.04)	0.31 (0.03)
Covariance matrix (SE)	0.30 (0.09)		
	0.00 (—)	1.00 (—)	
	0.00 (—)	0.00 (—)	0.38 (0.02)

Note. Results for within-school residual dependence dimensions are excluded, given that all means are 0 and variances are fixed to 1.

We specified this model as follows. On the individual (or based on syntax in flex-MIRT, cluster) side, we introduced four factors: Two factors represented individuals' initial status at pretest and latent change at posttest, and the other two factors represented the dimension formed by Items 1–4 (as identified in bifactor model analysis) at pretest and posttest. On the item (or block) side, we included one factor representing the relative difficulty of the items. We then constrained the slopes and intercepts to be equal across items loading on the same factor. To estimate the treatment effect, we again regressed the latent pretest and change factors on the condition indicator. To account for school effects, we further regressed the latent pretest factor on 23 school dummy indicators.

Table 10.17 shows the treatment effect estimates. Based on the estimates, the control and treatment groups did not differ significantly at pretest ($\hat{\beta} = 0.003$, $SE = 0.093$). Examining the coefficient relating to the latent change, there was a statistically

Table 10.16 Cross-Classified Item Response Theory Model With Individuals and Items as Crossed Factors: Data Structure

51	10	1	−9	−9	...	−9	0	−9	−9	...	−9	1	0	1	...

Note. Variable Cond denotes the condition, where 1 denotes the treatment condition and 0 denotes the control condition. Variable Indv ID denotes the individual ID. Variables with the prefix Sch are the school membership dummy indicators. Missing values are coded as −9. Pre = pretest; Pst = posttest.

Table 10.17 Cross-Classified Item Response Theory Model With Individuals and Items as Crossed Factors: Key Results

Regression Coefficient	Estimate	SE
Initial Status On Treatment Indicator	0.003	0.093
Latent Change On Treatment Indicator	0.982	0.197

Note. Estimates of school effects are not shown here because of space constraints.

significant and positive treatment effect on posttest deviations from the initial status (i.e., improvements in performance) ($\hat{\beta} = 0.982$, $SE = 0.197$). Estimates of school fixed effects ranged from -0.97 (School 2) to 1.59 (School 20).

Summary of Empirical Example 1

In sum, we have conducted classical and IRT-based item analysis. We noticed that the results appear to confirm the presence of additional dimensions due to assessment design. We explored several plausible models, including the item bifactor model, the multilevel bifactor model, and a DCM. We used a range of fit measures to help guide the down selection. We also incorporated the IRT model directly into several multilevel or cross-classified latent variable models that represented the school effects, random assignment, and the pre–post design. These models further refine the traditional HLM analyses. These models are all suggestive of the presence of a significant and practically noticeable treatment effect.

EMPIRICAL EXAMPLE 2

In this second empirical example, we examine a data set collected from an operational field test of an alternate English language proficiency assessment (*Alt ELPA*) to further illustrate issues around the treatment of item parameters as random effects. The Alt ELPA test is specifically developed for English learners who have significant cognitive disabilities.

Data Source

The field-test data contain item responses collected from 712 students in Grades 2–3 across nine states. The item responses are based on 80 items in two modalities: 40 items assessing receptive modality (listening or reading domains) and 40 items assessing productive modality (speaking or writing domains). All 40 receptive items and 28 productive items are dichotomously scored, and 12 productive items are polytomous scored (0, 1, 2, or 3). Students were randomly assigned forms (A or B) for the domains they were not exempted from and were presented with the items that corresponded to the assigned forms. As a result, students were presented with 40 items, if not exempted from any domain, or fewer if exempted from one or more of the domains. For example, consider a scenario in which a student is exempted from writing and is assigned forms A, B, and B for the remaining domains. In this case, the student will be administered 30 items from reading form A, listening form B, and speaking form B. Table 10.18 provides a summary of the characteristics of the forms. The main challenges are that the sample size is relatively small, and the data contain substantial missingness due to domain exemptions resulting from disabilities. These challenges are not due to sampling; the target population itself is small and heterogeneous, including dramatic variations in the type of cognitive disabilities.

Table 10.18 Summary of Alt ELPA Grade 2–3 Item Characteristics

Modality	Domain	Form A		Form B	
		Dichotomous	Polytomous	Dichotomous	Polytomous
Receptive	Reading	10	—	10	—
	Listening	10	—	10	—
Productive	Speaking	7	3	7	3
	Writing	7	3	7	3

Multidimensional IRT Model

The assessment designers and educators involved in the project envisioned a representation of English language proficiency composed of two modalities: receptive and productive. This corresponds nicely with a two-dimensional item factor model. The two correlated dimensions corresponded to the two modalities. The correlation can also serve to produce modality scaled scores that can borrow strength from the other modality (for more discussions on subscore augmentation, see Thissen & Wainer, 2001).

The fitted item factor model had an independent cluster structure (McDonald, 2000), where each item loads on only one of the two modalities. At the item level, the correct response probabilities of dichotomous items were modeled using the 2PL model (Equation 7), and those of polytomous items were modeled using the GPC model (Equation 9). To stabilize estimation under the limited sample size and considerable missingness by design, we constrained the item slope parameters to be equal within the groups of receptive dichotomous (RD) items, productive dichotomous (PD) items, and productive polytomous (PP) items. The next to last column of Table 10.19 shows the summary and key results of the multidimensional IRT model.

Cross-Classified IRT Model

The multidimensional model above treats item parameters as fixed effects and person parameters as random effects. Alternatively, one could treat the item responses to be cross-classified by items and persons, making both items and persons random facets. An immediate computational benefit of the alternate specification is that the number of structural parameters dramatically decreases, which stabilizes parameter estimation under small sample size.

We specified the model as follows. On the individual side, we included two correlated factors corresponding to individuals' proficiency in receptive and productive modalities, which we term person effects. On the item side, we introduced five factors: One factor indicates RD items' deviation from their overall difficulty, another factor indicates PD items' deviation from their overall difficulty, and the other three factors indicate PP items' deviations from their overall category-specific difficulties; we term these factors item effects. Each of the item effects was assumed to follow a normal distribution with mean zero and freely estimated variance. As in the standard

multidimensional IRT model, item slope parameters were constrained to equality within RD, PD, and PP items, and the slope parameters were considered fixed. The person scores were computed by a multiple imputation-based procedure (Huang et al., 2024; Yang et al., 2012).

For this model, the data set is restructured into a long format by collapsing the 80 items into three pseudo-items corresponding to the three item types—RD, PD, and PP—that are assumed to have equal item slopes. Table 10.20 presents the example data structure for two individuals.

The last column of Table 10.19 shows the summary and key results of the cross-classified IRT model. The point estimates closely matched those found in the MIRT model. The correlation between item difficulty estimates in the two models was .998 for dichotomous items and .997 for polytomous items. Similarly, the correlation between person scores from the two models was .994 for receptive modality and .991 for productive modality. In other words, the cross-classified model is entirely capable

Table 10.19 Model Fitting Summary and Key Results: Multidimensional Item Response Theory (IRT) Model Versus Cross-Classified IRT Model

		Multidimensional IRT Model	Cross-Classified IRT Model
Parameters	Person Scores	Random	Random
	Item Intercept	Fixed	Random
Number of latent variables (dimensionality)		2	7
Number of parameters		108 (1 correlation between person effects + 3 slopes for person effects + 68 intercepts for dichotomous items + 12 × 3 intercepts for polytomous items)	14 (1 correlation between person effects + 3 slopes for person effects + 5 variances of item effects + 5 overall intercepts [1 for RD, 1 for PD, and 3 for PP])
Estimates ^a	Correlation between person effects	0.822 (0.022)	0.822 (0.013)
	Slope for person effects	RD: 1.072 (0.050) PD: 1.422 (0.081) PP: 2.139 (0.160)	RD: 1.065 (0.032) PD: 1.413 (0.045) PP: 2.112 (0.079)
	Variance of item effects		RD: 0.420 (0.001) PD: 0.578 (0.002) PP: 0.159 (0.002), 0.229 (0.005), and 0.066 (0.002) for polytomous generalized partial credit intercepts

Note. PD = productive dichotomous; PP = productive polytomous; RD = receptive dichotomous.

^a The numbers in the parentheses are standard errors corresponding to the point estimates.

Table 10.20 Cross-Classified Item Response Theory Model: Data Structure (Example 2)

Indv ID	Item ID	Resp RD	Resp PD	Resp PP
1	RD_01	0	−9	−9
⋮	⋮	⋮	⋮	⋮
1	RD_40	1	−9	−9
1	PD_01	−9	1	−9
⋮	⋮	⋮	⋮	⋮
1	PD_28	−9	0	−9
1	PP_01	−9	−9	3
⋮	⋮	⋮	⋮	⋮
1	PP_12	−9	−9	1
2	RD_01	1	−9	−9
⋮	⋮	⋮	⋮	⋮
2	RD_40	0	−9	−9
2	PD_01	−9	0	−9
⋮	⋮	⋮	⋮	⋮
2	PD_28	−9	1	−9
2	PP_01	−9	−9	0
⋮	⋮	⋮	⋮	⋮
2	PP_12	−9	−9	2

Note. Variable Indv ID denotes the individual ID. Variable Resp RD is an item response if the item is receptive and dichotomous and missing otherwise. Variable Resp PD is an item response if the item is productive and dichotomous and missing otherwise. Variable Resp PP is an item response if the item is productive and polytomous and missing otherwise. Missing values are coded as −9. PD = productive dichotomous; PP = productive polytomous; RD = receptive dichotomous.

of offering what the standard fixed-item approach always offered in terms of item parameters and scaled scores.

The cross-classified IRT model yielded substantially smaller standard errors and can produce additional summaries not available in the standard approach. For instance, the correlation between the two person effects were estimated to be .822 in both models, but its standard error was 0.022 in the MIRT model and only 0.013 in the cross-classified IRT model. The smaller standard errors in item parameters imply less subsequent decision error in scaled score estimates and classification decisions, which rely on item parameter estimates.

By specifying both item and person variances, we can directly decompose variability into relevant sources in a similar manner as in generalizability theory. For the 20 RD items in the each of the test forms, for example, 73% of the total explained variance (i.e., $1.065^2 / (1.065^2 + 0.420)$) is attributable to persons, with the rest of the variance attributable to items. For a single RD item with a 2PL IRT model at the item level, the implicit error distribution is that of the standard logistic, with mean 0 and variance equal

to $\frac{\pi^2}{3} \approx 3.29$ (Bauer, 2009). Therefore, a rough index of dependability of absolute decisions with regard to model-based scaled scores in the receptive modality measured by 20 items could be computed as

$$\frac{1.065^2}{1.065^2 + (.42 + 3.29)/20} = .86.$$

This index is similar in spirit to Brennan and Kane's (1977) dependability coefficient in a $p \times i$ design. Without making items a random facet, we would be unable to decompose variances into relevant sources in this nonlinear model because the variance for the item facet would be unavailable.

Cross-Classified IRT Model With a Predictor

Another advantage of treating item parameters as random effects, in addition to the computational and conceptual benefits mentioned in the previous section, is that we can simultaneously study the impact of key predictors on the random effects (Huang & Cai, 2023). In the context of Alt ELPA, we adopted a principled assessment design process with standard setting embedded into the item development process (Lewis & Cook, 2020). In brief, under principled assessment design, each item is intended (hypothesized) to elicit observations that support measurement of a specific achievement level. Thus, the ultimate correspondence between the statistically estimated item difficulty levels and the targeted achievement level (hereafter, target level) is critical in lending support to the embedded standard-setting procedure and the ultimate scaled score interpretation and use. We employed the cross-classified IRT model to integrate the qualitative evidence from the item-writing process with the quantitative evidence from the calibration study using field-test data. We empirically assessed the alignment by incorporating a latent structural model into the measurement model discussed in the previous section, specifically by regressing the items' relative difficulty levels (estimated from the field-test data) on their target levels (assigned during the item-writing process). The target levels had been evaluated in four levels: 1, 2, 3, and 4. The number of items assigned to the four levels was 7 (17.5%), 14 (35%), 13 (32.5%), and 6 (15%), respectively.

For a simple illustration, we selected 40 RD items to apply the same cross-classified IRT model. We specified two latent variables: one person effect representing individuals' proficiency and one item effect representing RD items' relative difficulties. Then, to assess the predictive relationship between the items' target levels and their relative difficulties in the field test, we regressed the item effect on the target levels.

Turning our attention to the regression result, an estimated regression coefficient was $\hat{\beta} = -0.390$. The estimate had a standard error $SE(\hat{\beta}) = 0.043$ and was statistically significant ($p < .001$). The estimated coefficient suggests that a 1-unit increase in the

target level corresponds to a decrease of 0.390 in an item's deviation from the overall RD items' intercept. Since the intercept a product of minus the slope and the difficulty, we can also infer that a 1-unit increase in the target level results in an increase of 0.379 in an item's deviation from the overall RD items' difficulty (obtained by dividing 0.390 by the estimated item slope of 1.028). From analysis of variance perspective, the proportion of item random effect variance (relative item difficulty) explained by the target level predictor was 64%. The regression analysis follows the explanatory tradition of de Boeck and Wilson (2004) that would not be feasible if we had not parameterized and fitted the model as a random item model in the first place. Substantively, these results lend support to the claim that one could indeed produce items that are aligned with their intended target levels. This finding will help refine the assessment development process in the future.

CONCLUSION

A wide range of topics have been covered in this chapter. We started with general discussions around the sources of data and purposes of modeling in educational assessment. We introduced several core statistical modeling concepts, including latent variables, conditional distributions and conditional independence, Bayesian inference fundamentals (likelihood, prior, and posterior), and model fit evaluation in the context of fallible working models that do not fit exactly. We discussed parameter estimation and saw how the missing data formulation could lead to insights that benefit the development of estimation algorithms in statistical computing. We described a general multilevel latent variable modeling framework and connected it to various “named” models that see routine use in practical settings. We reviewed the distribution theory needed for constructing more refined and targeted tests of model fit. Inspired by information theory, we briefly touched on the philosophical dilemma that should be at the forefront of every researcher's mind—that good fit does not automatically lend unequivocal support to a statistical model (or the theory that it encodes), because the model may have an inherent propensity to fit well to many diverse data patterns. We then proceeded to analyze two empirical data sets to help illustrate the points we made earlier. The first example involved an integrated latent variable analysis combining item response modeling with multilevel modeling. The second example illustrated the benefits of using more advanced models with crossed random effects for the test items in the context of language proficiency assessments with special populations. Both examples had a cross-classified modeling component, with the second example further featuring a use case for modeling random item effects and regressing these effects on one explanatory predictor. These models not only offer inference and output comparable to more standard item response models with fixed item effects, but also provide more information about sources of variability. They support statistical modeling that can explicitly incorporate assessment design features in the assessment validation process.

We speculate that several important ongoing trends and developments in educational measurement are likely to impact the practice of statistical modeling. The first is the availability of cheap, distributed, and scalable options to conduct software-based data collection. We hope it is obvious to anyone reading this chapter that educational technology products on the market today or products that we have yet to see may be used for data gathering for assessment purposes. The increasingly voluminous data also prompted the increasing use, perhaps out of necessity, of tools derived from what Breiman (2001) aptly referred to as the algorithmic approach to statistical modeling. The ability to predict outcomes or some criterion in performance is paramount in this approach, rather than the more traditional method that seeks to gain an understanding of what may be part of the mechanisms or processes that led to the data in the first place. These new tools are incredibly powerful and undoubtedly useful. What remains to be seen is whether they will lead to increased ability for us to explain what we observed, or, in other words, more theory building, and conceptual clarity that is afforded by subjecting theories (with models as their embodiments) to statistical tests and rejecting them if necessary.

The second trend is the resurgent interest in connecting the design of assessment systems with the design of learning and instructional systems. In terms of statistical approaches, we must rise to the challenge of combining assessments taken at multiple time points, for example, throughout the school year in K–12 settings, to formulate reliable measurement of progress, achievement, or mastery. We must also be able to use the data more efficiently to provide feedback that is more timely and more relevant to instruction and improvement in learning. We are particularly enthusiastic about the prospects of multidimensional or DCM approaches to help meet this challenge.

The final development is related to the fairness and consequential validity of educational assessments. This is not a new topic. To address fairness issues, it is imperative that modelers of educational assessment data gain a more thorough understanding of the social contexts in which the assessment programs operate (see Ercikan & Solano-Flores, Lane & Marion, Rodriguez & Thurlow, and Zwick, this volume). To arrive at a fair interpretation of the results, one must also understand the historical and societal determinants of observed differences across subpopulations. Finally, the modeler should hopefully seek to understand better the implications of the use of statistical summaries resulting from educational assessments and develop methods to help mitigate any potentially unfair impact on the individuals and to communicate the assumptions and outcomes plainly to the stakeholders.

The first edition of *Educational Measurement* was published more than 70 years ago. Since that time, the theory and practice of statistical modeling have experienced transformative changes. Given the progress, we are hopeful that the readers of this chapter and the researchers in the field will continue to substantially improve the modeling of educational assessment data in the next 70 years.

ACKNOWLEDGMENTS

We would like to thank Tianying (Teanna) Feng and Yun-Kyung Kim for their contributions that greatly improved this chapter. The U.S. Department of Education supported the design and collection of the data sets mentioned in the empirical examples (R305C080015 and S368A150011).

NOTE

1. Notice that this model does not include the specific factors on Items 1–4, unlike the preceding bifactor models. This model is a direct replication of the latent growth model in Chung et al. (2014).

Scaling, Equating, and Linking

Tim Moses

Buros Center for Testing

Few wish to assess others,
Even fewer wish to be assessed,
But everyone wants to see the scores
(Paul Holland, quoted in Dorans, 2018)

There are many ways that a testing program can assign and report scores that reflect test performance. Score reporting can be based on performance standards set by content experts; on relative standing with respect to one or more test-taker groups; on performance, strengths, and weaknesses across a set of tests contained in a test battery; or on performance for a particular age group or grade level in a scale constructed to track growth in age- or grade-appropriate tests of increasing difficulty. It would be difficult to overstate the importance of reported scores for a large-scale testing program. As a testing program's most visible and widely used products (Dorans, 2002; Kolen, 2006; Zenisky et al., this volume), it is essential to understand and document how reported scores are produced, maintained, and, at times, related to the scores reported by other testing programs. This chapter focuses on procedures for producing, maintaining, and linking testing programs' reported scores.

This chapter is an updated version of prior writings on scaling, equating, and linking. The attempt is to build on the seminal and foundational work of the chapters in previous volumes of *Educational Measurement* (Angoff, 1971; Flanagan, 1951; Holland & Dorans, 2006; Kolen, 2006; Petersen et al., 1989). Extensive reviews of these chapters are, regrettably, not possible here, but are strongly encouraged. The major goal of the current chapter is to provide a "point-in-time" description of how issues and problems in the current testing field engage with, challenge, and build on prior chapters' discussions and frameworks for scaling, equating, and linking a testing program's reported scores.

- *Scaling* focuses on the theory and practice of establishing a testing program's reporting score scales.
- *Equating* focuses on the definition, requirements, history, and methodological practices of equating for maintaining a testing program's reporting score scales.
- *Linking* types are summarized with historical and recent examples for how a testing program might relate its reported scores to other scales.

In addition to the scaling, linking, and equating chapters in previous *Educational Measurement* volumes, the current chapter reflects two major influences. First, the testing program from which reported scores are produced represents a system of test production, administration, scoring, using, and interpreting test results, in multiple testing sites, and repeating in cycles over multiple points in time (Dorans, 2011; Holland, 1994, 2008). Understanding reported scores requires an understanding of the testing program's system, especially test specifications and development, administration conditions, and scoring procedures. The second influence pertains to the interpretations of reported scores. Testing standards emphasize that reported scores should be produced and maintained in ways that encourage

appropriate interpretations and discourage misinterpretations (American Educational Research Association [AERA] et al., 2014; Kolen, 2006; Petersen et al., 1989). The discussions in this chapter are intended to specify and elaborate on what this means and on ways to most effectively reflect “the overarching consideration . . . that users be given appropriate guidance about score interpretation and use” (Brennan, 2007, p. 175).

SCALING

The purpose of scaling is to establish the reporting scale(s) for the individual measures of a new or redesigned testing program. Scales are produced in the context of several activities of a testing program, such as the development of a test or measure from an established set of specifications for the content, construct, and individual items. Scaling is used in several testing contexts, including:

- admissions testing, where testing companies develop tests with relatively long scales for use in admissions decisions;
- K–12, where testing companies develop content-based tests associated with specific curricular standards adopted by policy makers to classify students at one or very few cut points for school and educator accountability, high school exit requirements, and instructional decisions;
- certification and licensure programs, where test content is determined with extensive input from practitioners and test takers are classified at cut points that indicate sufficient knowledge and skills to qualify for professional practice; and
- large-scale survey assessments developed by policy makers, educators, measurement and content experts, and other stakeholders for use in the estimation of trends in scale score distributions and classifications of populations and subpopulations over time.

Scaling activities also involve the administration of the developed test to test takers from a defined testing population under specific administration conditions, the scoring of test takers’ test items, and the conversion of test takers’ item scores into overall test scores or ability estimates. The data collection design for a test-taker sample from population p who take test form Y is shown in the first row of Table 11.1 (the terms and other designs in Table 11.1 are described throughout this chapter). The task in scaling is to develop a transformation that assigns numbers or ordered indicators to the test performance data.

The scaling process reflects the tests and their intended measurement, interpretations, and perspectives reviewed in the “Scaling Perspectives” section. Consider Y as a test form and a set of performance values test takers might receive, such that specific performance values are denoted $y = 0, 1, 2, \dots$. The y s can reflect sums of correct item scores, weighted summed scores, summed predicted probabilities of item-level models, or other indicators as described in the *Basic Unit of Scaling* section. Scale score transformations of

Table 11.1 Summary of Data Collection Designs for Scaling, Equating, and Linking

Description	Design Table					
	Population	Sample	Y			
Scaling/norming for a single test	P	1	$\sqrt$			
Single group	Population	Sample	X	Y		
	P	1	$\sqrt$	$\sqrt$		
Randomly equivalent groups	Population	Sample	X	Y		
	P	1	$\sqrt$			
	P	2		$\sqrt$		
Counterbalanced	Population	Sample	X_1	Y_1	X_2	Y_2
	P	1	$\sqrt$			$\sqrt$
	P	2		$\sqrt$	$\sqrt$	
NEAT	Population	Sample	X	A	Y	
	P	1	$\sqrt$	$\sqrt$		
	Q	2		$\sqrt$	$\sqrt$	
Common-item equating to a calibrated pool	Population	Sample	X_A	X_{New}		
	P	1	$\sqrt$	$\sqrt$		
Section pre-equating	Population	Sample	X_1	X_2	Y_1	Y_2
	P	1	$\sqrt$		$\sqrt$	$\sqrt$
	P	2		$\sqrt$	$\sqrt$	$\sqrt$
Item pre-equating	Population	Sample	X	New		
	P	1	$\sqrt$	$\sqrt$		

Note. NEAT = nonequivalent groups with anchor test. Depending on the context, X and Y can refer to alternate forms of a single test (equating) or to distinct tests (linking). For all but the NEAT design, P is assumed to be the target population for the test (T).

test performance are developed to produce reported scale scores that reflect increasing levels of achievement or proficiency, $sc(Y)$, that encourage specific interpretations. Two types of scales might be developed from the inputs, *primary* and *auxiliary*. Primary scales refer to reporting scales and test performance indicators that underlie the psychometric operations of a test (Kolen, 2006; Petersen et al., 1989), including the equating of scores from alternate test forms (see the *Equating* section) to the primary scale. Methods of establishing primary scale scores are described in the section *Scaling Methods for Primary Scale Scores*. Auxiliary scales are developed to facilitate interpretations and convey meaning in primary scales, and are described in the section *Auxiliary Scales*.

Scaling Perspectives

Early antecedents for educational and psychological testing and scaling include Horace Mann's efforts in 1845 to standardize oral exams of test-taker placement to control for the influence of different topics, examiners, and other efforts in psychophysics to apply scientific methods to study relationships between psychological sensations and physical stimuli (Briggs, 2022; Mislevy, 2018). Efforts to establish scales for nonphysical, psychological measures reflected these antecedents, as well as aspirations that measures and scales of nonphysical attributes might exhibit the measurement and scaling properties of physical attributes. The Binet–Simon Intelligence Test, released in France in 1905 by Alfred Binet and Theodore Simon, was an attempt to identify children in need of special services in ways that would be objective and free of teacher judgment and variations in the terminology, evidence, and reasoning used at that time (Binet & Simon, 1916; Cronbach, 1949). In the Binet–Simon test, test takers between ages 3 and 13 completed a series of 10 to 30 age-specific tests and were given a scale score designating an age and “intellectual level” corresponding to the test they were able to complete (Becker, 2003; Cronbach, 1949):

The fundamental idea of this method is the establishment of what we shall call a measuring scale of intelligence. This scale is composed of a series of tests of increasing difficulty, starting from the lowest intellectual level that can be observed, and ending with that of average normal intelligence. Each group in the series corresponds to a different mental level. (Binet & Simon, 1916, p. 40)

In another early example of scaling and measurement, Thorndike (1910) proposed a scale for handwriting quality by obtaining rankings of subsamples of handwriting samples of children in the fifth to eighth grades from competent judges and averaging these rankings to produce a scale for the entire sample. Thorndike (1910) described his scale of handwriting quality as one that ranged from “better than which no pupil is expected to produce, down to a quality so bad as to be intolerable, and probably almost never found, in school practice in the grammar grade” (p. 89). He also considered his scale of handwriting quality a way to assess educational outcomes similar to physical and scientific measures in other disciplines:

In general, the experience of constructing this scale gives great encouragement to the hope that for many educational facts, units and scales may be invented that shall enable us to think quantitatively in somewhat the same way that we can about facts of physics, chemistry or economics. (Thorndike, 1910, p. 150)

Scaling, measurement processes, and models were developed beyond the work of Binet and Simon (1916) and Thorndike (1910). For the Binet–Simon tests (i.e., items or questions) that were designed to be taken by children of specific ages, Thurstone (1925) developed a method to place the statistics of all Binet–Simon tests onto a single, continuous, normally distributed ability scale. This scale allowed Thurstone to evaluate and critique the *a priori* age groupings of the tests: “The questions are unduly bunched

at certain ranges and rather scarce at other ranges” (Thurstone, 1925, p. 448). Thurstone (1926, 1927) also provided a rationale and more fully developed theory of Thorndike’s (1910) scale in his law of comparative judgment (Coombs et al., 1970). This allowed for scales to be produced from any process of pairwise comparisons through modeling averages of pairwise differences and assuming they followed normal distributions. Guttman (1944) proposed a scaling approach that predicts an individual’s agreement/disagreement with an ordered set of unidimensional attitude statements in a deterministic model asserting that individuals who agree/disagree with a stronger/milder statement of attitude will also agree/disagree with all milder/stronger statements. Rasch (1960) proposed a scaling procedure based on a statistical logistic item response model of the probability of an individual’s response to an item based on one parameter for each item’s difficulty and one parameter for an individual’s ability (see the *IRT Ability Estimates* section; Wright, 1977).

Despite the methodological differences in previously described scaling approaches, comparative summaries have pointed out several similarities. The scaling approaches of Thorndike (1910) and Thurstone (1926, 1927) reflect an assumed “monotonicity property” in the nonphysical variables being scaled, implying consistency in judgments and subjective differences between stimuli (Coombs et al., 1970, p. 42). Thurstone’s, Guttman’s (1944), and Rasch’s (1960) approaches assume invariant comparisons in scales intentionally constructed to be unidimensional (Andrich, 1988). Engelhard (1984) compared the item calibration approaches of Thurstone (1925) and Rasch (1960) and another approach from Thorndike (1919), showing that these approaches produce similar empirical results and that they all attempt to eliminate the effects of samples and groups and thus achieve invariance. These scaling approaches can be described as giving increasingly greater emphasis to a particular model over data (Engelhard, 1984, p. 35). An implication of these approaches’ emphases on models is that uses and interpretations of the scales occur “only after a scale is developed that adequately fits the model” (Kolen & Brennan, 2014, p. 373).

Scaling has been addressed in fundamental definitions of what constitutes a measure and its scale. Early work was based on a classical perspective of discovering or estimating quantities and numerically representing them (Campbell, 1928; Hölder, 1901; Michell, 2008). From this perspective, attributes are established as quantitative and fundamental measures to the extent that they exhibit numerical properties that have a physical analogue, like length and concatenation (the adding or laying of objects end to end, Coombs et al., 1970; Hölder, 1901; Mislevy, 2018). An implication of these arguments is that measurement can be established only in the physical sciences. Psychophysical variables could not be established as measures because psychophysical variables would not exhibit concatenation operations or invariant relationships with established physical measures (Campbell, 1928; Ferguson et al., 1940).

Stevens (1946) provided a general typology of scales achieved through rules of assignment of numerals to a wide range of objects or events. By focusing on assignment rules rather than on requisite conditions for measurement (e.g., Campbell, 1928),

Stevens's (1946) scaling approach is more encompassing, alternatively described as paraphrasing (Stevens, 1946), circumventing (Mislevy, 2018), shifting (Briggs, 2022), or deflecting (Michell, 2008) the emphasis of earlier arguments on classical measurement and quantitative measures. For Stevens, scales are achieved in an operationalist (vs. classical) process of following (vs. discovering) rules for assigning numerals to objects according to their assumed level of measurement (vs. attributes of objects that must first be established as measurable; Briggs, 2022). The objects and measurements for which scales can be established include nominal (categorical labels), ordinal (ordered labels), interval (ordered labels that have equal intervals), and ratio (interval scales with a natural zero). In Stevens's arguments, the meaning and interpretation of scales depends on using admissible transformations for types of measurement (i.e., a monotonically increasing transformation for ordinal, linear transformations for interval) and on using permissible statistics for specific types of scales (e.g., medians for ordinal scales, means for interval scales). Stevens's scaling theory was further developed in subsequent work (Coombs et al., 1970; Krantz et al., 1971; Suppes & Zinnes, 1963).

Other approaches re-emphasized the classical focus on quantitative (interval or ratio) measurement through conditions other than concatenation (Coombs et al., 1970), including conjoint measurement (Luce & Tukey, 1964). One condition of conjoint measurement is double cancelation, which refers to a variable that consistently, additively, and noninteractively increases or decreases with two other variables (see the *Ability Estimates From Rasch and Other 1PL IRT Models* section).

Scaling approaches used in practice and described in measurement theory have been nearly separate pursuits in educational and psychological testing: "The axiomatic analysis of measurement models does not always provide feasible methods for constructing scales" (Coombs et al., 1970, p. 31). Binet and Simon (1916) described inconsistencies in the actual and aspirational measurement properties of their Binet–Simon test, simultaneously arguing for treating the scale of their test as equal to a quantitative measure even as they acknowledged that it reflected an ordinal scale of ordered, discrete classes:

This scale properly speaking does not permit the measure of intelligence, because intellectual qualities are not superposable, and therefore cannot be measured as linear surfaces are measured, but are on the contrary, a classification, a hierarchy among diverse intelligences; and for the necessities of practice this classification is equivalent to a measure. We shall therefore be able to know, after studying two individuals, if one rises above the other and to how many degrees, if one rises above the average level of other individuals considered as normal, or if he remains below. (pp. 40–41)

Another argument for treating ordinal measures as though they reflected interval scales in scaling practice appealed to pragmatics and usefulness over formal measurement properties:

Although, formally speaking, interval measurement can always be obtained by specification, such specification is theoretically meaningful only if it is implied

by the theory and model relevant to the measurement procedure. At various times in this book however, we shall treat a measurement as having interval scale properties, although it is clear that the measurement procedure and the theory underlying it yield only a nominal or, at best, an ordinal scale . . . from a pragmatic point of view, the only meaningful evaluation of this procedure is one based on an evaluation of the usefulness of the resulting scale. (Lord & Novick, 1968, pp. 21–22)

Some objections have been expressed about Stevens's (1946) arguments concerning levels of measurement and permissible statistics, such as Lord's (1953) argument that statistical operations seemingly reserved for interval scales could be appropriate even for nominal scales like numbers on football players' jerseys. Connections of measurement theory and scaling practice have been considered in terms of the statistical and probabilistic Rasch models and conjoint measurement (Embretson & Reise, 2000; Karabatsos, 2001; Perline et al., 1979). However, noted limitations in the fit of the Rasch model have raised questions about the inconsistencies of pursuits to establish scales that reflect measurement theory versus those that fit actual test data (Briggs et al., this volume; Embretson, 2006; Embretson & Reise, 2000; Thissen & Orlando, 2001; Wright, 1994).

The perspectives taken in describing the practice of establishing reporting scales for educational tests in the first four volumes of *Educational Measurement* make specific references to, and departures from, previous discussions of scaling and measurement (Angoff, 1971; Flanagan, 1951; Kolen, 2006; Petersen et al., 1989). Most of the *Educational Measurement* chapters present a basic definition of scaling similar to Stevens's (1946), one of assigning numerals or numbers to a test taker's test performance. Interpretation and meaning are less about requirements for measurement, statistics, or scaling transformations and more about the scale properties that might be desirable for other criteria and interpretations (described in the *Scaling Methods for Primary Scale Scores* and *Auxiliary Scales* sections). All of the *Educational Measurement* volumes discussed scale score interpretations in terms of scale score distributions on relevant testing populations (norms). Discussions of interval scales and other measurement issues either appear in other nonscaling chapters (e.g., Lorge, 1951) or are described in terms of their limited usefulness for scaling and psychological measures due to the absence of operational definitions that are agreed on by experts (Angoff, 1971) and the lack of a complete theory and definition for the psychological and educational constructs in need of scales (Kolen, 2006). Finally, perspectives on scaling for educational tests emphasize a starting point that differs from the one implied in measurement definitions and models. Petersen et al. (1989), Kolen (2006), and Brennan (personal communication, September 17, 2020) have distinguished educational measurement from other types of measurement because the starting point in educational measurement, that is, test content and specifications, comes from an external entity (e.g., one of the testing contexts summarized in the beginning of *Scaling*). They argue, consistent with Lindquist (1953), that

the objective is handed down . . . by those agents of society who are responsible for decisions concerning educational objectives, and what the test constructor must do is to attempt to incorporate that definition as clearly and as exactly as possible. (p. 35)

For educational measurement, content, test development, and measurement models influence the development of a test's reporting scale in choices for the basic unit used in scaling (see the *Basic Unit of Scaling* section), transformations of test performance measures to a reporting scale with desired properties (see the *Scaling Methods for Primary Scale Scores* section), and maintenance of the scale in subsequently developed forms through equating (see the *Equating* section).

Basic Unit of Scaling

The *Scaling Perspectives* section described fairly different views on scaling. These differences are apparent in the options for defining the basic unit of test performance used to establish a testing program's score scale. This section covers choices and implications for representing test performance, including different types of observed test scores that summarize observed test performance, and the latent abilities estimated using some item response theory (IRT) models. For other summaries of these options, including descriptions of approaches for scoring different types of items, see Kolen (2006) and Dorans (2018).

Observed Test Scores

Test performance indicators can be established as different types of observed scores. For test form Y that contains $i = 1$ to I items that are not distinguished with respect to content area or item format, the most common observed score is the sum of the $i = 1$ to I item scores, V_i

$$Y = \sum_i w_i V_i \quad (1)$$

where $w_i = 1$ for all I items. With this option, a test taker's score reflects equally weighted contributions from each item in the test. Other options involve the summing of differentially weighted item scores, where the item score weights might be chosen to maximize some measure of test reliability or validity (Gulliksen, 1950; Lord & Novick, 1968). Although these reliability and validity measures for maximization are defined by Gulliksen (1950) and Lord and Novick (1968), many issues concerning reliability, true score variance, and error variance for scaling procedures are, at best, imperfectly understood. Other texts should be consulted for comprehensive discussions of reliability (Brennan, 2001; Haertel, 2006; Lee & Harris, this volume). Different options suggested in Equation 1 can be used to summarize test takers' test performance on a specific set of test items.

Test form Y may also be a "composite" or "mixed format" test containing items with different content areas and/or item formats. When Y includes I multiple-choice (MC)

items and J constructed-response (CR) items, an approach to weighting the item type scores and obtaining observed composite scores is

$$Y = w_{MC} \sum_i V_{i,MC} + w_{CR} \sum_j V_{j,CR}. \quad (2)$$

One option is to nominally weight the scores from the MC and CR items so that the weighted scores reflect an intended number and percentage of composite score points. The Advanced Placement exams provide several simple and complex examples of MC item score weights and CR item score weights being set such that the weighted and summed scores contribute desired numbers of points to the composite score (College Board, n.d.; Moses et al., 2006). Another option is to determine effective weights such that the weighted scores reflect a desired proportion of the composite's observed score variance or true score variance. A third option is to select weights for the scores summed from different item formats such that some measure of composite score reliability is maximized.

The options for summing item scores produce measures of test performance with different implications. Sums of item scores that are equally weighted or weighted to reflect intended numbers of composite score points are the simplest methods of reporting test performance, associated with scoring rules that can be fairly easily communicated to test takers (i.e., "To do as well as possible, answer every item"). Simple summed scores can directly reflect expert judgments about the test as indicated by the numbers and weights of different items described in test specifications. Other options weight items based on statistics such as variances, maximized reliabilities, or validities and have interpretations based on those criteria. In addition, the weights reflect population and sample characteristics of those corresponding statistics. The scoring rules associated with these options for weighted observed test scores are more complex and may be more difficult to communicate to test takers depending on when these population-dependent weights are derived (i.e., test takers may approach the test in a way that is suboptimal or inconsistent with item weights that may be derived before or after the test is administered). Most of these observed score options should be understood to reflect an unspeeeded test where test takers have sufficient time to answer every item. Inadequate testing time can elicit rushed or random responding that could result in unintended measurement properties for those speeded items and the overall test. Equally or nominally weighted item scores may be suboptimal with respect to test score reliability, especially if these weights result in higher contributions from the scores of less reliable item types (i.e., higher contributions of CR scores relative to MC scores).

Observed test scores are direct indications of actual test performance and indirect reflections of unobservable latent abilities. As such, potential uses of observed test scores as estimates of latent abilities require supplemental measures of the reliability or generalizability of the scores to other possible item samples, test administrations, and admissible measurement conditions. When interpreted in terms of measurement and scale properties, test scores are often described as ordinal scales for some latent ability they are assumed to measure (Embretson & Reise, 2000). Alternatively, observed test scores could be considered interval scales from a pragmatic perspective

(Lord & Novick, 1968), or from a perspective where scores from a particular test form are regarded as indices of test performance rather than estimated abilities, such that a test form's scores exhibit equal increases with additional correct responses to test items (Mislevy, 2018, p. 316).

IRT Ability Estimates

Scales might be established on estimated latent abilities rather than on the test performance observed for a set of test items. In theory, the item response data from a test form might be modeled in ways that produce estimates of abilities that are independent of the test form. In practice, this involves fitting IRT models to data from a test and its fixed, specific set of items, such that the item characteristics require scaling procedures to account for their sample effects (described by Kolen & Brennan, 2014). The result is that test performance measures can be produced that may be regarded as estimates of latent ability, but that are essentially computationally complex summaries of observed item performance, in need of their own reliability estimates (Lee & Harris, this volume).

Assume test form Y contains dichotomously scored items with correct responses scored 1 and incorrect responses scored 0. Assume further that test takers' responses to the I items are conditionally independent given a latent and unidimensional ability, θ , and that the probability of a correct response follows a logistic model with up to three parameters, such that the probabilities monotonically increase with θ . The item response probabilities from the one-, two-, or three-parameter logistic models (1PL, 2PL, 3PL) can be expressed as

$$Pr(V_i = 1 | \theta, a_i, b_i, c_i) = c_i + (1 - c_i) \frac{1}{1 + \exp[-Da_i(\theta - b_i)]} \quad (3)$$

where a_i , b_i , and c_i are discrimination, difficulty, and guessing parameters for item i and D is a scaling constant that is sometimes 1 and other times set to 1.702 so that Equation 3's logistic function approximates a normal ogive (Haley, 1952). This section summarizes some approaches for estimating test takers' abilities, θ , based on test takers' scored responses to the items on test form Y , $v_1, v_2, \dots, v_I$ and on parameter estimates for all I items on the test form that are treated as population values (not estimated). IRT ability estimates reflect several choices for fitting IRT models to test data, including calibration decisions, estimation software, and approaches for polytomously scored items and mixed format tests (for additional discussions of IRT models, see Cai et al., this volume).

Three commonly used IRT ability estimates are the maximum likelihood estimate (MLE), the Bayesian expected a posteriori (EAP), and the test characteristic curve (TCC) estimate (for others, see Thissen & Orlando, 2001).

The MLE is obtained by solving for θ using an iterative procedure to maximize,

$$L(V_1 = v_1, V_2 = v_2, \dots, V_I = v_I | \theta) \\ = \prod_i Pr(V_i = 1 | \theta, a_i, b_i, c_i)^{v_i} [1 - Pr(V_i = 1 | \theta, a_i, b_i, c_i)]^{(1-v_i)}. \quad (4)$$

The MLE can be described as the ability estimate with maximum information (i.e., precision) and inverse sampling variance. The MLE corresponds to an optimally weighted observed score, $\sum_i w_i V_i$, for a particular IRT model (Lord, 1980; Yen & Fitzpatrick, 2006).

The Bayesian EAP estimate,

$$EAP = \frac{\int_{\theta} \theta L(V_1 = v_1, V_2 = v_2, \dots, V_I = v_I | \theta) Pr(\theta) d\theta}{\int_{\theta} L(V_1 = v_1, V_2 = v_2, \dots, V_I = v_I | \theta) Pr(\theta) d\theta}, \quad (5)$$

is the mean of a distribution of θ obtained as the product of the likelihood and an assumed prior distribution for test-taker ability, $Pr(\theta)$. In practice $Pr(\theta)$ is usually represented as a discrete approximation of the standard normal distribution, though it can also be obscure.

The TCC estimate is based on relating the IRT-expected summed scores given θ , $\tau_Y(\theta)$, to the observed summed score (Equation 1). Ignoring measurement error in the scores of test form Y and making other adjustments to account for true scores that are undefined in the IRT model, Equation 1 and a summed version of Equation 3 are set equal to each other and θ is estimated to preserve this equality:

$$Y = \sum_i w_i V_i = \sum_i w_i Pr(V_i = 1 | \theta, a_i, b_i, c_i) = \tau_Y(\theta) \quad (6)$$

Although the solution to θ in Equation 6 ensures that the IRT-expected summed score matches the observed score, this application of true score relationships to observed scores lacks justification (Kolen & Brennan, 2014, p. 201).

ABILITY ESTIMATES FROM RASCH AND OTHER 1PL IRT MODELS For the Rasch (1960) (all $a_i s = 1$, all $c_i s = 0$, and $D = 1$) and other 1PL models (all $a_i s = \text{constant}$, all $c_i s = 0$, and $D = 1.702$), ability estimates have a one-to-one relationship with the test score summed from equally weighted items, all $w_i s = Da_i$, and the TCC and MLE estimates are equal (Thissen & Orlando, 2001). When a uniformly distributed prior is used, $Pr(\theta)$, EAP ability estimates are also equal to those of MLE and TCC, except that the highest and lowest summed scores have estimates from EAP but are undefined with MLE and TCC. These results reflect a property of Rasch and 1PL models that the summed test score with equal $w_i s$ is a sufficient statistic that contains all information needed for estimating θ (Lord, 1980). Response probabilities from Rasch and 1PL models are additive and consistently ordered for item difficulties (or test-taker abilities), regardless of abilities (or items), always increasing as item easiness and test-taker ability increase. This means that the Rasch and 1PL models exhibit double cancelation and could be said to have a probabilistic relationship to conjoint measurement (Briggs et al., this volume; Embretson & Reise, 2000; Mislevy, 2018; Perline et al., 1979). Although this relationship has been the basis of attempts to establish quantitative measures with interval properties in test data, these attempts are challenging because of model–data fit limitations (see the *Scaling Perspectives* section). The relationship also reflects inconsistencies in

observed item responses, the probabilistic Rasch (1960) model of latent and estimated item parameters and abilities, and the deterministic framework of observed variables in conjoint measurement (Kyngdon, 2008; Mislevy, 2018; Perline et al., 1979).

As stated in the *Scaling Perspectives* section, Rasch models are more restrictive and less likely to fit observed data than other IRT models. These model–fit limitations can prompt calls to impose statistical consequences to the data or edit or remove nonfitting responses (Wright, 1977). Examples include “reinterpreting or modifying the frame of reference” (Andrich, 1988, p. 62) or reducing the intended scale:

The broader the domain of interest, the more difficult it will be to make targeted and testable hypotheses. This would suggest that vertical scales could only be plausibly supported for more narrowly defined latent variables. (Briggs, 2013, pp. 219–220)

Removal of test-taker data could potentially limit intended scale interpretations, such as by narrowing the intended scaling population (i.e., changing P in Table 11.1). Removal of nonfitting items could result in narrowing the construct defined in test specifications.

ABILITY ESTIMATES FROM 2PL AND 3PL IRT MODELS The 2PL (unique a_i s and c_i s = 0) and 3PL (unique a_i s and c_i s > 0) IRT models can be used to produce more complex ability estimates with unique contributions from individual items. The MLE and EAP estimates from 2PL and 3PL models reflect patterns of correct and incorrect responses to individual items, such that they differ from and convey more information than the TCC estimates. The MLE for the 2PL IRT model reflects item pattern scores and an optimally weighted test score where item scores are weighted by their discrimination, $w_i = Da_i$, and the resulting weighted test score is the sufficient statistic for θ . A TCC procedure usually based on equally weighted item scores differs from the MLE, but can produce the MLE estimate when modified to sum optimally weighted item scores (Lord, 1980). For the 3PL model, there is no sufficient statistic for θ , and the MLE estimate reflects a test score summed using optimal weights defined

$$\text{as } w_i = \frac{Pr(V_i = 1 | \theta, a_i, b_i, c_i) - c_i}{1 - c_i} \frac{Da_i}{Pr(V_i = 1 | \theta, a_i, b_i, c_i)}.$$

The MLE, EAP, and TCC ability estimates based on 2PL and 3PL IRT models have unique properties (S. Kim & Moses, 2025; Kolen, 2006; Kolen et al., 2011; Thissen & Orlando, 2001; Yen & Fitzpatrick, 2006). MLEs (Equation 4) are asymptotically unbiased estimates of θ , though for tests of realistic length they have conditional biases that are positively correlated with θ (Lord, 1983) and an overall variance that is larger than that of θ . MLE estimates are unavailable for some response patterns, such as those where the responses to the test items are all incorrect or all correct. EAP estimates from Equation 5 have conditional biases that are negatively correlated with θ (Lord, 1986), and they are less variable than the MLEs. The EAP estimates reflect shrinkage to the prior distribution of θ , meaning that θ values are overestimated for test takers below the mean in the population and underestimated for test takers above the mean. θ estimates based on EAP are available for all item response

patterns. Ability estimates based on EAP and MLE item pattern scores have smaller standard errors than those using the usual TCC approach, though their similarity with TCC estimates increases for longer tests with items that have smaller guessing effects (Yen & Fitzpatrick, 2006).

Ability estimates for 2PL and 3PL IRT models have implications for model–data fit, theoretical measurement properties, and score interpretations. These IRT models fit observed test data more closely than Rasch and 1PL models, but do so with added complexity. From a theoretical measurement perspective, interval properties in ability estimates from 2PL and 3PL IRT models are more difficult to defend than for Rasch models. Item characteristic curves for given items can cross for higher and lower test-taker abilities, and this nonadditivity means that 2PL and 3PL IRT models are not guaranteed to meet the double cancellation condition or have a probabilistic relationship to conjoint measurement. Ability estimates are nevertheless sometimes described as interval scales because 2PL and 3PL IRT models produce probabilities that are invariant under different linear transformations of their parameters for a specified functional form and population distribution (contrasting points are made about this description in Briggs et al., this volume, endnote 10, and Mislevy, 2018, pp. 316–317). Empirical research on interval scales from these IRT models has been encouraged (Michell, 2008), and statistical tests may be possible for the 2PL model (Kygndon, 2011).

From an interpretational perspective, MLE and EAP ability estimates from 2PL and 3PL models are more complex and more difficult to understand than those based on simple sums of equally weighted item scores (i.e., the usual TCC). The weighting of individual items in the scoring is likely to be less closely aligned to the intended test content as determined by test developers and described in test specifications (Kolen, 2006). The complexity of ability estimates based on pattern scoring implies more complicated scoring rules and increased difficulty in communicating, understanding, and explaining scoring and advising on how test takers might maximize their performance. For MLEs based on the 2PL model, items with higher discriminations make greater contributions to test takers' ability estimates, which creates fairness issues when these differentially important items are not communicated to test takers (Dorans, 2012). For the 3PL model, MLEs reflect differentially weighted items for different test takers (i.e., for less able test takers, correct item responses tend to count less and are more likely attributed to guessing; Lord, 1980, p. 75). This characteristic was described by Mislevy (2012) as “unsettling” and tough to explain (p. 39). The fairness of pattern scoring based on the 3PL model is questionable and has been described as a challenge for establishing comparability in adaptive tests (Phillips, 2016, p. 258). A complication with EAP estimates is that they reflect not only test performance in item pattern scores, but also a test-taker ability distribution (Kolen, 2006).

ABILITY ESTIMATES FROM MORE COMPLEX MODELS Scoring approaches have been developed and considered that are even more complex than those that have been previously described. These approaches are developed based on a range of motivations. One

is to obtain scores on noncognitive traits assessed with faking resistant forced-choice item formats using item parameter estimates obtained in previous administrations of those items in formats that are not faking resistant (Drasgow et al., 2012; Stark et al., 2005). Other efforts score tests composed of family-generated clone items using IRT methods like Equations 4–6 based on parameters from the item families rather than parameter estimates for the items test takers actually take (cautions provided in Drasgow et al., 2006; Harris, 2023; Luecht & Burke, 2020; van der Linden & Glas, 2010). Other efforts are being considered for measuring response processes like test-taking strategies, thought processes, and behaviors like reading, interpretation, and strategy formulation with response times, computer screen gazes, verbalizations, and other process information (Ercikan & Pellegrino, 2017). Deep-learning neural network models might be considered for automated scoring versions of subjective human scoring of test takers' writing (Zesch et al., 2023).

For complex scoring approaches, test takers' test performance measures might reflect not only their performance on the test and items they take, but also other unspecified aspects of the scoring procedures. Scoring based on item families can produce test-taker scores that reflect errors in the IRT parameter estimates of items they may not actually take. Complex scoring algorithms can be difficult to interpret and explain (Lottridge et al., 2023; Zesch et al., 2023), and the resulting test performance measures may reflect reduced accuracy and fairness, or unrepresentativeness in the data used to train the models (Broussard, 2020; Hussein et al., 2019; W. Lee & Harris, this volume). Performance measures that reflect test-taking processes can warrant validation efforts and attention to the processes different test takers use to optimize their performance (Kane & Mislevy, 2017; Wise, 2017). These approaches to representing test performance are mentioned here to illustrate recent trends for increased complexity and, likely, increased difficulty in explaining, justifying, and defending scales for the resulting performance measures.

Scaling Methods for Primary Scale Scores

The approaches to representing test performance described in the *Basic Unit of Scaling* section are usually considered inadequate for use as a testing program's reporting scale (Angoff, 1971; Kolen, 2006). Observed test scores represent test performance in ways that are specific to a test form, its items, and its measurement characteristics (difficulty, reliability, etc.). Under strong assumptions, IRT ability estimates may be regarded as theoretically independent of a test form and its items, but even if these assumptions are met in practice, the ability estimates have their own interpretational difficulties because of their similarity to standard normal variables, with means near zero, and small numbers with decimals that can be negative or positive. Consistent with the scaling discussions from earlier *Educational Measurement* volumes (Angoff, 1971; Flanagan, 1951; Kolen, 2006; Petersen et al., 1989), scale scores established from untransformed observed scores, $sc(Y) = Y$, or untransformed estimated IRT thetas, $sc(\hat{\theta}) = \hat{\theta}$, are not recommended.

The task in scaling is to develop a numeric transformation of a measure of test performance that assigns numbers or ordered indicators such that the scale scores,

$sc(Y)$, reflect monotonically increasing levels of achievement. For large-scale testing programs, this task of establishing scale transformations is intended to be applied not only to the scores of test form Y , but also to other alternate versions of Y developed, administered, and equated (see the *Equating* section) to Y . Another goal of scaling is that the scale scores be established to facilitate score interpretations and discourage misinterpretations. In this section, different scale score transformations are reviewed that focus on the structure, normative, shape, measurement, and content aspects of reporting scales. In each subsection, methods and intended interpretations are described.

Reporting Scale Basics

Some aspects to be determined for a testing program's reporting scale are structural, such as the scale score range and number of possible points. Recommendations are usually to establish the range of the scale scores in such a way that the scores cannot be easily interpreted as observed test score performance (Dorans, 2002; Kolen, 2006; Livingston, 2004). For example, scale score ranges such as 100–200 (Praxis) and 200–800 (SAT) are wide enough to impede unwarranted guesses about the relationship between the number of items and scale score points. The GRE scale score range (130–170) and the ACT range (1–36) are also not likely to be interpreted as simple transformations of raw scores.

Another aspect to consider in scale scores is the interval, or the number of possible scale score points reflected in the range of the scale scores. Most recommendations are to establish the scale score interval such that it represents the available information or precision of the test (Dorans, 2002; Flanagan, 1951; Kolen, 2006; Livingston, 2004). When intervals are too fine, the resulting scores could lead users to overinterpret score differences, such as on pre-1970 SAT scales of 200–800 in integer units (Livingston, 2004). When scale score intervals are more coarse than test performance (e.g., stanines), then the scale scores can result in lost information (Flanagan, 1951; Kolen, 2006) or test takers with very different test performance receiving the same scale score (Dorans et al., 2010).

Scale score intervals might be established based on simple recommendations, such as ensuring that the possible scale score points do not exceed the number of observed score points on the test (Dorans, 2002) or establishing desired confidence intervals for true scores or scale scores (Kolen, 2006). Kolen (2006) summarized two proposals for establishing scale score points that reflect desired confidence intervals for true scores for the Iowa Tests of Educational Development (ITED, 1958) and more generally (Kelley, as cited in Kolen, 2006, p. 165). These procedures are based on assuming that measurement error is normally distributed and constant across the scale, that the reliability of test performance is known or well estimated in population P , and that the scale score transformation is linear. With these assumptions, a scale score transformation that reflects true score confidence intervals could be established based on

$$6\sigma_{sc(Y),P} = 6 \frac{h}{z_Y \sqrt{1 - rel_{Y,P}}}, \quad (7)$$

where h is the width of the desired scale score interval, z_γ is the standard normal z -score associated with the desired γ 100% confidence interval, $rel_{Y,P}$ is the reliability of Y in population P , $\sigma_{sc(Y),P}$ is the standard deviation of $sc(Y)$ in P , and $6\sigma_{sc(Y),P}$, when rounded, provides a recommended number of distinct scale score points. For the ITED implementation in Equation 7, the scale score units are set such that adding or subtracting one scale score point establishes a 50% confidence interval for true scores (i.e., $h = 1$ and $z_\gamma \approx .6745$ for $\gamma = 50\%$). For Kelley's implementation of Equation 7, the scale score units are set such that adding or subtracting three scale score points establishes an approximate 68% confidence interval ($h = 3$ and $z_\gamma \approx 1$ for $\gamma = 68\%$). From Kolen's (2006) summary of these proposals, Kelley's rule generally leads to about twice as many scale score points as the ITED rule. For both approaches, the number of recommended scale score points decreases as reliability decreases. Equation 7 can be used with any measure of test performance for which a reliability estimate is available, including an IRT θ . Once used, a linear scale score transformation is found that produces scale scores with a range of units that is consistent with Equation 7.

Another structural aspect of scale scores is the level of truncation, where recommendations are for the range of minimum and maximum reported scale scores to be narrower than the actual scale score range (i.e., the working range, Dorans, 2002). Truncation of the maximum scale scores has been recommended because it avoids interpretational difficulties such as conveying perfect test performance on test forms that differ in difficulty and have different untruncated scale scores (Livingston, 2004). Truncation also helps make the resulting scale scores more resistant to shifts in score distributions due to changes in the population or in the difficulties of the test forms (Dorans, 2002). Establishing a minimum reported scale score that is higher than what is suggested by the scale score transformation can be useful for avoiding meaningless distinctions at test performance levels lower than theoretical guessing levels where measurement is less precise (Livingston, 2004).

Finally, consider that a reporting scale can be established to specify the scale score that should correspond to one or more specific observed scores of Y . The situation of interest is one for which a scale score transformation is established such that two observed scores of test Y , y_1 and y_2 , will have prespecified scale scores, $sc(y_1)$ and $sc(y_2)$:

$$sc(y) = sc(y_1) + (y - y_1) \frac{sc(y_2) - sc(y_1)}{y_2 - y_1} \quad (8)$$

This transformation has been described as a basis for a scale score range of 100–200 on Praxis (Livingston, 2004).

Normative

When establishing scale scores, a common desire is for the scale scores to represent a test-taker group of interest in terms of one or more statistics (i.e., statistics of a reference

group or sample of population P taking test Y ; Table 11.1). Scale score conversions might involve transformations of the observed test performance on Y to a specified scale score value. One commonly used linear transformation converts the mean and standard deviation of test performance in population P , $\mu_{Y,P}$ and $\sigma_{Y,P}$, to desired scale score values, $\mu_{sc(Y),P}$ and $\sigma_{sc(Y),P}$:

$$sc(y) = \mu_{sc(Y),P} + (y - \mu_{Y,P}) \frac{\sigma_{sc(Y),P}}{\sigma_{Y,P}}. \quad (9)$$

Equation 9 can be used to establish raw-to-scale score transformations that satisfy several scaling criteria. For example, to satisfy a recommendation that the scale score mean be set at the center of the possible scale score range (Dorans, 2002), Equation 9 might be used to set the mean test performance for a test-taker group to be $sc(y) = 500$ for a 200–800 range (SAT; Dorans, 2002) or 18 for a 1–36 range (ACT; Brennan, 1989). Also, Equation 9 might be used to produce a set of viable raw-to-scale score transformations that vary in how they satisfy different criteria for numbers of distinct scale score points (Equation 7) and how far the actual scale scores extend below and above a truncated range of scale scores, as well as to establish the means and standard deviations for nonlinear raw-to-scale score transformations (reviewed next).

Another example of a linear scale score transformation that reflects the normative information for a group of test takers is to establish a desired scale score standard deviation and a conversion of one particular score, y_1 , to $sc(y_1)$,

$$sc(y) = sc(y_1) + (y - y_1) \frac{\sigma_{sc(Y),P}}{\sigma_{Y,P}}. \quad (10)$$

where $\sigma_{sc(Y),P}$ is the intended standard deviation of the $sc(y)$ s in population P . Linear raw-to-scale transformations such as Equations 9 and 10 establish scale scores as linearly increasing indications of test performance, retaining the shape (skewness and kurtosis) of the raw scores in the scale scores.

Nonlinear Transformations

Nonlinear transformations can be used to establish scale scores that encourage interpretations based on scale score basics (see the *Reporting Scale Basics* section), distribution shape, or measurement precision. Rounding scale scores to integers or other units can establish scale scores that convey an intended range of possible scale score points. Truncating the lowest and highest possible scale score values to intended values also helps to consistently maintain the structural aspects of scale scores. Nonlinear raw-to-scale score transformations might also be developed to satisfy other criteria. These might be subjected to an additional linear transformation like Equation 9 to reflect aspects such as the intended range and number of possible scale score points.

One nonlinear transformation involves establishing scale scores that are approximately normally distributed. The resulting scale scores can then be described as symmetric and reflective of a shape that is familiar to test users (Dorans, 2002; Petersen et al., 1989). Normally distributed scale scores can be established by first obtaining the

percentile ranks or “percent at and below” for a measure of performance on test Y (Kolen & Brennan, 2014). For this discussion, consider the measure of test performance to be the raw scores obtained as the sum of I items, y_k , $k = 1$ to I , where the actual scores range from 0 to y_I . A continuized version of the scores is assumed where each individual score, y_k , ranges from $y_k - .5$ to $y_k + .5$ and the entire set of continuized scores ranges from $-.5$ to $y_I + .5$. The percentile ranks for these continuized scores can be computed as

$$\begin{aligned} G_P(y_k) &= 100 \left\{ \sum_{y_j < y^*} Pr_P(y_j) + \right. \\ &\quad \left. \left[y_k - (y^* - .5) \right] Pr_P(y^*) \right\}, \quad -.5 \leq y_k < y_I + .5 \\ &= 0, \quad y_k < -.5 \\ &= 100, \quad y_k \geq y_I + .5, \end{aligned} \quad (11)$$

where $Pr_P(y_k)$ is the relative frequency at score y_k for population P and where y^* is the closest integer to y_k such that $y^* - .5 \leq y_k < y^* + .5$. Values of the standard normal distribution are found, z_k , such that their cumulative distribution values, $\Phi(z_k)$, equal a function of the percentile ranks of the y_k s,

$$G_P(y_k) / 100 = \Phi(z_k) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{z_k} e^{-w^2/2} dw. \quad (12)$$

In Equation 12, w is a variable that assumes values ranging from $-\infty$ to z_k in the integration denoted by $\int_{-\infty}^{z_k} \dots dw$. The resulting z_k s can be linearly transformed to have an intended mean and standard deviation (Equation 9) and rounded and truncated to have the intended range of possible scale scores. The normal transformation was used to establish recentered SAT scales in 1995 based on the 1990 reference group of graduating seniors (Dorans, 2002). Other examples provided by Kolen (2006) and Kolen and Brennan (2014) illustrate that the normal transformation is approximate and that its closeness to the normal distribution depends on the distribution of the raw scores.

Another motivation for nonlinear transformations is producing scale scores that provide a stabilized version of conditional measurement error. That is, testing standards call for reporting conditional standard errors of measurement (CSEMs) for several scores if CSEMs differ across the score range (AERA et al., 2014). For most psychometric models, the CSEMs of scores are small for the highest and lowest unscaled true scores and large for true scores in the middle of the range (Lord & Novick, 1968). Kolen (1988) proposed an arcsine transformation developed by Freeman and Tukey (1950) for use as a scale score transformation of number-correct true scores. Assuming that the errors of number-correct true scores follow a binomial, compound binomial, or IRT model (Kolen, 2006), scale scores having approximately equal CSEMs across their range can be produced as

$$g(y) = .5 \left\{ \sin^{-1} \left[\frac{y}{I+1} \right] + \sin^{-1} \left[\frac{y+1}{I+1} \right] \right\}. \quad (13)$$

The resulting scale scores can be reported and described as reflecting a single standard error of measurement (SEM) value across the range of true scores (Kolen et al., 1992). They can also be further transformed to have an intended mean and standard deviation (Equation 9) and rounded and truncated to have an intended range of possible scale scores. Arcsine transformations have been used to establish scales for the ACT (Brennan, 1989) and the 2016 redesigned SAT (Y. K. Kim et al., 2016).

Nonlinear transformations to achieve normal distributions or to stabilize CSEMs can have interpretational difficulties. Both types of transformations can result in extreme stretching of the highest and lowest scale scores, exaggerating scale score results and creating gaps (missing scale scores) for the highest and lowest levels of test performance. These methods can also produce scale scores with inconsistent properties, such that arcsine transformations can result in more skewness (less symmetry) in the scale score distributions. A conceptual issue with CSEM stabilization is that the scales are established for true scores and applied to observed scores.

To produce a scale score transformation that could achieve symmetry with less extreme conversions of the highest scale scores, Moses and Golub-Smith (2011) proposed a cubic transformation of raw scores,

$$sc(y) = \delta_0 + \delta_1 y^1 + \delta_2 y^2 + \delta_3 y^3, \quad (14)$$

where the δ s are derived to achieve a desired mean, standard deviation, skewness, and kurtosis in the scale scores (and also to satisfy a constraint that the scale scores are monotonically increasing). This procedure can be used to approximate the normal distribution, but to varying degrees that produce less extreme transformations and fewer gaps at the highest and lowest scale score regions. This procedure was used to set the scales of the revised GRE (Golub-Smith & Moses, 2014). Another version of the cubic transformation was proposed by Moses and Kim (2017) to produce scale scores that would stabilize an inputted set of CSEMs. This procedure was used to set one of the scales of the 2016 redesigned SAT (Y. K. Kim et al., 2016). Moses and Kim (2017) also showed how cubic transformations could be established that satisfy a set of scaling criteria to varying degrees, such as by making scale score CSEMs more similar while also targeting scale score symmetry. Finally, because CSEMs are inputs in developing the scale score transformation, the cubic transformation can also target stabilizations for a limited number of scores involving consequential decisions (i.e., cut scores; Lord, 1985) or for different measures of test performance, such as CSEMs at IRT θ s or at true scores and test performance measures for mixed format tests. Another situation where the flexibility of the cubic transformation might be utilized is stabilizing true score intervals for a specified range of observed scores (Lord & Novick, 1968), an application that would likely produce different scaling results than those produced to stabilize CSEMs given true scores. Finally, the cubic transformation could be extended to fit even higher moments in a targeted distribution (Headrick, 2002).

Interval Scales

Some discussions of psychological measures (Michell, 2008) and vertical scales (Briggs, 2013) have taken issue with claims that psychological and educational measures can be interpreted as quantitative and as having interval properties. A recommendation from these perspectives is that assumptions for the treatment or interpretation of variables as quantitative should be explicitly acknowledged or, better yet, should prompt empirical evaluations such as empirical tests of whether the variables meet conjoint measurement conditions (see the *Scaling Perspectives* and *Basic Unit of Scaling* sections, Michell, 2008). As suggested in the *Basic Unit of Scaling* section, most available measures of test performance are difficult to establish as quantitative scales for the above notion of “quantitative.” Some apparent consequences have been described in the context of vertical scaling (Briggs, 2013), where the intent is to establish a scale where growth across grades can be measured and interpreted with respect to interval interpretations (see the *Vertical Scaling* section). Claims about vertical scales exhibiting interval properties might be made by test publishers, claims that have been discussed as inconsistent with growth rates observed to vary across lower versus higher grades or across lower versus higher parts of the scale score distribution (Briggs, 2013; Hoover, 1984). Empirical evaluations for the existence of intervals in vertical scaling results have been suggested by Briggs and Domingue (2013).

The starting point for establishing a scale with interval properties is a measure of test performance with interval properties. From the *Basic Unit of Scaling* section there are at least three possibilities:

- operationalist or pragmatic perspectives of the observed test scores as interval-based indices of performance for a specific test form
- Rasch ability estimates from test data shown to fit a Rasch model, specifically with empirically demonstrated double cancelation and conjoint measurement conditions
- ability estimates from 2PL or 3PL models, based on arguments about the specification and invariance of the probabilities from these models under different linear transformations

Following Stevens (1946), linear scale transformations (Equations 8, 9, and 10) of these test performance measures would retain the established, or argued-for, interval properties, whereas nonlinear transformations would not. Note that the linear transformation would apply to one of the three possibilities but not to all three, because the three possibilities cannot coexist because of inconsistencies in the assumed model (Rasch vs. 2PL or 3PL) and nonlinear relationships in observed test scores and IRT-based abilities.

Scales for Exams With Cut Scores

For K–12 and certification and licensure tests, the interest is in reporting performance for a limited number of performance categories rather than on the entire range of a score scale. For example, test takers might be placed into *Proficient* and *Nonproficient* categories or into levels of certification, achievement, or competence. The performance

reporting for these types of tests would be oriented more to classification results and less to the properties of an entire range of scale scores. Cut scores and classifications would have increased importance, such that representing test performance relative to cut scores involves a classification problem with unique implications for measurement, CSEMs (Lord, 1985), and other properties of the classifications.

Some proposed procedures for cut scores are adaptations of what was described in the *Reporting Scale Basics* section. For tests with a long range of reported scores, Dorans (2002) recommended scale scores centered at the midpoint of the scale, with a working range that extends beyond the reporting range and with scale score units that do not exceed the number of possible raw score points. For tests with a small number of cut scores, Dorans et al. (2010) recommended that scales be established that are centered near the cut score(s), with score points not exceeding the number of raw score points, and with working ranges wider than reporting ranges, all of which would accommodate shifts in test difficulty and potential additions of new cut scores. For both types of tests, the score scale should be regarded as infrastructure likely to require repair and corrective action. Recommendations are for test assembly and scaling procedures that focus on the cut scores of interest. Also, CSEMs that are equal across the entire range of a test's scores might be less important than ensuring that the CSEMs are small near a cut score of interest (Lord, 1985).

Other procedures for establishing scale scores for tests with cut scores are content based and not data, sample, or population based as described in Table 11.1. The most well known of these are standard-setting procedures (Hambleton & Pitoniak, 2006; Ferrara et al., this volume), which begin with a statement of what competent test takers know and are able to do and then search for potential cut scores judged to reflect these statements. Various standard-setting methods can be used to ask a set of judges to work with or produce statements for what they think test takers should be able to do at a specific performance level and then identify through judgmental processes the test questions and performance that correspond to these statements. Although the basis of standard-setting procedures is primarily judgment and test content, the process is often supplemented with test performance data, such as item and test performance, and results indicative of the impact of cut score recommendations on scale score distributions.

Scales for Test Batteries and Composites

For a battery of tests covering different content areas, scales might be established using the same scaling methods with all tests in the battery, as taken by the same test-taker group. The resulting scales for each test in the battery can facilitate similar interpretations for scores in each of the tests, such that test takers' strengths and weaknesses are revealed in their scores on the battery. One of the earliest examples of battery scaling was proposed by Kelley (1914, 1923) for establishing comparable units (i.e., same means and standard deviations in the reference population) for the handwriting scoring method proposed by Thorndike (see the *Scaling Perspectives* section) and another scoring method. From a discussion of alternative proposals for establishing comparable scores from the two scoring

methods of handwriting, Kelley proposed establishing comparable measures as standard scores similar to Equation 9. More recent examples of battery scaling are the recentered SAT (Dorans, 2002), where the SAT Math and Verbal scales were both established based on normal distributions with means of 500 and standard deviations of 110. The 2016 redesigned SAT also targeted similar Math and Evidence-Based Reading and Writing (ERW) Section score means and standard deviations (Kim et al., 2016). The ACT rescaling targeted means of 18 with constant SEMs (Brennan, 1989), but different scale score standard deviations. The scale scores for each of these batteries can encourage different types of interpretations, such that test batteries for normalized scales might facilitate references to percentiles of the normal distributions, those established with similar means and standard deviations might facilitate references to standard deviation units, and those established based on stabilized SEMs might encourage SEM-based score distinctions rather than distinctions based on standard deviation units (Kolen, 2006).

Composite scores might be formed based on linear combinations of the scores on each test in the battery. For example, the Total score of the 2016 redesigned SAT is the sum of the Math and Evidence-Based Reading and Writing Section scores, and the ACT Composite score is the average of the math, science, English/writing, and reading test scores. Both examples are reflections of nominally weighted scores. Other weighting procedures such as those based on effective weights and the proportional contribution of test score variances to the composites can produce different composite score scales, to the extent that the test scales have different standard deviations and the tests have different correlations with each other (Brennan, 1989; Kolen, 2006). The scaling characteristics of batteries and composites of multiple tests are affected by the scaling results for the individual tests, the scale score standard deviations of the individual tests, and the intercorrelations among the scale scores of the tests. Because scales are usually set and maintained on individual tests, the scale score characteristics for batteries and composites are more difficult to establish and maintain. The *Battery Scaling and Composites* section provides further discussion and an example of these issues.

Auxiliary Scales

After one or more primary scales are set, additional procedures and methods can be used to convey enhanced interpretations of the primary scale scores. For auxiliary scales, the goal is less about building interpretations directly into the scales themselves and more about supplementing the primary scales with additional interpretive information. Two categories of interest are based on normative information and on content.

Auxiliary Scales Based on Norms

Norms refer to the statistical information that could be provided and used to describe performance associated with different scale scores, such as the scale score mean, standard deviation, and percentile ranks (Equation 11 applied to $sc(Y)$) for one or more test-taker groups. Norms might be determined for groups sampled from particular populations. Sometimes the group used to establish norms is the same sample from

population P used to establish the scale scores, in which case the norms of $sc(Y)$ are consistent with the statistics (i.e., means, standard deviations) directly established in the distribution of $sc(Y)$. Previous volumes of *Educational Measurement* have listed options for norms groups and reporting (Angoff, 1971; Flanagan, 1951; Kolen, 2006; Petersen et al., 1989), presented here with an update.

- National norms: Describe test performance from nationally representative test takers at the age or educational level for which the test was designed.
- Local norms: Describe test performance from test takers from specific educational or geographic units.
- User norms: Describe test performance from test takers who take the test during a given time period.
- Convenience norms: Describe test performance from test takers who are available at the time a test is constructed.
- Group-level norms: Describe aggregated test performance from groups, such as average performance for schools, districts, or states.
- Item-level norms: Describe the performance on specific items for a norm group.
- Skill-level norms: Describe the performance on sets of items measuring a particular skill for a norm group.
- Growth norms: Describe test performance for a group of students (e.g., K–8) that takes at least two tests at different grades, usually where separate sets of norms on the second test are reported for subgroups of students obtaining different scale scores on the earlier test (Betebenner, 2009; Castellano & Ho, 2013).

Typically, national norms that describe test performance for nationally representative test takers need the most technically elaborate norming studies. National norming studies require that the national population of interest is precisely defined in terms of students, schools, etc. A sampling plan is developed to include test takers for whom norms will produce accurate estimates of the population norms. National norming studies may use several sampling approaches to increase the representativeness of the test takers and resulting norms, including simple random sampling, random sampling within defined strata of student characteristics (e.g., geographic region, school type), cluster sampling of test-taker groups (e.g., schools), or systematic random sampling that reflects the ordering of a variable related to the test scores of interest in the norms study. Often, national norming studies use a combination of sampling and statistical weighting procedures to obtain schools and test takers and increase their national representativeness. Approaches to national norming studies by the National Assessment of Educational Progress (NAEP, <https://nces.ed.gov>) and by ACT were compared in terms of their methods, complexity, and practical challenges by Kolen (2006). Other types of norms (user, convenience, etc.) might be produced using less elaborate procedures (e.g., test takers available at the time the norms are produced). Such norming groups may be less stable and more likely to change (Petersen et al., 1989).

Auxiliary Scales Based on Content

Some auxiliary scales are attempts to supplement primary score scales with content-based descriptions of specific scale scores. One example involves item mapping, or finding a set of items that represents various scale score points. In the case of NAEP, these items “help to illustrate what students know and can do in NAEP subject areas by positioning descriptions of individual assessment items along the NAEP scale at each grade level” (<https://nces.ed.gov>). For item mapping, the scores of individual items are regressed on scale scores using logistic regression or an IRT model. Then a response probability is adopted to divide test takers into groups with “higher” and “lower” probabilities of success on test items. The actual values used to divide the higher and lower probability groups could be .5/.5, .8/.2, or other probabilities for dichotomously scored items. In NAEP, these groups are divided using probabilities based on 74% for MC items and 65% for CR items. These response probability values were obtained based on work by Huynh (1998), who showed that these values correspond to the maximum IRT-based information provided by a correct response to MC or CR items. The result of item mapping is a list of test questions that represents various scale score points, with content-based descriptions that take the form of phrases that describe what test takers can do correctly, in general terms rather than for one or more specific items (Kolen, 2006; Kolen & Brennan, 2014).

Scale anchoring is another type of content-based auxiliary scale, with the goal of providing general statements about what students obtaining different scale scores would know and are able to do (Kolen, 2006). Item maps are a first step to scale anchoring. Additional steps involve choosing a set of scale score points across the score scale range, where items that map at or near these points are chosen to represent these points. Then subject matter experts review the items mapping near each point and produce statements presenting the skills of test takers scoring at these points, assuming test takers also know and are able to do all of the skills in the statements at or below the given score level. Scale anchoring has been used in NAEP (Allen et al., 1999) and in ACT (2001). The Binet–Simon (Binet & Simon, 1916) test described in the *Scaling Perspectives* section can also be viewed as a test with sets of items specifically anchored to different scale scores. Item-mapping and scale-anchoring procedures have raised questions about whether their outcomes actually facilitate score interpretations (Forsyth, 1991). The content-based labeling produced with scale anchoring appears to be the result of overly subjective and confusing judgmental processes (Pellegrino et al., 1999) that may not be supported by statistical analyses (Haberman, Sinharay, & Lee, 2011; Thurstone, 1925) or by items that are sufficiently discriminating (Dorans, 2018).

Summary of Primary and Auxiliary Scales

Reporting scales should be viewed as infrastructure in need of monitoring and possible repair (Dorans, 2002). For the primary scaling approaches reviewed in the *Scaling* section, potentially important checks for primary scales include checks for excessive accumulations at the top, middle, or bottom parts of the scale; checks that the score means do not excessively depart from the midpoint of the scale; and other checks that

properties like distribution shapes, CSEM values, etc., are established and maintained as intended. As described in the *Scales for Exams with Cut Scores* section, primary scales can also be established and monitored in terms of cut scores of interest, including distributions resulting from pass/fail decisions and CSEMs at or near those cut scores. These possible checks suggest different types of monitoring for primary scales established in different testing contexts. In admissions testing where testing companies develop tests for users to employ different parts of a relatively long scale, monitoring should focus on the entire score range. In K–12 and certification and licensure programs, the focus is primarily on classifications at one or very few cut points, and the monitoring of scale scores would likely focus on pass/fail distributions, classification accuracies, and CSEMs at specific cut scores. Scale maintenance for large-scale survey assessments like NAEP might focus on the estimation of population and subpopulation scale score distributions and classifications over time. In each of these contexts, scales established in special studies should be checked to ensure that their results will accurately apply beyond these scaling studies and to the intended testing population. The auxiliary scales that might be established and reported for a particular testing program should also be monitored for potential changes due to testing population changes and other potential changes in content-based descriptions. The equating procedures described in the *Equating* section are needed for preserving established primary and auxiliary scales.

EQUATING

For a large-scale testing program, the establishment of a reporting scale as described in the *Scaling* section usually comprises only an initial step for a single test form (Y). Usually Y is the first of many test forms to be developed and administered. Additional work is needed to develop, administer, and report scores for the subsequently developed test forms for that testing program. Equating is used to address unintended difficulty differences in the scores of these alternate forms, so that the previously established reporting scale is maintained (Holland & Dorans, 2006; Kolen & Brennan, 2014). This section describes equating in an updated version of the discussion from Holland and Dorans (2006), which itself was a continuation of previous discussions from Petersen et al. (1989), Angoff (1971), Flanagan (1951), and others.

The *Distinguishing Equating From Other Forms of Linking* section describes some general concepts about equating and its distinctions from other types of linking based on goals, interpretations, and computational procedures. Equating history and requirements are covered in the *History of Equating* and *Equating Requirements* sections. The data collection designs used in different types of equating are described in the *Data Collection Designs* section. The final section covers *Methodological Implementations of Equating*. The different equating approaches covered in these discussions are summarized in Table 11.2 in terms of the equating definition, method(s), assumptions, and likely data collection designs.

Table 11.2 Summary of Types of Equating

Definition of Equating	Method(s)	Assumptions	Data Collection Design(s)
Align the means and standard deviations of observed scores of alternate test forms (common population)	Linear scale alignment	Tests measure the same construct; population invariance; equity	Randomly equivalent groups; single groups; counterbalanced
Align the distributions of observed scores of alternate test forms (common population)	Equipercentile		
Align the means, standard deviations, and/or distributions of observed scores of alternate test forms (different populations)	Tucker, Braun–Holland; frequency estimation/poststratification	Tests measure the same construct; population invariance in the conditional test-given-anchor distributions; equity	NEAT
	Chained linear; chained equipercentile	Tests measure the same construct; population invariance in the two chained functions; equity	NEAT
	Levine observed score; modified frequency estimation	Tests and anchors are congeneric; population invariance in the conditional Test-given- $\hat{\tau}_A$ distributions; equity	NEAT
	IRT observed score	Items measure the same construct; the IRT model fits the data; IRT parameter estimates for all items are on the same scale and invariant across administrations; equity	NEAT (this method is also used with randomly equivalent groups, single group, and counterbalanced)
Align the means and standard deviations of true scores of alternate test forms (different populations)	Levine true score	Tests and anchors are congeneric; true score results can be applied to observed scores; equity	NEAT
Link true scores via an expected test-given-ability relationship based on an IRT model	IRT true score	Items measure the same construct; the IRT model fits the data; IRT parameter estimates for all items are on the same scale and invariant across administrations; true score results can be applied to observed scores; equity	Randomly equivalent groups; single group; counterbalanced; NEAT
Score test takers using item parameter estimates obtained and linked in previous administrations	IRT ability estimation	Items measure the same construct; the IRT model fits the data from the previous calibrations; parameter estimates are invariant across administrations with minimal context and order effects; equity	Pre-equating

Note. IRT = item response theory; NEAT = nonequivalent groups with anchor test.

Distinguishing Equating From Other Forms of Linking

Equating is one type of linking procedure for transforming the scores of one test form to another (Holland, 2007; Holland & Dorans, 2006; Pommerich, 2016). Specifically, equating adjusts the scores of test forms constructed and administered in the same way for unintended difficulty differences. Within a linking hierarchy, equating is the strongest among several types of linking, distinguished in terms of interpretations and computational methods (Angoff, 1971; Flanagan, 1951; Holland & Dorans, 2006; Mislevy, 1992; Petersen et al., 1989).

Different categories of linking can be used to achieve different goals and support particular interpretations of the linked scores. When equatings of alternate forms of the same test are produced (X and Y), the expected result is interchangeability in the reported scores, meaning that when form X is equated to form Y , the resulting X -to- Y scores can be used in place of Y 's scores for any purpose, as if those scores came from the same test (Dorans, 2013; Pommerich, 2016). For other types of linking involving different tests (i.e., X and Y are different tests), weaker and more limited results are expected. One alternative goal is comparable scales (Angoff, 1971; Kelley, 1923; Pommerich, 2016), which is one component of interchangeability that can be defined as the result of a symmetric alignment of scale score distributions that facilitates comparisons of the resulting scores. In the absence of interchangeability, comparability is group dependent (see the *Linking* section).

Another goal of linking is “best” prediction, which is an asymmetric conversion from the scores and scales of one test to another, such that prediction error is minimized. Predictions are distinguished from interchangeability and comparability in that predictions are often group dependent and always asymmetric (i.e., for given X scores, the best prediction from X to Y does not equal the best prediction from Y to X).

Scale-Aligning Computations

Scale-aligning methods are one type of computation used in test linking, including equating (Holland & Dorans, 2006). These methods can be described as score transformations that result in the scores of two test forms having the same distribution (Kelley, 1923). For example, consider test Y as a form for which a scale score transformation has been established, $sc(Y)$, and X is another test form whose scores are intended to be transformed to align to the same scale. The transformation of X to the scale of Y may be achieved through matching the marginal distributions of these forms obtained from test takers representing target population T (Holland & Dorans, 2006, p. 202, defined T as the source of the equating data and also presented other perspectives on target populations in equating). An equipercentile X -to- Y transformation produces Y scores with percentile ranks that equal those of every X score for X and Y test takers from the target population T . The equipercentile linking is produced through computing percentile ranks at each score of X (Equation 11 for score x on the distribution of X , $F_T(x)$) and obtaining the inverse of Equation 11 on the distribution of Y (i.e., $G_T^{-1}[y]$) in T ,

$$e_{Y,T}(x) = G_T^{-1}[F_T(x)]. \quad (15)$$

Equation 15 produces a symmetric X -to- Y conversion that equals the inverse of the Y -to- X conversion at the same x scores, $e_{X,T}^{-1}(y)$ at x . The X -to- Y scores have a distribution on X that approximately equals the distribution of the Y scores in population T . Simpler versions of Equation 15 can also be produced by using a version of Equation 9 to solve for X -to- Y scores that match the mean and standard deviation of Y but not other aspects of Y 's distribution,

$$l_{Y,T}(x) = \mu_{Y,T} + (x - \mu_{X,T}) \frac{\sigma_{Y,T}}{\sigma_{X,T}}, \quad (16)$$

where $\mu_{X,T}$ and $\mu_{Y,T}$ denote the population means of X and Y in T , and $\sigma_{X,T}$ and $\sigma_{Y,T}$ denote the population standard deviations. Equations 15 and 16 establish comparability through symmetric transformations that match the score distributions (Angoff, 1971; Holland & Dorans, 2006; Kelley, 1923; Pommerich, 2016). Once the results are obtained from either Equation 15 or Equation 16, X -to- Y scores can be transformed to the reporting scale by applying one of the $sc(Y)$ scale transformations described in the *Scaling* section.

Projecting and Predicting Computations

Projecting and predicting are types of linking procedures that differ from scale-aligning approaches like equating. Rather than aligning the scores of form X and form Y to have comparable score distributions for a particular group of test takers, these methods are used for the goal of producing an asymmetric, best prediction of scores or a projection of score distributions for one test to those of another. Predictions and projections can also be produced for the IRT-based thetas from different tests (Holland & Hoskens, 2003; Thissen et al., 2015). One example of a projected distribution is the percentile rank of $Y = y$ for a subgroup of test takers obtaining a specific score on $X (= x)$, $F_T(y|x)$. Another example is the prediction of the means of Y given X using a linear X -to- Y regression,

$$reg_{Y,T}(x) = \mu_{Y,T} + (x - \mu_{X,T}) \frac{\sigma_{Y,T}}{\sigma_{X,T}} \rho_{XY,T}, \quad (17)$$

where $\rho_{XY,T}$ is the XY correlation. The prediction shown in Equation 17 is a linear regression that provides an expectation of Y given X that minimizes prediction error, the variance of $Y - reg_{Y,T}(x)$, an essential supplement to Equation 17's point estimates (Thissen et al., 2015). Unlike some computational methods for scale aligning, projecting and predicting functions require data collection designs where test takers take both X and Y . Also unlike scale-aligning functions, predicting functions are not symmetric, meaning that $reg_{X,T}^{-1}(y)$ at x is not equal to $reg_{Y,T}(x)$.

Some results are of special interest for situations in which there is a perfect one-to-one relationship in X and Y . For linear functions, this situation means that the correlation between X and Y is 1 and the X -to- Y regression in Equation 17 produces the same results as the X -to- Y scale alignment in Equation 16. This result has several uses. One use is defining a situation in which a regression can be used to align scales. For example, consider the second half of Equation 6, $\sum_i w_i \Pr(V_i = 1 | \theta, a_i, b_i, c_i) = \tau_Y(\theta)$,

which can be described as a regression of IRT-implied true scores on θ (Lord & Novick, 1968, p. 386), such that these true scores have a perfect and functional (not statistical) nonlinear relationship with θ under the IRT model. When same-scale IRT parameter estimates are available for the items of tests X and Y , the IRT-based true score regressions of X and Y can be combined to produce a scale alignment of the true scores of X and Y , $\tau_Y[\tau_X^{-1}(\theta)]$, where $\tau_X^{-1}(\theta)$ denotes the inverse of the θ -to- τ_X function (i.e., τ_X -to- θ , Lord, 1980). In addition to these IRT applications, perfectly correlated X and Y true scores might also be assumed and used to produce scale alignments of τ_X and τ_Y based on classical congeneric theory (see the *Equating Requirements* section; Kolen & Brennan, 2014; Levine, 1955). Another use of the relationship of Equations 16 and 17 is to describe the strength of a linking of tests with scores that are not perfectly correlated. For example, in concordances of different tests (see the *Concordances* section), the correlation has been used as a measure to diagnose the strength of the resulting concordances (see the *Correlations and Prediction Error* section), such as by describing the extent to which a scale alignment might be used to produce score predictions that approximate the accuracy of projection or prediction functions (Dorans, 1999; Moses, 2014a).

History of Equating

The origins of equating date to the early 20th century, when an intelligence test known as the Army Alpha was developed for selection into the military for World War I (Yoa-kum & Yerkes, 1920). Alternate test forms were developed by randomly assigning items to the forms, to prevent cheating and to establish forms of approximately equal difficulty. The difficulties of the alternate forms were subjected to empirical evaluations, and for the subset of forms surviving these evaluations, the unadjusted observed scores were treated as interchangeable. The linear linking function (Equation 16) was recommended over the nonsymmetric regression function (Equation 17) for establishing comparable measures on the basis of approximating scale score distributions (Otis, 1922; Thorndike, 1922). Kelley (1923) provided more discussions of linear linking functions and an introduction of the equipercentile method (Equation 15). Nevertheless, “the need, or at least the desire, to equate scores on alternate forms of the same test probably arose decades after the invention of scaling methods and of the two standard methods for equating—the linear and equipercentile methods” (Holland & Dorans, 2006, p. 196).

Equating was described in general and in practice for the Cooperative Achievement Tests by Flanagan (1939, 1951). These discussions covered equating for the data collection designs currently referred to as the single group, randomly equivalent groups, and counterbalanced designs (see the *Data Collection Designs* section). Other emphases were on form construction and linear and equipercentile methods. Test equating for nonequivalent groups with an anchor test (the NEAT design, see the *Data Collection Designs* section) has been traced to the SAT, which administered two editions in 1938 and employed anchor equating in 1941. For this SAT application, a method attributed to Tucker and eventually named Tucker equating (Angoff, 1971) was used to implement a linear scale alignment (Equation 16) with regression-based predictions of the X and Y means and standard deviations for a hypothetical target group (Gulliksen, 1950; Holland & Dorans, 2006; Lord, 1950).

Since the early SAT equatings, additional discussions and uses have been provided, including Flanagan's (1951) comprehensive treatment of test development methods in equating, computational methods, data collection designs, a definition of comparability in equating, and, notably, a warning about likely population sensitivities and group dependences in linking results (p. 748). Lord (1950) provided a statistical overview of linear equating procedures and standard errors for various data collection designs. Angoff (1971) provided another comprehensive discussion of equating, computational methods and data collection designs, which, in contrast with Flanagan (1951), emphasized the goal of equating to produce results that are relatively group invariant (p. 563). Angoff also described situations where a linear equating function approximates the equipercentile function (i.e., when the shapes of the X and Y distributions are similar) and recommended linear functions for these situations (p. 564). Angoff's (1971) chapter has been a foundational and influential reference for decades of practice and literature on equating, scaling, and linking.

Updates to the statistical aspects of equating were provided by Holland and Rubin (1982), including a discussion of the mathematical properties of commonly used equating methods (Braun & Holland, 1982) and section pre-equating (Holland & Wightman, 1982). Interspersed in this history, proposals were made to describe and implement equating based on measurement theory, including classical true score theory (Levine, 1955), IRT (Lord, 1980; Lord & Wingersky, 1984), and other works focusing on theoretical properties such as equity of equating results with respect to true scores (Hanson, 1991; Morris, 1982) and IRT (van der Linden, 2011). The IRT developments were especially important for providing alternative theoretical and practical implementations for equating, including proposals for item-level pre-equating and IRT-based adaptive testing (Lord, 1980). Discussions and updates have continued, including the chapters in the third and fourth editions of *Educational Measurement* (Holland & Dorans, 2006; Petersen et al., 1989), subpopulation invariance evaluations (Angoff & Cowell, 1986; Dorans & Holland, 2000; Harris & Kolen, 1986), several texts (Dorans et al., 2007; Holland & Dorans, 2006; Kolen & Brennan,

2014; Linn, 1993; Livingston, 2004; Mislevy, 1992; von Davier, 2011; von Davier et al., 2004a), and software packages (Brennan, 2004; Brennan et al., 2009; Gonzalez & Wiberg, 2017).

In practice, equating has been implemented using different data collection designs for different testing programs, including programs that equate with randomly equivalent groups designs (ACT and the 2016 redesigned SAT) and others that use anchor tests to equate through nonequivalent administration groups designs (the SAT prior to the 2016 redesign). Other programs use designs suited for small samples (Puhan et al., 2009), and for pre-equating (CLEP or College-Level Examination Program, Gao et al., 2012). These implementations of test equating are summarized in Table 11.2.

Equating Requirements

In discussions of linking frameworks (Holland & Dorans, 2006), equating is described as the strongest form of linking and is subject to the strictest requirements. These requirements were listed by Holland and Dorans (2006) as a culmination of several previous discussions of equating (Angoff, 1971; Dorans & Holland, 2000; Flanagan, 1951; Kolen & Brennan, 2014; Linn, 1993; Mislevy, 1992; Petersen et al., 1989). The equating requirements are summarized in this section, including updates and clarifications from Brennan (2010), Dorans and Walker (2007), and Kolen (2007).

An equating can be used to align the scales of X and Y , such that X -to- Y and Y scores can be used interchangeably, thereby maintaining a testing program's reporting scale. For an X -to- Y transformation to be considered an equating, the X and Y test forms and the X -to- Y transformation must satisfy the following requirements:

- a. The equal construct requirement: Test forms X and Y should measure the same constructs.
- b. The equal conditions of measurement requirement: The same administration and measurement conditions should be used for X and Y .
- c. The equal and high reliability requirement: The reliabilities of X and Y , $rel_{X,T}$ and $rel_{Y,T}$, should be equal and high.
- d. The equity requirement: The X -to- Y equating should make it a matter of indifference whether test takers take X or Y , for test takers at every given ability level.
- e. The (sub)population invariance requirement: The X -to- Y equating should be population invariant, in that the choice of (sub)population used to estimate it does not matter.
- f. The symmetry requirement: The X -to- Y equating function should be the inverse of the Y -to- X equating function.

Discussions of the equating requirements describe them as aspirational concepts (Brennan, 2010; Dorans & Moses, 2023) that provide an intuitive theory of test equating (Holland & Dorans, 2006). These requirements are not likely to be perfectly met in practice, sometimes prompting criticisms for being vague, impractical, stringent,

unnecessary or impossible (Dorans & Holland, 2000; Livingston, 2004; Lord, 1980). Nevertheless, the equating requirements specify the goals of the test development, administration, scoring, and linking processes that are useful for producing interchangeable scores that maintain the reporting scales of a testing program for a target population of test takers. As described in *Linking*, the equating requirements are also useful for characterizing nonequating types of linking.

Equating requires that the test forms being equated are assembled according to the same content and statistical specifications, such that they exhibit the same measurement properties (Requirement a). Equating Requirement b emphasizes consistency in administration conditions for tests that are equated (Kolen, 2007). In describing conditions of measurement, Kolen (2007) listed aspects under the control of the test developer such as that tests *X* and *Y* are administered with the same instructions, layout, timing, scoring procedures, aids, and modes (computer or paper–pencil). Other measurement conditions that are not under the direct control of the test developer can also affect the quality of equating outcomes, including stakes for test performance, reasons test takers take the test, and type of test preparation activities.

Requirement c, that the test forms are highly and equally reliable, has received ongoing and updated clarifications. The equal reliability aspect of this requirement reflects earlier recommendations, meaning that the test forms being equated must have the same measurement precision. The requirement that forms' reliabilities be high is a more recent addition, which conveys that equating requires scores that are precise and close reflections of their true scores, that support high correlations and prediction accuracy, and that make subpopulation invariance (Requirement e) and equity (Requirement d) more likely (Brennan, 2010; Dorans & Walker, 2007; Flanagan, 1951; Holland & Hoskens, 2003; Kolen, 2004; Lord, 1980).

As stated in the *Scaling* section, many issues concerning reliability, true score variance, and error variance are, at best, imperfectly understood. They are also increasingly complex when reliability and equating are considered in greater detail and in relation to other equating requirements. The reliability requirement depends on consistently following test development procedures and specifications for test length, content, items, administration, and scoring procedures (Requirements a and b). Test forms developed from different sets of items that meet the same specifications could be assumed to be parallel in the classical test theory sense (equal reliabilities, equal true scores, and errors with equal variances). In practice, assembled forms can be imperfectly or nominally parallel (Lord & Novick, 1968) and might have unintended differences, such as differences in their mean scores attributable to their unique samples of items. Equating can be described as the application of scale-aligning adjustments that address errors attributable to forms' item samples, errors that are realized in fixed difficulty differences of the specific form(s) being equated (Li, 2023; Moses & Kim, 2015). Equating does not address the reduction of relative errors (i.e., interactions of test takers and items, as well as other unspecified sources of error; Li, 2023).¹

Forms' error variances can also be considered conditional on test-taker ability, variances that are assumed to be equal according to Equity Requirement d. One proposal based on equity applies conditional, ability-specific scale-aligning adjustments (van der Linden, 2011, 2013), which could be interpreted as an attempt to adjust scores for IRT-implied relative errors, with the forms' items and parameters being treated as fixed. As described in the *Local, Ability-Specific Test Linking* section, these local adjustments likely violate other equating requirements concerning consistency in scoring rules for a given form (Requirement b) and subpopulation invariance (Requirement e).

Different score models and associated reliability measures have equating implications and provide unique representations of reliability and error, including model-implied error variances based on fixed items (commonly used IRT models), score models that treat items as random samples, and more complex score models that account for errors across a range of admissible measurement conditions. These issues illustrate the lack of a single framework for measurement error and other types of equating error, the need for greater specificity in reliability and equating, and the importance of test form reliabilities that are high and equal in some sense for reducing the impact of these ambiguities on equating results.

Equity Requirement d states that the conditional distributions of Y and X -to- Y equated scores are equal for test takers at specific values of a latent ability based on a particular measurement model (Brennan, 2010; Hanson, 1991; Lord, 1980; Morris, 1982; van der Linden, 2011). Equity was originally defined in terms of IRT models, θ s, and θ -conditional frequency distributions (Lord, 1980). Equity is commonly expressed based on θ -conditional cumulative distributions (Kolen & Brennan, 2014; van der Linden, 2011),

$$F_{\theta}[e_{Y,T}(x)] = G_{\theta}[y] \quad \text{for all } \theta, \quad (18)$$

where the θ subscript indicates conditioning on θ .

Equity discussions based on classical test theory have focused on relationships among equating functions of observed scores, true scores, and equating requirements (Holland & Dorans, 2006; Hanson, 1991; Kolen & Brennan, 2014; Morris, 1982). Holland and Dorans (2006) attributed an equity theorem to Hanson (1991) and synthesized several equating requirements. To summarize, assume that X and Y measure the same construct and follow a congeneric model (i.e., their true scores are perfectly and linearly related) and the functional relationship of the true scores, τ_X and τ_Y , can be expressed as a scale aligning function,

$$\tau_Y = l_{\tau_Y}(\tau_X) = \mu_{Y,T} + (\tau_X - \mu_{X,T}) \frac{\sigma_{Y,T}}{\sigma_{X,T}} \frac{\sqrt{rel_{Y,T}}}{\sqrt{rel_{X,T}}}. \quad (19)$$

Substituting observed X scores into true score conversions like Equation 19, $l_{\tau_Y}(x)$ satisfies first-order equity where the conditional mean of $l_{\tau_Y}(X)$ given $l_{\tau_Y}(\tau_X) = \tau_Y$ equals the conditional mean of Y given τ_Y for all τ s. Hanson (1991) showed this first-order equity result in Levine true score equating for observed scores (see the *True Scores* section) with the nonequivalent groups with anchor test (NEAT) design (see the *Data Collection Designs* section). Holland and Dorans (2006) additionally stated that when X and Y are equally reliable, $l_{\tau_Y}(x)$ equals $l_{Y,T}(x)$ in Equation 16 and satisfies second-order equity where the conditional variance of $l_{\tau_Y}(X)$ given $l_{\tau_Y}(\tau_X) = \tau_Y$ equals the conditional variance of Y given τ_Y for all τ s. Brennan (2010) provided a related discussion that considered quadratically represented curvilinear equating functions, showing that curvilinear equating functions are more likely to satisfy first- and second-order equity if the reliabilities of X and Y are not only equal, but also high (nearly linear equating functions are also helpful, but less realistic). Altogether, these results connect several equating requirements, such that X and Y are assumed to measure the same constructs (Requirement a), are administered under the same conditions (Requirement b), with scores that have equal and high reliabilities (Requirement c), and where the equating is a symmetric scale alignment of the forms' observed scores (Requirement f) that approximates the functional relationship of their true scores and achieves first- and second-order equity (Requirement d) (Holland & Dorans, 2006). The results represent one of the most general theories of equating available, including all but one equating requirement (i.e., the subpopulation invariance requirement is out of scope, since the results are based on a fixed target population, T ; Holland & Dorans, 2006).

Equating Requirement e emphasizes that the same X -to- Y linking results should be obtained if estimated in T and in subpopulation T_g ,

$$e_{Y,T_g}(x) = e_{Y,T}(x) \quad \text{for each } T_g. \quad (20)$$

The subpopulation invariance requirement is more likely met when X and Y are constructed to be similar and of high reliability (Dorans & Holland, 2000; Flanagan, 1951; Kolen, 2004). The invariance requirement of equating has been especially important for use in the empirical evaluations of nonequating types of linking (see the *Linking* section) and also for linkings intended to be used as equatings. Indices for quantifying the extent to which equating functions vary by subgroup are summarized in the *Subpopulation Invariance Evaluations* section.

Requirement f indicates that asymmetric prediction and projection functions cannot be used as equating functions because asymmetric functions mean that it is not a matter of indifference which form test takers take. Symmetric functions like Equations 15 and 16 can be described as a computational realization of comparable scales (i.e., comparable scale score distributions; Holland & Dorans, 2006; Kelley, 1923).

Data Collection Designs

Data collection designs for test equating are summarized in Table 11.1 and described in detail in several texts (Angoff, 1971; Dorans, 2018; Dorans et al., 2010; Holland & Dorans, 2006; Kolen & Brennan, 2014; Kolen, 2007; Petersen et al., 1989; von Davier et al., 2004a). Each design is an approach to obtaining test data such that an equating of the forms' scores will estimate differences in test difficulty and other characteristics, where the estimates (a) control for the abilities of the test-taker groups taking both X and Y and (b) reflect target population T . Successful data collection designs are essential for obtaining data from which accurate equating and other scale alignment and projection functions can be estimated.

The simplest test equating design shown in Table 11.1 is the single group design, where one sample of test takers from population $P (= T)$ takes both X and Y . This design can use relatively small samples to produce statistics that accurately reflect their population values. The necessary conditions for this design are that it must be realistic for test takers to take both tests and that the resulting data are not adversely affected by timing issues, testing fatigue, learning, or order effects. Scale-aligning, predicting, and projecting methods are all possible with the single group design, but satisfying the necessary conditions can be challenging. One advantage of this design is that a correlation between the two tests can be estimated to enable a direct check on Requirements a and c, provided that Requirement b is also met.

Another design shown in Table 11.1 is the randomly equivalent groups design, where two independent samples of test takers from population $P (= T)$ are randomly assigned to take X or Y . In large-scale testing, the random assignment is usually implemented with spiraling, where X and Y are alternated in their delivery, resulting in systematically assigned test forms to the test-taker groups. Groups end up being more equivalent than would be expected with simple random sampling (von Davier et al., 2004a). Because independent samples are used, the randomly equivalent groups design requires larger sample sizes to produce statistics for test forms X and Y with the same precision as obtained with the single group design. When test-taker sample sizes are large and the test forms can be reused and readministered without security problems, the randomly equivalent groups design has advantages in that it avoids order effects that can arise with the single group design. Scale-aligning methods are used with the randomly equivalent groups design.

In the counterbalanced design shown in Table 11.1, independent samples are drawn from population $P (= T)$, one where test takers take form X and then Y , and another where test takers take Y and then X . This implementation combines the single group and randomly equivalent groups designs, allowing for order effects to be estimated based on the differences in test linking results for data reflecting each testing order. To the extent that order effects are observed, various choices can be made for linking forms X and Y with the counterbalanced data (von Davier et al., 2004a), including the use of all available data to represent both testing orders, the use of only subsets of the data that do not reflect order effects (where some test takers take X first and other test takers take

Y first), and other weighted combinations of these. Usually a counterbalanced design is implemented in a special study where the estimation of order effects is of interest, rather than in a typical test administration where testing orders are fixed. As with the single group design, Requirements a and c can be checked, as can Requirement b.

Another data collection design shown in Table 11.1 is less direct, where X is linked to Y through scores on an anchor test, A . This is the NEAT design (Holland & Dorans, 2006), which is also referred to as the common-item nonequivalent groups design (Kolen & Brennan, 2014). Samples from two different populations take X or Y , and both samples take A . Because the samples represent different populations, estimates of population differences are needed for the X -to- Y linking, and the groups' performance on A provides these estimates. The NEAT design contains two single group designs. In practice, A can be a set of items common to X and Y (an internal anchor) or a test or set of items that is separate from X and Y (an external anchor). The quality of the final linking results based on internal or external anchors reflects the extent to which A is representative of X and Y . Accordingly, data collections and procedures are encouraged that strengthen the anchor test (Dorans et al., 2011; Holland & Dorans, 2006).

The NEAT design is more complex than the single group, randomly equivalent groups, and counterbalanced designs. Specifically, the NEAT design requires invariance assumptions for estimating test-taker group performance on the test that test takers do not take (assumptions about the unobserved Sample 1 from population P on Y and about the unobserved Sample 2 from population Q on X). Invariance assumptions must be made to produce an equating that applies to the target population. Two major approaches and their associated assumptions involve chaining through A and estimating X and Y distributions by projecting from A for a synthetic population defined as a combination of P and Q (described in the *Approaches to NEAT Equating* section).

An approach similar to the NEAT design involves assembling X using items from an item pool that have IRT parameter estimates on the same scale, X_A , along with other newly administered items, X_{New} . In this common item equating to a calibrated pool design (Table 11.1, Kolen & Brennan, 2014), the X_A items are used as an anchor to obtain scaled IRT parameter estimates for the X_{New} items that expand the item pool. Then, as described in the *IRT* and *Distinguishing Equating From Other Forms of Linking* sections, an IRT conversion to the θ scale, to Y , or to any other form that might be assembled from the item pool, is produced for the scores of the complete X form (X_A and X_{New}). Parameter estimates for the item pool and the equating results should all apply to population P ($= T$). Common item equating to a calibrated pool is more flexible than the NEAT designs with respect to the source of the anchor items, but it requires an IRT implementation and the meeting of IRT assumptions (Kolen & Brennan, 2014).

The final rows in Table 11.1 present two pre-equating designs for linking X to Y using data from previously administered sections or individual items to equate X before it is ever administered as an intact test. Section pre-equating involves the administration of a complete old form, Y , composed of two mutually exclusive sections (Y_1 and Y_2) and one of two mutually exclusive sections of new form X (X_1 or X_2) to randomly

equivalent samples of population $P (= T)$. The statistics for the complete X form could be estimated using data from the administration of the X_1 or X_2 sections, and these estimated statistics could be used to link X to Y (Holland & Wightman, 1982). The use of two sections is the simplest case for this design. In their discussion of section pre-equating, Petersen et al. (1989) presented implementations with three and four sections of X and Y administered to three and six random samples of P .

Pre-equating can also be implemented in individual items rather than test sections. The final row of Table 11.1 presents an implementation of item pre-equating that is similar to common item equating to an item pool except that the new items, *New*, do not contribute to the equating and scoring of X (Kolen & Brennan, 2014). That is, X is assembled from items from a calibrated item pool rather than one specific form and is pre-equated and scored using the IRT parameter estimates from these calibrated items prior to the administration of X . Then, in a subsequent step after the administration of X , scaled IRT parameter estimates are obtained for the *New* items using X and these are added to the item pool for assembling and pre-equating additional forms. Parameter estimates for the item pool and the pre-equating results for other forms assembled from the item pool should all apply to population $P (= T)$. A more complex item pre-equating design involving multiple tests and populations is presented by Petersen et al. (1989), and is a basis of adaptive testing and linking (see the *Linking Adaptive Tests* section).

Pre-equating designs are relatively complex and require stronger assumptions than the other designs described, namely, that the test, section, and item statistics estimated in a pre-equated administration are accurate when used to produce equating and other linking functions. Inaccuracies can result from population differences or from context and order effects where the pre-equating administration involves administering the items and subsections of X in different orders and contexts than those from the actual administration of the intact form X (Davey & Lee, 2011). In addition, for implementations where a typical IRT model is used that assumes test-taker ability is unidimensional, pre-equating could introduce biases when pre-equated IRT statistics based on unidimensionality assumptions are used to approximate a linking for the full multidimensional test (Kolen & Brennan, 2014). Estimates of X from pre-equating could be biased reflections of the actual X , resulting in inaccurate equating results that might be corrected with “postequating” using actual administration data and one of the traditional designs in Table 11.1.

Methodological Implementations of Equating

This section provides a summary of research, discussions, and studies on the methodological issues in equating. The methodological issues covered here pertain to material covered in the following sections: *Data Use and Smoothing*, *Continuization*, *Choices Among Data Collection Designs*, *Approaches to NEAT Equating*, *True Scores*, *IRT*, and *Accuracy Evaluations*. Many of these procedures can and should be implemented using open-source computational programs that provide critical supports for transparency

and for the independent replication of results (Brennan, 2004; Brennan et al., 2009; Gonzalez & Wiberg, 2017). In addition to the methodology covered in this section, important aspects of equating implementations include checks that test that development and administration practices are standardized and similar, that quality control procedures are implemented to ensure administration conditions are followed, and that tests, items, and answer keys are all working and displayed as intended. The implications of altered questions and answer keys are covered by Kolen and Brennan (2014, pp. 331–336).

Data Use and Smoothing

Equating procedures are statistical operations performed on sample data. Ideally, the sample data should come from an established data collection design and should be a large and sufficiently representative sample that can produce precise adjustments for the test linking. The question *How large?* depends on the data collection design and can be addressed based on standard errors of equating for the specific design (Kolen & Brennan, 2014). The question *How representative?* might be answered in terms of data or sample selection procedures, such as exclusion procedures for test takers who are not part of the target population (e.g., from nonrepresentative grades) or who are nonnative English speakers or exam repeaters (Dorans et al., 2011).

Once equating data are obtained, there are additional choices about how to use the data to produce the test-linking results. The most direct choice is simply to use the sample data as originally collected to compute test-linking results. A long-standing interest in the test-equating field is the extent to which equipercentile linking results can be improved by smoothing the test data. The goal of smoothing is to reduce statistical sampling error while not substantially inducing bias. Early methods based on hand smoothing and moving averages of frequencies (Angoff, 1971; Flanagan, 1951) have been replaced with methods that are more accurate, formalized, and efficient.

One smoothing method for equipercentile linking is log-linear presmoothing (Holland & Thayer, 2000). This smoothing method is based on fitting log-linear models to the distributions of the test scores to be linked. The model fitting process produces fitted distributions that match a user-specified number of moments of the unsmoothed data. The process smooths out irregularities and provides plausible nonzero probabilities and frequencies at all possible scores. Log-linear models can be applied to the univariate distribution of the scores of a single test, to the bivariate distribution of two tests, and to the complex structure of a bivariate distribution of a test, an internal anchor and its impossible scores (i.e., structural zeros; H. Kim et al., 2017). Log-linear models can also be used to model other complexities that occur with bivariate distributions of weighted composite scores (Moses, 2014b). Because log-linear models have statistical implementations, they have associated model fit indices including chi-square statistics (e.g., likelihood ratio) and information criteria (Akaike information criterion, Bayesian information criterion, etc.) that lend themselves to statistical selection strategies (Moses, 2011; Moses & Holland, 2010). Finally, estimated variance–covariance

matrices for the smoothed distributions are an output of the modeling that can be used to estimate standard errors of equating and other linking functions that explicitly reflect the smoothing results (Moses & Holland, 2008; von Davier et al., 2004a).

Another smoothing method used in equipercentile equating is known as cubic spline postsmoothing (Kolen, 1984). The “post” in postsmoothing indicates that this smoothing is implemented after an equipercentile X -to- Y equating is computed in order to directly smooth the equating function. The postsmoothing produces adjacent and connected score-level cubic functions that are numerically solved to produce the smoothest possible function that reflects the unsmoothed equipercentile function up to a user-specified smoothing constraint. The implementation, special procedures for the highest and lowest scores, and other procedures for approximating symmetry in the postsmoothed results are described by Kolen and Brennan (2014). Studies have demonstrated that cubic spline postsmoothing and alternatives are useful for reducing error in equipercentile equating functions (Cui & Kolen, 2009). Alternative strategies for selecting postsmoothing parameters have been considered (C. Liu & Kolen, 2018).

Both pre- and postsmoothing introduce bias into equating results. The logic behind both smoothing procedures is to reduce random error without substantially introducing bias. There is no definitive answer to the question, Which is better? It is clear, however, that presmoothing introduces bias before subsequent equating steps are performed, whereas postsmoothing does so when conducted after other equating steps are performed. Also, presmoothing can be automated if one adopts certain prespecified equating criteria, but doing so can be risky without examining smoothed plots before proceeding with equating. By contrast, postsmoothing involves somewhat subjective judgments about smoothing degrees.

In equating practice, data screening, presmoothing, and postsmoothing are important tools for improving the accuracy of equipercentile linking and equating functions. Reasonably large sample sizes are another important matter for ensuring accurate equating results (Dorans et al., 2011; Kolen & Brennan, 2014). When equating data are collected using small sample sizes, equipercentile functions must rely on models that make additional assumptions (e.g., pre-equating data collection designs and assumptions that work under some situations but not others; see Livingston & Kim, 2011).

Continuization

Equating functions based on scale alignment produce a set of “in between” scores that reflect plausible estimates of the difficulty differences between test forms, but that are in fact impossible to obtain. For example, if test X was to be equated to Y and X was easier than Y , then converting number-correct points that adjust for the easiness of X might result in X -to- Y scores that are lower but in between the scores that could actually be obtained (e.g., a score of 28 on X might convert to 27.6). The process of treating discrete test scores as if they are continuous is referred to as “continuizing” (von Davier et al., 2004a). The percentile rank function shown in Equation 11 is one approach to continuizing based on the assumption that the in between scores are uniformly

distributed within boundaries for each score (the score $\pm$ half of the score interval). The linear scale-aligning function (Equation 16) is another approach to continuization based on standard deviation units. The continuization process in equating is described in detail by von Davier et al. (2004a), who showed that the traditional continuization approach based on percentile rank functions produces continuous distributions that can be irregular and can imprecisely reflect the original discrete distribution (i.e., overestimate variance by 1/12).

Von Davier et al. (2004a) described and developed an alternative continuization for equating based on Gaussian kernel smoothing (i.e., kernel equating; Holland & Thayer, 1989). Kernel equating is smoother, is more accurate with respect to variance, and approximates equipercentile, linear, and compromises of these functions through a user-specified kernel smoothing parameter. Several alternative continuization approaches have also been considered, including those based on log-linear models (T. Wang, 2011), exponential families (Haberman, 2011), and alternative kernel functions (Lee & von Davier, 2011). When continuization approaches work to produce values in between two adjacent, attainable scores, different approaches usually exhibit small differences from each other. They can even be shown to be iterative versions of Equation 11's percentile rank computation (Moses & Holland, 2008). One exception is when these approaches are used to equate the highest and lowest scores of a test. Equipercentile equating based on percentile rank functions will connect the highest X and Y scores to each other, whereas equatings based on kernel and linear continuizations may produce results that go further beyond the defined score ranges for the tests (Dorans et al., 2011; Kolen & Brennan, 2014; von Davier et al., 2004a). Another possible exception is scores with unequally spaced values because these are not completely suitable for Equation 11's percentile rank calculations that assume scores with ranges of integers. Flexible continuization approaches could be especially appropriate for tests with unequally spaced score ranges.

Choices Among Data Collection Designs

Each design described in the *Data Collection Designs* section and Table 11.1 presents a particular trade-off of advantages and disadvantages in test equating. These designs can be compared with respect to statistical precision, specifically the sample size of test takers needed to achieve a particular standard error of equating. For a given level of statistical precision, the randomly equivalent groups design and equipercentile equatings require more data than a single group design and linear equating (Kolen & Brennan, 2004). Designs can also be compared with respect to the complications and security concerns they introduce in test administrations (more complexity and security concerns for randomly equivalent groups designs than NEAT designs) and statistical assumptions (minimal assumptions for randomly equivalent groups, more stringent assumptions for NEAT and pre-equating designs; Kolen & Brennan, 2014). Based on the strengths of each design, a recommended ideal design is one in which large samples of test-taker data are collected in a securely implemented randomly

equivalent groups design with an external anchor test that is administered after the tests (Dorans et al., 2011; Holland & Dorans, 2006). This design exploits the simplicity of the randomly equivalent groups design, but also allows for increased statistical precision through use of the anchor test as a statistical covariate. Administering the anchor externally is advantageous in that only the anchor could be affected by context or order effects, and the anchor would not need to be used if these effects were found. Pre-equating designs are usually not recommended based on their complexity and strong assumptions about IRT parameter estimates holding across multiple contexts (Davey & Lee, 2011). However, pre-equating designs could be considered for situations where a test linking must be estimated before that test is actually administered (Kolen & Brennan, 2014).

Approaches to NEAT Equating

Equating texts and studies have given extended attention to the complexities of equating using the NEAT design, considering aspects such as options and designs of the anchor test and computations based on assumptions made about the relationship of the test and anchor scores. One choice is whether the anchor will be internal or external to the tests being equated (Dorans et al., 2011; Holland & Dorans, 2006). External anchors are separately timed, and scores on them do not count toward the X and Y scores.

External anchors or sections have considerable flexibility and multiple uses, such as equating, pretesting, or the tryout of new item types. Potential drawbacks of external anchors are that they must be sufficiently disguised so that test takers do not respond differently to the anchors than they respond to the tests. In particular, test takers should not be able to determine which set of items (or test) is an external anchor, because the goal is that test takers try as hard on the external anchor as they do on X or Y . If that is not true, then scores on the anchor test will almost certainly lead to biased equating results. Recommended practices for equating with external anchors are to use data-screening procedures to identify and exclude test takers with anchor performance that is inconsistent with test performance.

Internal anchors are administered and scored within X and Y , which usually results in higher (anchor, test) correlations than external anchors, but also increases the risk of context and order effects. Recommended practices for equating with internal anchors are to administer the anchor items in similar positions on X and Y and to evaluate and possibly screen the anchor items for differential performance (i.e., differential item functioning).

The predominant recommendation is that external and internal anchors should be designed to be representative of the test, with similar average difficulties (though not necessarily equal difficulty spread; Sinharay & Holland, 2006a, 2006b). The anchor(s) should also be relatively long and reliable (Moses & Kim, 2007), where the long-standing recommendation is for at least 20 items or 20% of the items on the test (Angoff, 1971). Also, they should be administered and screened to reduce atypical test-taker performance, context, and order effects. Following these guidelines helps ensure that

the anchors will be as highly correlated as possible with the tests being equated, which supports accurate NEAT equatings.

Once the NEAT data are obtained for a sample of population P that takes X and A and a sample of population Q that takes Y and A (Table 11.1), different options are available for using the anchor data to equate X and Y in T . Two major approaches involve chaining scale-aligning functions through the anchor and computing scale-aligning functions from test distributions estimated for a single hypothetical group on both X and Y .

The chained approach involves computing a scale alignment function from X to A in the P data and another scale alignment function from A to Y in the Q data and chaining them together. The assumption is that both scale alignment functions are population invariant (i.e., apply to other populations, and specifically to target population T ; Holland & Dorans, 2006). Expressed in equipercentile functions (Equation 15) with percentile rank functions for A in P and Q , $H_P(a)$ and $H_Q(a)$, and linear functions (Equation 16), the chained equipercentile and chained linear scale alignment functions are

$$e_{XT}(x) = G_Q^{-1}(H_Q\{H_P^{-1}[F_P(x)]\}) \quad (21)$$

and

$$l_{YT}(x) = l_{YQ}[l_{AP}(x)], \quad (22)$$

where $l_{YQ}[\]$ denotes the A -to- Y linear function in the Q data.

The second approach (scale aligning) is referred to as frequency estimation or poststratification and involves projecting (see the *Distinguishing Equating From Other Forms of Linking* section) the X and Y distributions conditional on A for T . The projection is based on assumptions that the conditional $X|A$ distribution observed in population P applies to population Q and that the conditional $Y|A$ distribution observed in population Q applies to population P . The resulting X and Y distributions are estimated for a synthetic, combined group of P and Q test takers that comprise the target population $T = w_P P + w_Q Q$ ($w_P + w_Q = 1$, and w_P and w_Q range from 0 to 1),

$$Pr_T(x) = \sum_a Pr_P(x|a)[Pr_T(a)] = \sum_a Pr_P(x|a)[w_P Pr_P(a) + w_Q Pr_Q(a)] \quad (23)$$

and

$$Pr_T(y) = \sum_a Pr_Q(y|a)[Pr_T(a)] = \sum_a Pr_Q(y|a)[w_P Pr_P(a) + w_Q Pr_Q(a)]. \quad (24)$$

The X and Y distributions produced with Equations 23 and 24 are estimated for the same target population and can be used in percentile rank and scale-aligning functions like Equations 11 and 15. Different linear scale-aligning functions based on poststratification are possible, such as those that use the means and standard deviations from the distributions obtained from Equations 23 and 24 in Equation 16 (Braun & Holland, 1982). Another method attributed to Tucker (Angoff, 1971) makes assumptions that the conditional means of the tests are linear and invariant given anchor scores and that the conditional variances of the tests are constant and invariant given anchor

scores, producing estimated means and variances of X and Y on T from anchor-to-test regression equations like Equation 17 (Gulliksen, 1950; Lord, 1950).

The chained and poststratification approaches to equating tests with the NEAT design have been compared in several research studies. Von Davier et al. (2004b) showed that these methods produce identical results when the (anchor, test) correlations are perfect or when the anchor distributions are identical in the P and Q samples. These results underscore the view that in ideal equating situations, such as those where (anchor, test) correlations are high and where administration groups are similar, different equating methods can produce very similar results (Dorans et al., 2011). Studies have also considered situations where the chained and poststratification methods give different results, where a choice of equating method is more consequential for reported scores. Summaries of these studies indicate that the poststratification approaches have smaller standard errors than the chained approaches and less overall equating error when group differences are small, whereas the chained approaches are less biased and have less overall equating error when group differences are not small (Dorans & Puhan, 2017; Kolen & Brennan, 2014; Kolen & Lee, 2011, 2012, 2014, 2016, 2018).

True Scores

The equating of true scores is a long-standing theoretical interest. This interest involves equating procedures based on theory and measurement models, especially classical test theory (see the *Equating Requirements* section, Equation 19; Angoff, 1971; Levine, 1955). For the NEAT design, the test forms and anchors are usually assumed to follow a classical congeneric model, and versions of Equation 19 are used to compute linear τ_X -to- τ_A and τ_A -to- τ_Y functions that are chained together for a Levine equating of τ_X and τ_Y (Hanson, 1991; Kolen & Brennan, 2014; Levine, 1955),

$$l_{\tau_Y}(\tau_X) = l_{\tau_Y}[l_{\tau_A}(\tau_X)], \quad (25)$$

where $l_{\tau_Y}[\]$ denotes the τ_A -to- τ_Y linear function. The relationships of the true test and anchor scores are assumed to be population invariant (Holland & Dorans, 2006).

Equating functions for true scores address theoretical interests while introducing conceptual difficulties for practice. The main difficulty is that true scores are unobserved and unavailable in practice (Lord, 1980; Lord & Wingersky, 1984) so that true score equating functions like Equation 25 typically use observed scores, $l_{\tau_Y}(x)$. Although the interchangeability claims that true score equating functions support apply to true scores, the equity discussions described in the *Equating Requirements* section show that specific types of equity are achieved in observed score applications when test forms and anchors are classically congeneric. Still, such applications are inconsistent, lack compelling reasons (Kolen & Brennan, 2014), and do not reflect the measurement error in X that is unaccounted for when equating is attempted with true score conversions (especially beyond the conditional means addressed in first-order equity). From the *Equating Requirements* section, the strongest connections in theory and practice are achieved

when the test forms and anchors are constructed and administered in the same way (reflecting congeneric theories and first-order equity) and the test forms are equally and highly reliable (such that observed scores approximate true scores and $l_{TY}(x)$ functions reflect second-order equity).

Another version of Levine linear equating is based on the same assumptions for X , Y , and A and their true scores as used in Equation 25, but equates the observed X and Y scores in a hypothetical target population (defined with respect to true anchor scores) using frequency estimation and poststratification assumptions about X and Y scores given the true anchor scores (Holland & Dorans, 2006; Kolen & Brennan, 2014; Levine, 1955). Levine equating has been shown to perform well in some situations where administration group differences are large (Kolen & Brennan, 2014; Mroch et al., 2009), though these results depend on the accuracy of the Levine assumptions.

Equipercntile scale-aligning functions based on true scores have been developed by Chen et al. (2011) and T. Wang and Brennan (2008). T. Wang and Brennan's (2008) proposal is to modify the frequency estimation equipercntile procedure in Equations 23 and 24 so that these equations are based on a projection from estimated true anchor scores (i.e., $Pr_p(x|\hat{\tau}_A)$). Chen et al.'s (2011) approach generalizes chained and post-stratification equipercntile approaches developed in the kernel equating framework so that these are based on true scores.

IRT

IRT can also be used to produce equating functions of observed or true test scores or θ estimates. IRT applications require that the IRT assumptions hold and that parameter estimates for X and Y items are on a common scale. When these item parameters for the X and Y tests are estimated with a single population design such as the randomly equivalent groups data collection design (Table 11.1) using the same specification of the θ scale, the parameter estimates can be interpreted as being on the same scale. When tests are administered to nonequivalent groups as in the NEAT design, procedures are needed to transform the parameter estimates to a common scale, either through special linear transformations based on the two sets of IRT parameter estimates for the anchor items or through concurrent calibrations of the X and Y test items and anchor items (Kolen & Brennan, 2014).

For IRT observed score equating, an IRT-based recursive algorithm can be used to estimate probability distributions for X and Y given θ , $Pr(x|\theta)$, and $Pr(y|\theta)$ (Lord & Wingersky, 1984). Once obtained, these conditional distributions are averaged over a target distribution of θ ; specifically,

$$Pr_T(x) = \int Pr(x|\theta) Pr_T(\theta) d\theta \quad (26)$$

and

$$Pr_T(y) = \int Pr(y|\theta) Pr_T(\theta) d\theta. \quad (27)$$

Equations 26 and 27 can be described as IRT-based presmoothed distributions (Holland & Dorans, 2006), which can be used in equipercentile equating. IRT-based true score equatings can also be produced (see the *Distinguishing Equating From Other Forms of Linking* section). Finally, if a testing program's scale scores are produced using θ as the test performance measure (see the *Scaling Methods for Primary Scale Scores* section), equating procedures may be bypassed altogether and test takers' $\hat{\theta}$ s may be estimated by applying IRT ability estimation procedures to their item-level performance (see the *IRT Ability Estimates* section) and scaling these estimates to the reporting scale, $sc(\hat{\theta})$.

Accuracy Evaluations

Once estimated, test equating functions should be evaluated for accuracy. Most of the accuracy evaluations reviewed in this section are comparative, where an equating function based on one method and associated assumptions is evaluated in comparison to one or more other equating functions based on different methods and assumptions. For example, an equipercentile equating function might be of interest and evaluated in terms of how different it is from a simpler equating approach, such as a linear equating, or the use of raw scores to consider whether equating is needed at all. In subpopulation invariance evaluations, equating functions obtained from subgroup data are typically compared to a function based on the total group, usually for purposes of evaluating subgroup dependencies. These comparisons require the estimation of two or more plausible equating functions and evaluating whether their differences are "large," based on material covered in the following sections: *Differences That Matter*, *Standard Errors*, *Subpopulation Invariance Evaluations*, *Correlations and Prediction Error*, and/or *Evaluations and Recommendations for Drift in Equating Chains*.

Differences That Matter

Evaluations of the magnitude of equated score differences are based on whether those differences are big enough to alter test takers' reported scores. Criteria for these differences, known as "differences that matter" (Dorans & Feigenbaum, 1994), are traditionally defined based on the differences that are considered so large that they are not eliminated when reported scores are rounded, such as half of the integer of the equated scores (0.5 points for equatings based on raw summed scores) or half of the unit of the scale score interval. These values can provide benchmarks for evaluating the magnitude of equated score differences based on two equating functions, but because very similar equated scores can round to different values, the differences-that-matter criteria should not be treated dogmatically (Kolen & Brennan, 2014). Clarifications were provided by J. Liu and Dorans (2012), who proposed a procedure for evaluating whether test takers who take a test under altered conditions should be scored based on a conversion specifically produced to reflect those altered conditions. Liu and Dorans's procedure distinguished four categories of equated score differences, comprising a 2

$\times 2$ table of rounded reported scores (are they the same or different for two possible conversions?) and the magnitude of the differences in the unrounded scores (are they trivial or nontrivial?). Based on these distinctions, Liu and Dorans recommended that a separate equating for scores based on the altered test conditions should be considered only when more than half of the test takers whose reported scores are altered (when the separate conversion is applied) also have nontrivial differences in their unrounded scores.

Standard Errors

Standard errors of equating can be useful for evaluating the extent to which potential equating functions differ by more than can be attributed to test-taker sampling errors. Standard errors of linear equating functions have a history that can be traced to Lord (1950), with updated discussions reflective of equipercentile and kernel functions, different data collection designs, distributional assumptions, and log-linear presmoothing models (Angoff, 1971; Braun & Holland, 1982; Jarjoura & Kolen, 1985; Liou & Cheng, 1995; Lord, 1982; Moses & Holland, 2008; Moses & Zhang, 2011; Ogasawara, 2001, 2003; von Davier et al., 2004a). The standard errors of equating are defined relative to the standard deviation of the distribution of equated scores produced from random samples of test takers from their respective populations,

$$SEE_{YT}(x) = \sigma[\hat{e}_{YT}(x)]. \quad (28)$$

Standard errors of equating are usually based on assumptions that the tests, their items, test-taker sample size(s), and other decisions made in the equating (e.g., smoothing) are fixed and not varied across replications of the test-taker sampling. Most of the cited sources present standard errors that are asymptotically derived, though standard errors can also be estimated through simulations and resampling approaches (Kolen & Brennan, 2014).

Standard errors for a single equating function might be used in evaluations of equated versus raw score differences, essentially questioning whether test score equating affects test scores more than can be attributed to statistical error from the test-taker sample(s). One application is estimating the test-taker sample size(s) needed to obtain a given level of equating precision (Kolen & Brennan, 2014, pp. 273–276). Another application is the situation where a testing program might offer different editions of its test in which the items, item sets, and/or test sections appear in different orders. The extent to which order effects are observed in test scores can be evaluated through equating the scores of the alternate editions to each other and evaluating how different the equated and nonequated test scores are. To the extent that the differences are “large,” the equating function used to evaluate the item order effects might also be used to adjust scores for the order effects. Standard errors for an equating function provide a basis for evaluating whether equated and nonequated scores differ more than can be attributed to test-taker sampling. These ideas were used to evaluate order effects in the SAT (Dorans & Lawrence, 1990) and in Advanced Placement (Moses et al., 2007).

For questions about differences in equated scores from two plausible equating functions, each of which reflects sampling error, standard errors of equating differences (SEEDs) have been developed (Moses & Holland, 2008; Moses & Zhang, 2011; Moses et al., 2010; von Davier et al., 2004a),

$$SEED_{Y,T,1,2}(x) = \sigma[\hat{e}_{Y,T,1}(x) - \hat{e}_{Y,T,2}(x)]. \quad (29)$$

SEEDs can be used to evaluate differences between two equating functions, addressing several possible questions. Equated score differences of interest include curvilinear and linear kernel equating functions (von Davier et al., 2004a), traditional equipercentile and linear equating functions (Moses & Zhang, 2011), poststratification equating functions obtained from different target populations (von Davier et al., 2004a), counterbalanced design equating functions based on different weights of the samples taking the tests in different orders (von Davier et al., 2004a), poststratification equipercentile and chained equipercentile equating functions (von Davier et al., 2004a; Moses & Holland, 2008), and poststratification equating functions based on one or two anchor scores (Moses et al., 2010).

Subpopulation Invariance Evaluations

The subpopulation invariance requirement of equating (see the *Equating Requirements* section; Equation 20) as described by Dorans and Holland (2000) prompted several empirical evaluations of the sensitivity of linking results with respect to subpopulations (Dorans, 2004a; von Davier & Liu, 2007). Recent studies indicate renewed interest in a long-standing question in test equating (Kolen, 2004), one that can be traced to Flanagan's (1951) statements that group dependencies in equating are to be expected (p. 748) and to Angoff's (1971) statements that equating functions should be independent of the individuals used to compute them (p. 563). The inclusion of subpopulation invariance as a requirement for test equating corresponds to research and expectations for subpopulation invariance in equating. Empirical checks are important for determining whether test linkings exhibit desired equating properties and for evaluating intended equating results for tests that undergo transitions, such as in their specifications and possibly in their constructs (J. Liu & Dorans, 2013).

Consider the subpopulation invariance measure in Equation 20, for which Dorans and Holland (2000) developed two measures to quantify the lack of invariance in intended equating functions for an exhaustive set of mutually exclusive subpopulations:

$$RMSD(x) = \frac{\sqrt{\sum_{T_g} w_g [e_{Y,T_g}(x) - e_{Y,T}(x)]^2}}{\sigma_{Y,T}} \quad (30)$$

and

$$REMSD = \frac{\sqrt{\sum_{T_g} w_g E\{[e_{Y,T_g}(x) - e_{Y,T}(x)]^2\}}}{\sigma_{Y,T}}, \quad (31)$$

where the $\mathbf{E}$ denotes an expected value and where w_g is the proportional sample size for T_g in T . The basis of the $RMSD(x)$ and $REMSD$ measures is quantifying the lack of subpopulation invariance in test equating functions of T_g from that of T , at the individual score level and also at an overall level. In their discussion of the $RMSD(x)$ and $REMSD$ measures, Kolen and Brennan (2014) suggested that these measures could mask other issues, such as the extent to which the test linking results for two subpopulations differ from each other. They proposed several additional measures that could directly address this question based on examining

$$e_{Y_{T1}}(x) - e_{Y_{T2}}(x). \quad (32)$$

Additional measures of invariance can also be computed for specific subgroups of interest (J. Liu & Dorans, 2013),

$$RES_{D_{T_g}} = \sqrt{\sum_x Pr_{T_g}(x) [e_{Y_{T_g}}(x) - e_{Y_T}(x)]^2}, \quad (33)$$

where $Pr_{T_g}(x)$ is the relative frequency at $X = x$ for subgroup T_g .

Subpopulation invariance investigations were conducted using Equations 30–33 and other measures in Dorans (2004a), von Davier and Liu (2007), Kolen and Brennan (2014), J. Liu et al. (2010), and Yin et al. (2004). Standard errors for these measures were developed and studied by Moses (2008) and Rijmen et al. (2009).

One suggestion for practice is to apply subpopulation invariance concepts to conduct population invariance evaluations that address invariance for populations that are intended applications of an equating function but not necessarily represented in the actual equating study. Experience suggests that some of the most serious problems with equating and linking results involve estimating linking functions in data from one group (e.g., special studies, small subgroups of an administration used for randomly equivalent groups designs, pre-equated conversions) and applying these linking functions to other groups, testing conditions, and administration data. These experiences led to recommendations that equatings and linkings conducted in special studies with nonrepresentative scoring, administration conditions, and test-taker data should be regarded as limited in the score interpretations they suggest and subject to additional research to support their use and interpretations with the general testing population(s) (W. Lee & Brennan, 2021; Moses, 2022). This additional research can include invariance investigations for different groups as well as special data reviews that ensure that the test equating is working reasonably well for particular users and administration groups. These checks could be as simple as reviewing the scale score distribution(s) from applying an estimated equating function to the administration group and comparing it to historical distributions for that group.

Correlations and Prediction Error

Equating and other linking functions can be produced to support multiple purposes and interpretations, such as to align test scales based on score distributions and to

provide predictions of test takers' scores. The scale-aligning computations used to support interchangeability across alternate forms in equating, or comparability across distinct tests in concordance studies (see the *Concordances* section), might have other intended uses as predictions of test takers' performance on those alternate forms or tests. To the extent that test correlations and reliabilities are high (see the *Distinguishing Equating From Other Forms of Linking* section), scale-aligning functions are more likely to support both aligned scales and accurate predictions. As test reliabilities and correlations decrease, the differences between scale-aligning functions and prediction functions increase, such that the predictions from scale-aligning results are increasingly biased. If the scales of independent random numbers were aligned, the results would have no predictive utility because they would not reflect the reliabilities and correlations of the "scores" (Dorans, 2004b).

When describing these issues, Dorans (1999) used a coefficient of alienation based on the prediction error of regression functions,

$$\frac{\sigma_{YT} - \sigma_{YT} \sqrt{1 - \rho_{XY,T}^2}}{\sigma_{YT}} = 1 - \sqrt{1 - \rho_{XY,T}^2}. \quad (34)$$

In words, Equation 34 indicates the proportion that uncertainty is reduced from predicting Y from using a linear X -to- Y regression function compared to using the mean of Y . Dorans and colleague (Dorans, 1999; Dorans & Walker, 2007) argued that concordances should only be produced when scores for tests X and Y are correlated at least .866, in which case Equation 34 indicates a 50% reduction in prediction uncertainty in standard deviation units using an X -to- Y regression. For tests correlated less than .866, scale-aligning methods result in biased predictions and should be replaced with prediction or projection methods (Dorans, 1999, 2004b). Although the correlation in Equation 34 suggests the need for a data collection design where test takers take both X and Y , Equation 34 can be used to evaluate equating results from other designs where X and Y are alternate forms assumed to be parallel. For the equating of alternate forms, the XY correlation can be estimated from the test reliabilities (Gulliksen, 1950; Lord & Novick, 1968).

These discussions were updated by Moses (2014a), who provided analogues to Equation 34 based on the prediction error from a linear scale-aligning function (Equation 16),

$$\frac{\sigma_{YT} - \sigma_{YT} \sqrt{2[1 - \rho_{XY,T}]}}{\sigma_{YT}} = 1 - \sqrt{2[1 - \rho_{XY,T}]}. \quad (35)$$

Equation 35 indicates that equatings, concordances, and other linkings produced from linear scale-aligning functions reduce prediction uncertainty by 50% when X and Y are correlated at least .875. Results were provided by Moses (2014a) to compare linear regression and scale alignment functions in terms of prediction error, showing that these

functions are similar for high XY correlations but that linear regressions are increasingly favored when correlations between X and Y are low. Additional insight can be obtained by decomposing prediction error variances for regression and scale alignment functions into their proportional contributions of true score and error variances (Moses, 2014a) and by using other related measures of proportional reductions in mean-square error (Dorans, 2022).

EVALUATIONS AND RECOMMENDATIONS FOR DRIFT IN EQUATING CHAINS Established testing programs must produce several editions of a test that are developed, administered, equated, and used to score test takers. This history means that testing programs can have several previously administered and equated forms potentially available for the equating of additional test forms. Such programs would also have historical expectations about the reasonableness of scale score distributions for given administration groups. An increasing number of test equatings back to the scale is expected to cause drift due to the accumulation of random error (Kolen & Brennan, 2014). Large numbers of previous equatings also provide opportunities for monitoring historical equating results and for evaluating the consistency of current equating and scale score results.

One way that testing programs can improve test equating accuracy is to conduct their equatings to link their tests back to two or more previously equated forms (Holland & Dorans, 2006; Kolen & Brennan, 2014). From 1994 to 2016, the SAT conducted external anchor equatings to link new forms back to four old forms. Multiple links to past forms provide ways to detect aberrant equating results and scale score conversions. Multiple links also make the final equating and scale score conversions less reliant on any one previously developed equating that may be problematic.

Established testing programs can also monitor their current and historical equating results for evidence of scale score drift. Modu and Stern (1975) monitored SAT scales from 1963 to 1973, finding evidence that the verbal and mathematics sections had drifted. More recently, Haberman and Dorans (2011) delineated several contributors to scale score inconsistency, including anchors for the NEAT design, sampling errors (random and nonrandom), accumulated random error, and model misfit. Some practices were noted to exacerbate scale drift, such as continuous testing where more new forms are administered and equated with smaller groups of test takers (increasing standard errors and the accumulation of standard errors in chains of equatings). When equatings and raw-to-scale conversions are available for several administered forms, additional methods for evaluating drift have been described, such as harmonic regression and time series analyses for evaluating seasonality effects in scale score conversions (Y. Lee & Haberman, 2013) and quality control charts and time series methods to support continuous monitoring, adjustment of variations, identification of abrupt shifts, and the assessment of autocorrelation. More recent evaluations of scale stability in the SAT have also been conducted, such as studies of the extent to which drift in equating chains is affected by different degrees of postsmoothing (S. Y. Kim et al., 2020)

and the drift due to the accumulation of random and nonrandom errors observed from readministering and re-equating an old form and comparing this to more recently equated forms (Guo et al., 2012). Another study evaluated the extent to which scale score drift and variability in the SAT were controlled by equating back to two or three old forms rather than one (J. Liu et al., 2014). These studies provide examples of how equating drift might be assessed and potentially reduced.

LINKING

In the *Equating* section, equating was described as the strongest type of linking, subject to the strictest requirements, used to adjust the scores of alternate forms of a single test for unintended difficulty differences for the purpose of establishing interchangeable scores. The *Linking* section describes other types of linkings for the scores of tests that are distinct and not expected to meet all of the equating requirements of equal constructs, same test specifications, equal and high reliabilities, same administration conditions, etc. Linking efforts might be undertaken to promote particular interpretations, such as appropriate comparisons or predictions from distinct tests. These goals are not as ambitious as the interchangeability goal of equating. Although the comparability established in linking might be general in intention (e.g., score comparisons across different tests and testing contexts), the results of linking distinct tests are nevertheless weaker (i.e., less precise) than equated results, with interpretations that must usually be qualified and limited in some way. For example, the score comparability achieved through scale aligning methods is considered to be “assured only for that specific group taking the tests under specific conditions (Angoff, 1971)” (Pommerich, 2016, p. 117). Predictions and regressions are also noted to be group specific (Linn, 1993; Mislevy, 1992).

This section summarizes types of linking other than equating, their uses, and their limitations. The linking types covered in earlier linking frameworks include those in the *Concordances*, *Vertical Scaling*, *Battery Scaling and Composites*, and *Predicting and Projecting* sections, all of which are summarized in Table 11.3 based on a tabled version of Holland and Dorans’s (2006) linking framework. Some linking types described in previous discussions are omitted because of ambiguities and updates in terminology (*calibration* was part of earlier linking frameworks, but is avoided here because it sometimes refers to vertical scaling and other times to fitting IRT models; Holland & Dorans, 2006). Approaches described in the *More Recent Linking Types* section are also covered, including linking for exams administered in different testing modes, linking subjectively scored tests, local linking, linking adaptive tests, linking exams administered to different test takers using weak anchors, and linking state tests to NAEP (Table 11.4).

Concordances

Concordances are scale-aligning linkings for tests built from similar but not identical test specifications, where the tests have similar uses, lengths and reliabilities. One

Table 11.3 Summary of Nonequating Types of Linking

Type of Linking	What Is Dissimilar?	What Is Similar?	What Is Equal?	Likely Data Collection Design	Computation	Interpretations
Concordance		Constructs; reliability; difficulty	Population	Single group; approximated counterbalanced	Scale aligning	Comparable scales for the overall concordance group, but not necessarily to subgroups
Vertical scaling	Difficulty; populations	Constructs; reliability		NEAT with common items or scaling test, or random groups	Scale aligning	Comparable scales that depict growth based on the methodological choices for how the vertical scales were established
Battery scaling	Constructs		Population	Single group or randomly equivalent groups		Comparable scales that indicate test takers' relative performance across the test battery
Composite scales			Population	Single group taking the individual tests	The composite is a sum of the scale scores of the individual tests, which are maintained through scale-aligning equatings	Composite scales are indirectly maintained to the extent that the scales of the individual tests are maintained and the intercorrelations of the individual tests do not change
Predicting and projecting			Population	Single group; counterbalanced	Predicting and projecting	Best prediction for a prediction group

Table 11.4 Summary of Recent Linking Examples

Type of Linking	What Is Dissimilar?	Likely Data Collection Design	Computation	Interpretations
Linking across conditions of measurement	Conditions of measurement	Various	Scale aligning	Comparable scales, with caveats about limitations when testing mode differences are large
Linking subjectively scored tests	Scoring that drifts	Various	Scale aligning	Comparable scales, depending on high reliability and procedures to account for trends and rater drift across administrations

(continued)

Table 11.4 (continued)

Type of Linking	What Is Dissimilar?	Likely Data Collection Design	Computation	Interpretations
Local, ability-specific test linking	A form's scale alignments at different abilities	Various	Conditional scale aligning	θ -Conditional comparable scales
Linking adaptive tests	Forms and form difficulties at different abilities	Pre-equating	IRT ability estimation	Comparable scales at specific levels of adaption, influenced by the item pools, and the accuracy of the IRT models, scores and adaptations
Linking tests using weak anchors	Test-taker groups; collateral information vs. the tests	NEAT design without a suitable anchor	Scale aligning on projected distributions	Comparable scales for hypothetical groups defined by the weak anchor(s)
Linking state tests to NAEP	State tests and NAEP	Single group or counter-balanced	Scale aligning or projecting	Comparable scales or projected results are more supported within states than across them

Note. IRT = item response theory; NAEP = National Assessment of Educational Progress; NEAT = nonequivalent groups with anchor testing.

example is the concordance of the SAT and ACT reporting scales. Other concordance discussions and examples involve the ACT and ITED tests (Yin et al., 2004), and, arguably, those described in the *Linking State Tests to NAEP* section. Concordances are intended to align the tests' scales using scale-aligning functions and support additional desires to use the resulting concordance tables as surrogates for test takers' scores on the test they did not take.

Early arguments about concordances for the ACT and SAT were summarized by Pommerich (2007), including concordance table proposals for avoiding excessive testing in schools and arguments from Angoff (1962) and Lindquist (1964, February) against concordance tables because of problems in these proposals and possible misuses of their results. Since these early arguments, several ACT/SAT concordances have been produced (College Board/ACT, 2018; Dorans, 1999; Dorans et al., 1997; J. Liu et al., 2010; Marco & Abdel-Fattah, 1991). These ACT/SAT concordance studies are based on obtaining data from test takers taking the ACT and the SAT at least once, in either order, selecting the ACT and SAT scores to use for the test takers who take either test more than once and screening the test-taker data to avoid large time differences between ACT and SAT testings. Linking results are produced from the screened data as equipercentile conversions for some combinations of ACT and SAT tests (e.g., the ACT Summed score and the SAT Total scores in 2018, the ACT Summed score and the SAT Verbal + Math

score in 2010). Decisions about which ACT and SAT tests to concord are usually based, in part, on the size of their correlations (see the *Correlations and Prediction Error* section; Dorans, 1999). Content similarities and political issues often inform these decisions as well. The usual data collection design is a single group design that ignores testing order. In some ACT/SAT concordance studies, testing order is accounted for by weighting data for each order similar to a counterbalanced design, but for nonequivalent groups (College Board/ACT, 2018; Marco & Abdel-Fattah, 1991). Other statistical weighting procedures have also been used to improve the representativeness of the concordance data and resulting concordances for the test-taker populations of each test, who do not necessarily take both tests (College Board/ACT, 2018).

Because of differences in the specifications of the tests in concordance studies, concordance results are not expected to provide interchangeable scores. In fact, concordance tables are expected to be group dependent. For example, the concordance of the ACT Summed score and the SAT Verbal + Math score differs for females and males and across different race/ethnicity groups. These differences can be attributed in large part to the fact that math content contributed 25% to the ACT Summed score and 50% to the SAT Verbal + Math score (Dorans, 2020). In addition, concordances produced from very specialized conditions of measurement, scoring, or with restricted samples or in special studies may not generalize to entire testing populations and may warrant additional studies to update results (Dorans & Moses, 2023; W. Lee & Brennan, 2021; Moses, 2022).

Vertical Scaling

Vertical scaling is used to establish “developmental” scales for reporting performance on versions of a test that are appropriate for specific ages or grade levels represented in schooling, and usually K–12 testing (Kolen, 2006; Kolen & Brennan, 2014). In Holland and Dorans’s (2006) linking framework, vertical scaling involves the linking of tests that measure similar constructs at similar reliabilities, but that differ in difficulty and in the test-taker populations. Thurstone (1925, 1938) proposed vertical scaling methods for item difficulties and then modified them for summed scores (later described as a method of absolute scaling for age and grade-based scales; Flanagan, 1951; Gulliksen, 1950). Rasch IRT models were considered for vertical scales in the 1970s and 1980s (Briggs & Weeks, 2009). More recent vertical scales include CTB/McGraw–Hill’s Terra Nova (CTB/McGraw–Hill, 2001), the Iowa Test of Basic Skills (Hoover et al., 2003; Kolen 2006; Petersen et al., 1989), the ACT scales (Brennan, 1989), tests of English acquisition and English as a second language (ETS, 2005; J. Wang & Smith, 2003), and the 2016 redesigned SAT Suite (Y. K. Kim et al., 2016). Typically, a separate vertical scale is established for each test in an overall testing battery, serving as potential inputs to battery scaling (see the *Scales for Test Batteries and Composites* and *Battery Scaling and Composites* sections). The resulting developmental scales and scores are used to provide a means by which students’ growth is measured, observed, and used to plan instruction and instructional support across schooling. Because the tests being linked in the

vertical scale differ in difficulty, length (usually), timing, content, and other aspects, vertical scaling results do not produce interchangeable scores across levels (Kolen & Brennan, 2014).

Several issues affect the production and results of vertical scales (Kolen, 2006), including definitions of growth, grade-based testing content, data collection designs, linking methodologies, and implementation choices in an IRT model, scoring, and estimation.

How Growth Is Defined

Vertical scalings can reflect different definitions of growth, such as *grade to grade*, where growth is defined over the test content appropriate to particular grades (usually two adjacent grades), and *domain*, referring to growth over all content in the domain (Kolen & Brennan, 2014).

Grade-Based Testing Content

For subject matter areas closely tied to a school curriculum, students tend to exhibit different amounts of growth depending on the content areas on which students are tested. For example, if division by whole numbers is taught in Grades 3 and 4, then growth in the third and fourth graders is expected to be greater in this area than growth in fifth and sixth graders (Kolen & Brennan, 2014). Different vertical scaling results might result from conducting the scaling on either grade (Holland, 2007, p. 18). Growth rates would be different across vertically scaled tests measuring domains that are differentially associated with school curriculum. Vertical scaling results can also be affected by how well the difficulty levels are represented in tests for earlier and later grades (Kolen, 2006, p. 178).

Data Collection Designs

Three designs are usually contrasted for vertical scaling (Kolen & Brennan, 2014). For vertical scales established with the NEAT design, adjacent grade-based tests are taken by students from those corresponding grades, and the blocks of items representing overlapping content for those two grades serve as the anchor test. The randomly equivalent groups design can also be used, where test takers in each grade are randomly assigned to take either a grade-specific test or a test designed for an adjacent grade. The NEAT and equivalent groups designs both involve the chaining of test linkings for tests administered to adjacent grades, and both designs reflect a grade-to-grade definition of growth.

A third data collection design is the scaling test design, which is similar to the NEAT design where an external “scaling” test that is built to reflect content from the entire domain and represent all of the grades of interest is used as the anchor. Typically, the scaling test is administered to students along with the grade-specific tests to be scaled. The scaling test design reflects a domain definition of growth. The scaling test design has been used with the Iowa Test of Basic Skills, ACT, and SAT testing programs.

Linking Methodologies

Vertical scales can make use of methods based on several measures of test performance (Kolen, 2006). For summed scores, Hieronymous scaling involves the linking of summed score medians across tests. Thurstonian scaling is based on linking grade-based summed score distributions after they are transformed into normal distributions. The untransformed raw scores could also be vertically scaled, such as through chained equipercentile procedures (Y. K. Kim et al., 2016). IRT scoring methods can also be used to establish vertical scales.

IRT Implementations

The use of IRT for vertical scaling involves choices of an IRT model, estimation choices, and the IRT-based scores to use (Briggs & Domingue, 2013; Briggs & Weeks, 2009; Kolen, 2006). IRT models such as the Rasch, 2PL, or 3PL models could be used. Test items' IRT parameter estimates could be obtained through calibrations conducted separately for each grade-specific test, items, and test-taker data or concurrently for the tests, items, and test takers from all grades. Vertical scales could be established from different proficiency estimators, including MLE (Equation 4), EAP (Equation 5), or TCC approaches (Equation 6).

The test score linkings resulting from vertical scales have been characterized as a “folding ruler” and as a “ruler that bends” (Yen, 2007, pp. 274–275). What causes vertical scales to fold and bend? As noted previously, the grade-specific tests can show more growth for content that is specifically taught in the curriculum for those grades (perhaps suggestive of grade-to-grade growth). Reviews of vertical scales from the 1980s describe a shrinkage phenomenon where the scores from several types of vertical scales tended to have standard deviations that shrunk from earlier to recent tests and grades (Briggs, 2013; Kolen, 2006; Yen, 2007). Shrinkage was most often shown in vertical scales established with IRT, potentially affecting the ordering of schools based on their gain scores (Briggs & Domingue, 2013). Shrinkage in IRT scales results in a depiction of growth that differs from the growth depicted in vertical scales established with non-IRT approaches, where shrinkage suggests more rapid growth for lower achieving students who catch up to higher achieving students (Briggs, 2013; Hoover, 1984). Although the source of the scale shrinkage in vertical scales from the 1980s was never definitively established, suggested explanations point to early IRT estimation methods (i.e., joint maximum likelihood estimation), multidimensionality within and across the tests, and a failure to establish interval scales. Vertical scales since the 1980s have generally not exhibited shrinkage (Yen, 2007), coinciding with updates in IRT procedures.

Additional influences on vertical scales have been elaborated (Briggs & Weeks, 2009), including the chosen IRT model (scales based on 3PL models result in greater scale score variability than those based on Rasch models), IRT estimation (MLE results in greater score variability than EAP), and calibration (concurrent calibration decreases scale variability vs. separate calibration). IRT limitations can also affect vertical scales, such as strong and potentially unrealistic assumptions that item parameter estimates

fit item response data and are invariant across ages and grades, as well as assumptions that items and test-taker abilities can be modeled as unidimensional. Multidimensional approaches that account for changes in constructs measured across grades can show limitations with unidimensional approaches (Weeks, 2018). For these and other issues described in the cited sources, vertically scaled scores across grade- and age-specific tests can produce inconsistent estimates of test takers' growth, estimates that reflect choices in methodology, test development, and administrations. Altogether, these results indicate that scores from different tests in the vertical scale are not interchangeable.

Battery Scaling and Composites

Battery scaling can be described both as an approach to establishing scales (see the *Scales for Test Batteries and Composites* section) and as an indirect way to link the scores of a battery of tests designed to measure different constructs that are administered to a common population of test takers (Holland & Dorans, 2006). The purpose of establishing the scales in a similar way for all the tests in a battery is so the resulting scales can facilitate interpretations about relative performance and strengths and weaknesses across the battery. Examples include an early proposed battery scale for different scoring methods for handwriting (Kelley, 1914) and for establishing scales for recent versions of the SAT and ACT batteries (Brennan, 1989; Dorans, 2002; Y. K. Kim et al., 2016). It is likely and expected that the linkings of test scores produced in battery scaling do not produce interchangeable test scores. One way that this lack of interchangeability can be observed is in subpopulation dependencies, such as for subgroups of test takers who do relatively better (or worse) on a mathematical measure and also do worse (or better) on a verbal measure.

Composite scores are usually derived from individual tests in a battery, making the comparability of composite score scales indirect and difficult to maintain. To illustrate some challenges with composite score scales, consider a situation where the scales of two tests are established and maintained through equating, and let these two tests for which alternate forms would be developed be represented as Y_1 and Y_2 . A composite score is also of interest, defined here as the sum of the two scale scores, $sc(Y) = sc(Y_1) + sc(Y_2)$. For this situation, the distribution of $sc(Y)$ is a function of the scale score distributions of $sc(Y_1)$ and $sc(Y_2)$ and also the joint distribution of $[sc(Y_1), sc(Y_2)]$. Specifically, the mean of $sc(Y)$ can be obtained as the sum of the means of both tests' scale scores, the variance of $sc(Y)$ is obtained as the sum of the variances of both tests' scale scores plus two times their covariance, and the skewness and higher moments reflect higher moments in $sc(Y_1)$ and $sc(Y_2)$ and in the joint distribution of $[sc(Y_1), sc(Y_2)]$. These relationships indicate that except for its mean, the distribution of the composite scale scores $sc(Y)$ is a function of the $sc(Y_1)$ and $sc(Y_2)$ scale scores that would be maintained through equatings of the Y_1 test forms to each other and the Y_2 test forms to each other, as well as the covariance and higher moments of the joint distributions of $[sc(Y_1), sc(Y_2)]$ that would not be maintained through the Y_1 equatings and the Y_2 equatings. Examples of composites produced from multiple tests

include those reported by ACT, SAT, and other programs. Kolen and Brennan (2014) summarized how a change in composite score standard deviation coincided with the change in intercorrelations of separate battery tests' scale scores and recommended specific checks for composite score comparability: "When composites are created for tests in a battery, it is important to check whether the composites are also comparable" (p. 425). Analogous results have been shown in linking situations involving latent composites (Dorans et al., 2014; Weeks, 2018). An implication is that composite score scales are best maintained directly rather than linked through indirect reliance on equated battery tests.

Predicting and Projecting

Predicting and projecting are the oldest and earliest examples of test linking (Holland & Dorans, 2006). Although these linkings are not symmetric like scale-aligning functions, various applications have been described in the psychometric literature. Predictions and projections have been recommended because of their increased prediction accuracy versus scale-aligning functions, such as when there are low correlations in the scale scores for which a concordance is desired (Dorans, 1999; 2004b), or in the IRT thetas of distinct measures intended to be linked (Holland & Hoskens, 2003; Schalet et al., 2021). Other uses are for establishing auxiliary scales, such as reports of normative growth using conditional norms (i.e., relative growth rather than the absolute growth intended to be shown in vertical scales). Conditional growth norms might be used to forecast how younger test takers obtaining specific scores on an earlier test are expected to perform on a later test (Betebenner, 2009; Castellano & Ho, 2013). For example, PSAT-to-SAT prediction tables are descriptions of expected growth at the student and school levels (Y. Kim et al., 2018a, 2018b). As described in Holland and Dorans's (2006) linking framework (also Linn, 1993; Mislevy, 1992), predictions and projections are the least restrictive type of linking in terms of requirements. They do, however, require a sample of test takers who took both tests. The usefulness and accuracy of prediction and projection tables are higher when the tables are applied to test takers who are most similar to the test takers used to produce the tables (Holland & Dorans, 2006). In other situations, the group dependences noted in prediction and projection tables can make them unstable, inaccurate, and "precarious" (Mislevy, 1992, p. 63), such as in applications to nonrepresentative groups or to groups over time (Thissen, 2007).

More Recent Linking Types

Since Holland and Dorans (2006) presented their test linking framework, different types of linking have been proposed and developed. Some prominent examples are summarized in this section and in Table 11.4. A focus of this discussion is the extent to which these more recently proposed linking types differ from those in the *Equating Requirements* section. Several of these proposals are based on desires to offer tests in more specific ways to test takers by offering tests in an increased number of administration modes (see the *Linking Tests Across Conditions of Measurement* section), supporting tests

with subjective scoring procedures (see the *Linking Subjectively Scored Tests* section), or developing the tests or the intended linking function tailored to specific test takers (see the *Local, Ability-Specific Test Linking*, and *Linking Adaptive Tests* sections). Additional proposals expand on methods for linking across nonequivalent groups (see the *Linking Tests Using Weak Anchors* section) and the *Linking State Tests to NAEP* section.

Linking Tests Across Conditions of Measurement

Testing programs might allow test takers to take their tests in different administration modes, such as translated into different languages, with modifications and accommodations for special populations, and in multiple delivery systems that include paper-pencil tests and computerized tests delivered online. When offering alternative editions of their tests that are administered under different conditions, the testing program can be faced with two choices. One choice is to ignore administration effects and treat the scores from a test given in different administrations in the same way. This choice could raise fairness concerns and result in an unknown degree of comparability in scores across measurement conditions (Pommerich, 2016). The other choice is to conduct linking studies to estimate and apply score adjustments that account for administration effects on scores (i.e., mode comparability studies). This choice may be possible for evaluating score effects from computerized versus paper testing modes, but is less feasible for tests administered with and without accommodations or in different languages where standard data collection designs may be less available (Thissen, 2016).

Mode comparability studies and linkings produced in these studies do not meet the equating requirement for equal conditions of measurement (see the *Equating Requirements* section) and are not expected to produce interchangeable scores. However, these studies might improve or at least inform the fairness of score reporting. Some reviews of paper-pencil versus computerized mode comparability studies suggest that scores from these modes are comparable more often than not (Pommerich, 2016), whereas other studies suggest that computerized testing can favor some subgroups over others (Kolen & Brennan, 2014). The mixed findings could be due to challenges in conducting mode comparability studies with traditional data collection designs (see the *Data Collection Designs* section) and the extent to which the administration modes differ.

Traditional data collection designs can be challenging to implement with mode comparability studies (Kolen, 2007). Mode comparability studies with randomly equivalent groups designs require that test takers be randomly assigned to an administration mode (paper-pencil, computerized, etc.), an assignment that can differ from the typical administrations of tests and modes by a testing program. A NEAT design implementation would require that test takers take an anchor test given in a single administration mode that may differ from the mode in which they take their actual test. Single group and counterbalanced designs can produce scores with order effects (Eignor, 2007). Traditional designs have been implemented in special studies for large-scale assessments like NAEP, the Programme for International Student Assessment (PISA), and the Trends in International Mathematics and Science Study (TIMSS; Jia & Xi, 2021) and

have found that digitally administered items in mathematics and reading (NAEP) and math and science (TIMSS) were more difficult for fourth and eighth graders. Other studies have assessed mode effects in paper–pencil and online administrations of credentialing, licensure, and placement exams, using a variety of methods to account for test-taker nonequivalence and finding mixed results (Jones et al., 2022; S. Kim & Walker, 2021; Moses et al., 2021; Puhan & Kim, 2022).

A major question is how different the tests are when administered in each mode, such as in terms of their display of items and other test material, the test administration(s) (fixed, adaptive, etc.), and the extent of proctoring for the computerized administration (proctored at test centers vs. unproctored or online administrations). Discussions of these issues suggest that mode comparability linkings are most dissimilar with equatings that produce interchangeable scores across testing modes when the computerized test is adaptive and unlikely to exhibit equity with the paper–pencil scores (Eignor, 2007). In summarizing the transitions many admissions and placement programs made to online testing in efforts to continue administering tests in the COVID-19 pandemic, Camara (2020) noted that online administrations with especially large differences from paper–pencil tests risked the integrity, accuracy, reliability, validity, and fairness of the resulting scores and would “likely mean score trends and comparability cannot be maintained” (p. 13).

Altogether, the challenges with data collections and with potentially large differences in administration modes make mode comparability studies challenging in their implementation and their interpretation. Thissen (2016) provided a general discussion of testing and linking across different translations, grade levels, accommodations, and paper–pencil versus computerized modes, concluding that empirical investigations of fairness are needed for tests and linkings across conditions of measurement:

Continued vigilance is required. There is no way to guarantee that a use of a test is fair. All that can be done is to catalog carefully the ways in which comparisons could be unfair, and then check, with either statistics or reasoned judgment, whether unfairness exists. (Thissen, 2016, pp. 212–213)

Linking Subjectively Scored Tests

Tests that are composed of CR items present challenges for linking, such as tests that usually contain a small number of items and data collection designs that do not work the same way as for tests containing MC questions (Kolen & Brennan, 2014). The use of human raters to score tests containing a small number of CR questions can reduce reliability. Automated essay scoring approaches may avoid reliability reductions from human rater scoring, but they can also introduce their own challenges for score interpretability and fairness (see the *Ability Estimates From More Complex Models* section). The previously described issues about unreliable scores having less utility and producing linkings with less equity indicate that linkings for tests with CR items are not likely to produce interchangeable scores. Tests with small numbers of questions can also result

in inadequate coverage of the content domain, such that alternate forms may measure different constructs. Low reliability and inadequate content coverage can make equating and score interchangeability less likely for tests with CR questions.

When tests containing CR questions must be linked using a NEAT design, linking accuracy depends on a number of factors and procedures. A crucial issue with NEAT designs for CR tests is what to use for the anchor test. When the anchor contains CR questions, the scores from these anchors can reflect a particular type of bias due to leniency/stringency differences in human raters from the two administration groups (Tate, 1999, 2000; S. Kim et al., 2010a, 2010b). Trend scoring procedures are recommended for these biases, where the responses to a set of CR questions from a single group of test-takers are scored by raters in both administrations. A scale-aligning transformation for the sets of scores from these administrations is produced to account for the unintended differences in rater leniency/stringency across administrations and to produce scores that can be used more effectively as an anchor for linking the tests. The use of trend scored CR questions as an intact anchor, or as part of an anchor with MC question scores for mixed format tests, improves accuracy when linking mixed format tests with the NEAT design (S. Kim et al., 2010a, 2010b). Another choice available for mixed format tests is to use anchor tests composed only of MC items. This approach is most effective when the administration groups are similar to each other on the MC and CR sections, when the correlations of the MC and CR scores are high and similar across forms, and when the number of score points attributable to MC scores is large (Kolen & Lee, 2011, 2012, 2014, 2016, 2018).

Local, Ability-Specific Test Linking

If an equating satisfies equity, then it is a matter of indifference whether test takers at every given ability level take form X or Y (see the *Equating Requirements* section; Lord, 1980). Consider Lord's original definition of equity, defined over every ability level (θ value from an IRT model), and emphasize "each" ability level (van der Linden, 2011, p. 209; van der Linden, 2013, p. 262). A set of X -to- Y linking functions could be defined to satisfy this interpretation of equity at specific values of θ :

$$e_{Y\theta}(x) = G_{\theta}^{-1}[F_{\theta}(x)] \text{ such that } F_{\theta}[e_{Y\theta}(x)] = G_{\theta}[y] \text{ for each } \theta. \quad (36)$$

The goal of Equation 36 is to estimate each set of θ -conditional X and Y distributions (Lord & Wingersky, 1984) and use them to produce θ -conditional X -to- Y equipercentile functions. This proposal contrasts with the usual recommended practice to average the conditional distributions of X and of Y given θ (Equations 26 and 27) and conduct an equating for $e_{YT}(x)$ on the averaged distributions (Kolen & Brennan, 2014). If test takers' estimated θ s were available from an IRT model, a set of equating functions at each estimated θ value could be used to evaluate lack of equity in the equated scores, $e_{Y\theta}(x) - e_{YT}(x)$, rather than in distributions (Equation 18), analogous to evaluations of subpopulation invariance (Equation 20; Dorans & Holland, 2000).

One proposal is to use Equation 36 to produce and report θ -conditional scores to test takers, to satisfy equity and address equating bias attributable to θ -conditional measurement error (van der Linden, 2011, 2013). This proposal has been criticized for theoretical reasons and practical issues (Dorans, 2013; Holland, 2013). Some questions are discussed next to elaborate both perspectives, the proposal for θ -conditional procedures and counterarguments.

- Does the target population for equating, T , contain test takers at all θ values or is it θ -conditional? One perspective is that there are multiple θ -conditional target populations (van der Linden, 2011, p. 209). Another perspective defines T in terms of all test takers taking a test in a data collection design from Table 11.1 (i.e., test takers at all θ values). From the perspective that T contains test takers at all θ values, θ -conditional linking functions that differ from $e_{Y,T}(x)$ are an indication that the subpopulation invariance requirement is violated (Requirement e, Dorans, 2013). A θ -conditional interpretation would consider these differences to reflect different populations.
- Should administration conditions like scoring rules be applied in the same way to test takers at all θ s or should different scoring procedures be applied to test takers at different θ s? Unique scoring rules might be applied to test takers at specific θ values or consistently to test takers at all θ values. Note, however, that θ -conditional linking functions would imply that the equal measurement conditions requirement of equating is not satisfied (i.e., test takers with different θ values who take test X are scored differently from each other and likely from Y). Psychometricians have usually argued for the use of uniform scoring for all test takers taking a given test form (Livingston, 2004; Petersen, 2007).
- What are the implications of θ -conditional linking functions for score comparability? From one perspective, θ -conditional equipercentile functions correct for θ -conditional measurement errors (van der Linden, 2011, 2013). Another perspective is that θ -conditional equipercentile functions result in differential treatment of test takers (Dorans, 2013; Holland, 2013) and θ -conditional score interpretations that would be contradictory to interchangeability across different θ values (i.e., score comparisons across θ values are not supported).
- Is equating an adjustment for the estimated difficulties of X and Y in T or an adjustment for θ -conditional measurement error? One perspective is that the equating of observed scores involves adjusting for θ -conditional measurement errors (van der Linden, 2011, pp. 213, 223). The perspective of most other works cited in the *Equating* section is that equating involves adjusting test form scores for unintended differences in overall difficulty (see the *Equating Requirements section*), where the test forms involved are equally and highly reliable.

Rather than use Equation 36 to report θ -conditional linking functions to test takers, the recommendation in this chapter is to re-emphasize high reliability as a requirement for equating. This means that a single X -to- Y conversion applied to all test takers of X

would reflect less measurement error, would be a closer approximation of the equity requirement, and would have small differences from θ -conditional X -to- Y functions. The requirement for high and equal reliability in test forms being equated means Lord's (1980) theorem that only perfectly reliable true scores can be equated is more closely approximated. This perspective makes use of Equation 36 not as a score reporting strategy, but as one possible check for equating adequacy, namely, a check on the extent to which θ -conditional measurement error and (in)equity affect equating accuracy.

Linking Adaptive Tests

Adaptive testing is based on the premise that a test can be more precise when it is constructed so that its difficulty is matched ("tailored," Lord, 1980, p. 150) to test-taker ability. This matching of test-taker ability and test difficulty implies increased efficiency, in that a matched test can be shorter but measure at a precision that is similar to or higher than that of a longer test that may be too easy or too difficult for an unmatched test-taker group. Adaptive tests are usually IRT based in their scoring, linking, and scale scores, relying on a large pool of available test items with IRT statistics obtained from pretest and pre-equating data collections and using computer-based algorithms to administer the tests (van der Linden & Glas, 2010).

When the test is administered, a computer program implements sophisticated algorithms to obtain preliminary IRT-based ability estimates as a test taker takes test items. Then the computer program selects and administers subsequent test items with difficulties that match test takers' ability estimates. The computer might stop the test when the test taker's ability estimate reaches a predetermined level of precision. Additional procedures are needed to ensure that the item pool is adequately maintained, that items are not being overly selected or exposed so as to raise security concerns, that content specifications are met, and that items' IRT parameter estimates are not drifting during repeated use. Adaptive testing could be implemented at the item level (i.e., every subsequent item a test taker takes is based on his/her ability estimated from previously taken items). Adaptive testing could also be implemented at a small number of stages where test takers are routed to collections of items of differing difficulty (i.e., multistage tests, MSTs). Several examples of item-adaptive tests and MSTs are described by van der Linden and Glas (2010).

Computer-adaptive tests present several challenges for score linking. The adaptive tests are highly dependent on the item pools, such that systematic changes in the item pool through item reduction or the use of different exposure controls can result in test scores that are not interchangeable because of increased measurement error, violations of second-order equity, and changes in the distribution of reported scores (T. Wang & Kolen, 2001). Even when alternate item pools are built to be very similar, they might produce scores that are different enough to warrant additional linking beyond what is provided in the adaptive test (Segall, 1997). Adaptive tests rely on assumptions that scoring parameters are correct and item order and context effects are either minimal or

can be controlled. More thoughtfulness has been encouraged about these assumptions (Harris, 2023), and special research has been prompted to assess pretested items administered in varied positions (Davey & Lee, 2011). Importantly, the design of an adaptive MST will reflect one of several possible trade-offs of adaption and the extent to which content specifications are met:

More modules per stage may make a test more adaptable to a wider range of examinee proficiency levels, but then, more easy items and hard items are needed to build the MST modules. The items must also be selected to simultaneously meet all requisite content specifications for any test route taken by the examinee. This is often very challenging when the modules at a given stage must be matched on content and also span a fairly wide range of item difficulty. Similarly, fewer items per stage likewise encourages the use of more adaptation, but can result in routing decisions being made on smaller and smaller slices of the content domain. (Zenisky et al., 2010, p. 356)

Adaptive tests have some resemblances to vertical scales (see the *Vertical Scaling* section), in that they involve tests developed to differ in difficulty and possibly in content being administered to test takers of specific estimated ability. Both linking types can fail to meet the equating requirement for content and difficulty (Requirement a, see the *Equating Requirements* section) and both raise comparability challenges. Similar to how different vertical scaling results could be produced as students of different ages and/or grades take the tests being vertically scaled, different scores from computer-adaptive tests could be produced if test takers of higher and lower ability take one of several unique and adaptive tests differing in their difficulty and possibly content. These issues might be a matter of degree where, for example, simulations of MSTs that administer modules with relatively small differences in difficulty and content may not show large scoring errors in misrouted test takers (S. Kim & Moses, 2014). However, as the quote from Zenisky et al. (2010) suggests, it is possible that the adaption in adaptive testing could be more extreme, as is the case with item-level routing, such that tests targeted at specific ability levels differ from those that target other ability levels in their difficulty and content coverage. Greater degrees of adaption and larger differences in the adaptive tests administered to test takers can reduce the comparability of scores across test takers of different ability.

When unidimensional IRT models are employed, it is virtually impossible for test-taker scores to be successfully equated for adaptive “forms” because, by design, the adaptive routes differ in difficulty and indirectly modeled content, at least in part, as well as the test-taker groups that take the different routes. In effect, different ability groups take different test forms that are intentionally designed to be nonequivalent, which rules out equating as an attainable goal. (Similar statements apply to linking scores on paper–pencil and MST forms.) Just about all educational tests are multi-dimensional by design and by content specification. When a unidimensional IRT model is used and adaptations reflect ability, difficulty, and incompletely modeled

multidimensional content, statements about scores for test takers who take different test forms and routes being on the same scale are difficult to defend. Linkings of some kind may be possible, but the characteristics of any linked scores can be ascertained only through empirical studies that consider the accuracies of the IRT parameters and scores, the item pool, the adaptive settings, test forms for higher and lower ability test takers, etc. The strong claims supportable by an actual equating are not expected in such linkings.

Linking Tests Using Weak Anchors

Consider the situation where a linking is desired for tests X and Y , but the test data are not collected in one of the recommended data collection designs (Table 11.1). If these test data were obtained in a manner similar to a NEAT design in which X and Y were taken by nonequivalent groups, but with no anchor score data, what linking approaches might be available? One example of this situation occurs when the data from a paper-pencil test were intended to be collected in a randomly equivalent groups design, but test book spiraling procedures failed. Another situation occurs when the administration of a common anchor to both groups is not feasible because of security concerns. Finally, testing programs might intentionally introduce this type of design by offering their test in different administration modes and giving test takers the option to self-select into different test administration modes.

Two issues that determine the quality of linking are the similarity/dissimilarity of the administration groups and the representativeness of the available anchor(s), $A(s)$ for X and Y as indicated in the anchor, test correlations. An ideal situation occurs when the administration groups are samples from the same population. For this case, Holland and Dorans (2006) described the role of the anchor as one of reducing random variability and improving statistical precision, even when the anchor does not represent the tests:

When $P=Q$, the NEAT design is called an EG [randomly equivalent groups] design with anchor test. The two samples are drawn from a common population and the role of the anchor test changes. The anchor test becomes a covariate as in a randomized experimental design. It is used to gain precision in the estimation of the relevant parameters, rather than to adjust for group differences. For this special case, it is not necessary for A to measure the same construct that X and Y do, or even to be a test score. All that matters is for A to be correlated with both X and Y . When this is the case A is useful as a precision-increasing covariate. (p. 199)

For less than ideal situations where the populations of the administration groups cannot be considered equivalent, the anchor must reduce bias and variability (Holland & Dorans, 2006). The potential for greater linking error when administration groups are not equivalent means that it is especially important that the anchor be representative of, and correlated with, test scores. Although the use of inadequate anchors for a linking test administered to nonequivalent groups might improve linking accuracy, this use

may not sufficiently account for test-specific group differences or produce equatings that support interchangeable scores.

Several linking methods have been considered for situations where the administration groups differ and where multiple anchors and/or background variables might be available that could be incorporated into a test linking. Suggestions for using multiple scores were made by Angoff (1971) in a generalization of regression methods (Equation 17). Livingston et al. (1990) suggested propensity score matching as a way to incorporate multiple scores. Dorans and Wright (1993) showed that linking results obtained from matching administration groups based on a selection variable could be more accurate than methods based on matching groups with traditional anchors. Liou et al. (2001) described how demographic background variables might be used in test linking by making assumptions about the missing data and using corresponding imputation methods. Moses et al. (2010) showed how frequency estimation based on projected distributions (see the *Distinguishing Equating From Other Forms of Linking* section), categorized propensity scores, and missing data imputation could all be used to produce similar linking results when these methods were used with two anchor scores. Studies of categorized propensity scores based on background variables (Livingston, 2014; Wallin & Wiberg, 2019) and linear scale alignments with linear regressions of multiple background variables (Bränberg & Wiberg, 2011) showed that these approaches can increase precision and reduce variability in test linking. Statistical weighting procedures based on log-linear models have also been described for test linking based on background variables (Haberman, 2015) and on test takers' previous test scores (Y. Lee et al., 2019).

Most of these methods produce scale-aligning results that are similar to those obtained from projecting test score distributions for hypothetical administration groups defined by one or more anchors and/or background variables. It is possible that the linking results based on using an anchor and/or background variable have improved accuracy compared to an inappropriate randomly equivalent groups approach. However, to the extent that the anchors and/or background variables do not represent (and correlate highly with) the tests being linked, and also do not account for administration group differences, the linking results will likely have inadequacies, such as insufficiently controlled group differences that preclude interchangeable scores.

Linking State Tests to NAEP

The National Research Council published *Uncommon Measures* (Feuer et al., 1999) to address a debate in the late 1990s between those who favored voluntary national tests as a means of assessing the educational progress of students across the nation and those who believed that statistical linkages among existing tests could be used to achieve that purpose. The *Uncommon Measures* report examined the feasibility of linking the results of commercial and state tests, such as by linking these tests to each other and to the NAEP scales to support comparisons of students' achievement with national and international benchmarks and with students in other places. Feuer et al.

demonstrated that it was not possible to link state assessments for several reasons, including differences in the NAEP and state tests with respect to their content, format, margins of error, intended and actual uses of the tests, and the consequences attached to the test results.

Attempts to link state tests to the NAEP scale have continued since Feuer et al.'s (1999) report (Dorans, 2020), prompting discussions and questions about the interpretational value of the results. Thissen (2007, 2016) discussed an approach based on projection methods (Williams et al., 1998), and listed concerns about lack of population invariance, indications that linking results were not stable over time, study cost, and the unknown levels and differences in motivation for students taking a standardized test versus the NAEP test, which is more of a survey that lacks direct personal consequences for test takers. Other attempts involve linking state standards to NAEP scales using equipercentile methods (Braun & Qian, 2007; McLaughlin, 2000; McLaughlin & Bandeira de Mello, 2002). These attempts prompted concerns about whether the inferences and interpretations were too strong, about potential instabilities of the results over time (Koretz, 2007), and about comparisons that may not be defensible for the states and state tests that differ from NAEP with respect to content frameworks, implementation, and stakes (Ho & Haertel, 2007).

In another attempt to use the NAEP scale to connect disparate state assessment results, Reardon et al. (2021) reported linear scale-aligning linkings of school district means on state tests to the NAEP scale, based on statistically inferring the district means on the state tests from published passing rate distributions. Commentaries on Reardon et al.'s article by Bolt (2021), Davison (2021), Moses and Dorans (2021), and von Davier (2021) re-emphasized long-standing cautions about the large variation in blueprints used by different state tests and other differences with NAEP in terms of content, administration conditions, stakes, and test-taker motivation. Moses and Dorans (2021) provided empirical demonstrations that state-based linkings of district means from one test to another are not invariant across states, even when correlations in the district means of these scores are very high (.98 or higher). These discussions suggest that cross-state invariance evaluations are needed to support cross-state comparisons of districts.

DISCUSSION

The reporting scales for a large-scale testing program are the focus of five chapters of the previous editions of *Educational Measurement* (Angoff, 1971; Flanagan, 1951; Holland & Dorans, 2006; Kolen, 2006; Petersen et al., 1989). The current chapter updated these discussions. The *Scaling* section covered approaches to setting the scales for the test(s) of a large-scale testing program. The *Equating* section covered equating approaches for alternative versions of the same test. The *Linking* section discussed other linking approaches for relating the scores and scales of different tests. In these discussions, scaling, equating, and linking activities were described and related to a wider context

of testing activities, including test specifications, test form assembly, test scoring, test administration conditions (including data collection designs), and the intended purposes and uses of the test(s). When testing activities are consistent and tests are similar with respect to construction, administration, and purposes, the resulting scales are more likely to reflect their intended interpretations. When testing activities are inconsistent or are altered in tests that are scaled and linked to each other, the resulting scaling, linking, and equating procedures may not produce results that adequately support intended score interpretations.

Recent testing trends create and increase the challenges in establishing, maintaining, and relating the score scales of tests. Pursuits of alternative online administrations have increased since the COVID-19 pandemic, with mixed administration effects on reported scores (see the *Linking Tests Across Conditions of Measurement* section). There are also calls to revise testing in ways that address increasingly diverse testing populations, such as to develop and administer tests under less standardized conditions (Sireci, 2020), in ways that reflect test takers' sociocognitive backgrounds (Mislevy, 2018). In situations where testing programs compete for dwindling numbers of test takers, some programs have attempted to link their tests to other tests using substandard linking methodologies (Dorans & Moses, 2023). In other cases, unlinked scores are released with the presumption, but not necessarily the communication, that scores are linked based on nonempirical and untestable assumptions (Baldwin & Clauser, 2022; Dorans & Middleton, 2012). Assessment approaches can make different trade-offs of standardization, reliability, and comparability versus validity, group fidelity, and local uses (Brennan, 2006; Mislevy et al., 2025). Some of these trade-offs prompt recommendations to limit unwarranted score interpretations and broad comparisons of test takers that can be unfair (Dorans & Haberman, 2022; Moses, 2022, 2025).

As discussed in this chapter, large numbers of forms administered to smaller administration groups using weak data collection designs and little or no linking efforts can simultaneously inflate several types of error (random, systematic, violations of the equal construct requirement, etc.). They also raise concerns about the comparability of scores being released and used to make comparisons (Baldwin & Clauser, 2022; Moses, 2022). Experience indicates that these concerns have especially serious consequences for test score users when testing organizations are not forthcoming in communicating the procedures they use, the assumptions they make with their procedures, and the extent to which comparability in their scores is (un)supported. For these and other challenges, the recommended practices described in this chapter include checks to monitor and ensure that reported scales continue to reflect their intended interpretations. Additional recommendations are for checks on equating and linking results, especially those produced under limited and unique study conditions that may warrant interpretations that are restricted to the conditions of those linking studies rather than generalized to uses in broader testing populations (W. Lee & Brennan, 2021; Moses & Dorans, 2021; Moses, 2022).

The entity that produces reported scores has the ultimate responsibility for establishing and maintaining their reporting scales and for ensuring that the resulting scores and their interpretations are clearly communicated to test users (AERA et al., 2014). It is crucial that reported scores have clear, useful, and defensible interpretations and explanations based on sound scaling, equating, and (if necessary) linking, along with other supporting information. The ultimate goal is that reported scores, especially how they are produced and interpreted, should be integral and defensible evidence in support of validation arguments about test scores. It should be noted as well that this goal is unlikely to be attained without the active cooperation with and/or input from those who design, develop, administer, and market tests. Defensible scaling, equating, and linking is not simply the application of complex psychometrics to testing issues. All applied psychometrics involves assumptions, and the defensibility of results rests heavily on the credibility of these assumptions in the specific testing context under consideration, with appropriate attention given to quantifying and communicating likely error in reported scores:

Whether scores are equated, linked in some weaker sense, or rescaled, however, the overarching consideration in my opinion is that users be given appropriate guidance about score interpretation and use. Part of that guidance ought to be explicit indications of the amount of error in scores and in the likely uses made of scores, as well as admonitions about likely misinterpretations of scores. (Brennan, 2007, p. 175)

ACKNOWLEDGMENTS

My chapter was greatly improved by reviews from my reviewer-collaborators, Robert Brennan, Neil Dorans, and Michael Kolen, an early review from Derek Briggs, helpful discussions with Jonathan Weeks, and suggestions from editors Linda Cook and Mary Pitoniak. I am very thankful for these reviews. I am also grateful for the collaborations with all of my coauthors cited throughout this chapter.

NOTE

1. The variance of mean-score differences plus the relative error variance in classical test theory is the absolute error variance in generalizability theory (Brennan, 2001).

Standard Setting

A Cognitive and Social Model

Katherine Reynolds
Boston College

Standard setting is policymaking. Educational performance standards represent the aspirations that a governing entity holds for the learning and educational achievement of its school-age children. Credentialing performance standards represent the minimal level of competence necessary to ensure that professionals can provide safe and effective practice. In both situations, Cizek and Bunch (2007) noted that standard setting is “a procedure that enables participants . . . to bring to bear their judgments . . . to translate the policy positions of authorizing entities into locations on a score scale” (p. 19).

Standard setting is also a technology. It is a set of concepts, tools, methods, and procedures that we implement to create reasonable and defensible performance standards. As Reckase (2006) described it, standard-setting procedures are “mechanism[s] for helping panelists translate their intentions to the score scale” (p. 5, see also Reckase, 2023). In educational testing, performance standards are composed of a test (or test design), performance levels and descriptors, and corresponding cut scores. In credentialing testing, performance standards are composed of a test (or test design), defined expectations for minimum competency in a professional role (i.e., knowledge, skills, abilities), and a cut score. Most research in standard setting has focused on the components of this technology, including comparing methods, investigating components of individual methods, and exploring participant experiences.

Standard setting has been defined as the “level of performance on a test [that] is required for a test taker to be classified into a given performance category . . . [and] the process of deriving those levels” (Cizek, 2012b, p. 4) and, more specifically, “the proper following of a prescribed, rational system of rules or procedures resulting in the assignment of a number to differentiate between two or more conceivable states or degrees of performance” (Cizek, 1993, p. 100). Performance standards that are created from a standard-setting process define intended, appropriate “interpretations of test scores [and other information] for the intended uses” (American Educational Research Association [AERA] et al., 2014, p. 1). For example, performance-level labels like *Proficient* and *Advanced* and their associated descriptors guide interpretation of individual and group performance on state educational summative assessments. Candidates who achieve a “pass” on a credentialing exam have satisfied the knowledge and skill requirements for the license, certification, or certificate. These interpretations of test performance, based on performance standards, are claims that require validation.

“Standard setting is perhaps the branch of psychometrics that blends more artistic, political, and cultural ingredients into the mix of its products than any other” (Cizek, 2001, p. 5). The key concepts in these views on standard setting—policymaking and translating policy intentions to a test score scale, levels of performance, and a technology with prescribed concepts, tools, and procedures—highlight elements of standard setting that we address, to varying degrees, in this chapter. We focus especially in this chapter on the role and influences of human judgment and decision-making in standard setting.

Most standard settings include a workshop where experts (i.e., panelists), working independently and collectively to achieve a shared goal (i.e., usually convergence,

FIGURE 12.1
Typical Standard Setting Workshop Process

not consensus), are guided by a workshop facilitator through a method and set of procedures. Numerous methods exist for guiding a standard setting, and a typical process is shown in Figure 12.1. This begins by preparing the panelists to participate in the standard setting through orientation and training led by an expert facilitator. The process then moves into multiple rounds of standard-setting judgments where panelists can apply the standard-setting method (Round 1), review feedback as to how their judgments compare to those of the entire panel (listen and interact), and then make a second round of judgments. Regardless of method, participating in a standard-setting workshop has been described as “a challenging judgmental process executed by well-meaning persons (with specific areas of relevant expertise and experience) who are subject to all the laws of social psychology and cognitive psychology (for good and for ill)” (J. Pellegrino, personal communication, February 25, 2019).

The importance of the human element in standard setting cannot be overstated. Human judgment is the cornerstone on which standard-setting deliberations are based and recommendations are formulated. Each standard-setting method is defined by its own approach to framing these judgments and guiding expert panelists to complete a specific cognitive-judgmental task. Human judgment is subject to influences and biases that play out as internal and external factors, and their potential impact on standard setting cannot be ignored.

In this chapter, we examine the cognitive-judgmental tasks involved in making standard-setting judgments. To explore this angle on standard setting, we draw on findings in judgment and decision-making research literature and consider what may be going on in the minds of standard-setting panelists when they participate in standard-setting workshops and make judgments about cut scores. We address three claims:

1. The cognitive-judgmental task (inherent in the standard-setting method) is a critical aspect of standard setting and should be central to the design, preparation, execution, and evaluation of the workshop.
2. In addition to the cognitive-judgmental task, there are other influences on panelist judgment and decision-making in standard setting. Some are design features and are desirable; some are not.

3. Standard-setting results should reflect a well-executed process that was led by experts who helped panelists make their judgments avoiding undesirable influences.

Following this overview, the second section of the chapter is a review of the history of standard setting, including the significance of major research and policy milestones. In the third section, we propose a *cognitive and social model of standard setting* that illustrates the cognitive and social influences on panelist judgment and decision-making in standard setting. At the center of this model is the cognitive-judgmental task required by a given standard-setting method. The fourth section provides a framework by which standard-setting methods can be categorized by the type of task required. The fifth section further explores these categories of methods by describing how panelists complete the task and the cognitive processes, heuristics, and biases that may influence how they do so.

The chapter then shifts, in the sixth section, to review how all of this is operationalized in the standard-setting workshop process and the related cognitive and social influences that can come from the workshop design and execution. In the seventh section, we provide a review of the research on standard setting that supports the claims made in this chapter and suggest directions for future research. The chapter concludes in the eighth section, with some predictions for the evolution of the practice in standard setting.

With this focus on the cognitive-judgmental task of standard setting, this chapter is not the typical introduction to standard-setting concepts or methods; there are excellent resources that provide this level of information for those new to this topic. Readers interested in this level of information are referred to the second section of this chapter, which outlines the publication of key resources in the history of standard setting, introducing specific methods and providing a comprehensive picture of the practices.

HISTORY OF STANDARD SETTING

The concept of setting standards has existed for decades, even before it was commonplace in educational and credentialing testing. Standards exist to help professionals identify acceptable or unacceptable values on measures in fields such as medicine (e.g., temperature of 100.4 °F or higher indicates a fever) and environmental safety (e.g., the maximum levels for more than 90 contaminants in drinking water; Environmental Protection Agency, n.d.).

Standard setting in educational and credentialing testing has a rich history. In Table 12.1, we present an overview of the major milestones in this history, including key publications, introduction of selected methods, and other events that illustrate how the practice of standard setting has developed since the 1950s.

As is evident in Table 12.1, standard-setting methods have proliferated in recent decades, workshop designs and procedures have evolved since the early 2000s, earlier debates about the defensibility of standard setting have quieted, and innovations have flourished.

Table 12.1 Selected Milestones in the History of Standard Setting

Milestones	Significance
1950s	
Lindquist (1951) <i>Educational Measurement</i>	The first edition of this volume provided a baseline on standard setting by including a discussion of measurement for classification and placement and predicting future achievement (e.g., Chauncey & Frederiksen, chap. 4; Cook, chap. 1).
Nedelsky (1954) <i>Absolute grading standards for objective tests</i>	Introduction of Nedelsky's method is "perhaps the first widely disseminated criterion-referenced method for setting cut scores" (Cizek & Bunch, 2007, p. 69).
1960s	
Glaser (1963) <i>Instructional technology and the measurement of learning outcomes: Some questions</i>	Another early reference to criterion-referenced measurement; criterion referencing established the need to differentiate levels of performance, that is, performance standards. See also Glaser and Klaus (1962).
1970s	
Angoff (1971) <i>Scales, norms, and equivalent scores</i>	Angoff introduced his idea for setting standards in a footnote in his chapter; numerous implementations since the original publication have adapted his idea and are captured under the umbrella of modified Angoff methods.
Shepard (1978) <i>Journal of Educational Measurement</i> [Special issue on standard setting]	Among other topics, Shepard highlighted the current debate on standard setting. Glass condemned judgmental standards as arbitrary and therefore unsafe; Linn argued that standards may be arbitrary but not necessarily capricious; Popham defended standard setting as an "important but largely unstudied problem" (p. 300); Levin condemned performance standards as an "appearance of accountability" (p. 316).
Other standard-setting methods introduced Ebel (1972) – Ebel method Berk (1979) – Contrasting Groups method Zieky and Livingston (1977) – Borderline Group method	
1980s	
Livingston and Zieky (1982) <i>Passing scores: A manual for setting standards of performance on educational and occupational tests</i>	The first practically oriented manual on standard-setting methods
Berk (1986) <i>A consumer's guide to setting performance standards on criterion-referenced tests</i>	Provided a comprehensive review of 38 standard-setting methods highlighting the range of approaches
Linn (1989) <i>Educational Measurement</i> (3rd ed.)	This third edition provided a brief discussion of standard setting in two chapters: Jaeger, chap. 14; Petersen et al., chap. 6

(continued)

Table 12.1 (continued)

Milestones	Significance
Other standard-setting methods introduced Jaeger (1982) – Structured Judgment process Hofstee (1983) – Hofstee Compromise method Beuk (1984) – Beuk Compromise method Legislation and professional standards AERA et al. (1985) <i>Standards for Educational and Psychological Testing</i> Public Law 100-297 (1988) establishes the National Assessment Governing Board to guide achievement-level setting for the National Assessment of Educational Progress (see Loomis & Bourque, 2001)	
1990s	
Shepard et al. (1993) <i>Setting performance standards for student achievement. A report of the National Academy of Education Panel on the evaluation of the NAEP trial state assessment: An evaluation of the 1992 achievement levels</i>	Evaluation of NAEP standard setting concludes that “the approach [to standard setting] is fundamentally flawed” (pp. 127–128).
Kane (1994) <i>Validating the performance standards associated with passing scores</i>	Kane defined a validity framework for supporting cut scores including procedural, internal, and external evidence to support the interpretation and use of performance standards.
Hambleton and Plake (1995) <i>Using an extended Angoff procedure to set standards on complex performance assessments</i>	Introduction to the extended Angoff method, which enabled standard setting for assessment activities scored in multiple levels
Lewis et al. (1996) <i>Standard setting: A bookmark approach</i>	Introduction of the Bookmark method, one of the most commonly used methods in educational achievement testing See also Lewis et al. (2012)
Impara and Plake (1997) <i>Standard setting: An alternative approach</i>	Introduction of the Angoff yes/no method, an alternative to modified Angoff, reflecting Angoff’s original ideas
Pellegrino et al. (1999). <i>Grading the nation’s report card: Evaluating NAEP and transforming the assessment of educational progress</i>	A second evaluation of NAEP standard setting, which concluded that “the current process for setting NAEP achievement levels is fundamentally flawed . . . the current processes are too cognitively complex” (p. 7)
Other standard-setting methods introduced Jaeger (1995a; 1995b)—Judgmental Policy Capturing method Plake et al. (1997)—Dominant Profile method Legislation and professional standards AERA et al. (1999)— <i>Standards for Educational and Psychological Testing</i>	
2000s	
Cizek (2001) <i>Setting performance standards: Concepts, methods, and perspectives</i>	First edited volume that is dedicated to standard-setting methods, approaches, and issues
Cizek (2005) <i>Applied Measurement in Education</i> [Special issue on vertically moderated standard setting]	Journal special issue focused on vertically moderated standard setting (also called “vertically articulated” standard setting) in response to reporting mandates from No Child Left Behind

Milestones	Significance
Buckendahl (2005) <i>Applied Measurement in Education</i> [Special issue on qualitative inquiries of participants' experiences with standard setting]	Special issue focused on participants' experiences in standard setting. The guest editor's introduction acknowledges the cognitive demands of standard-setting tasks and observes that the process involves translating "a participant's mental model of the target test taker . . . into judgments" (p. 219).
Cizek (2006) <i>Standard setting</i>	This chapter appeared in the first volume of the <i>Handbook of Test Development</i> , acknowledging the role of standard setting in overall test design and development.
Hambleton and Pitoniak (2006) <i>Setting performance standards</i>	Standard setting was addressed in its own chapter for the first time in <i>Educational Measurement</i> (4th ed.), providing a comprehensive treatment of existing methods and procedures.
Standard-setting methods introduced Jaeger and Mills (2001)—Integrated Judgment procedure Kingston, Kahl, Sweeney, and Bay (2001)—Body of Work method Plake and Hambleton (2001)—Analytical Judgment method Haertel (2002)—Briefing Book method Roeber (2002)—Reasoned Judgment method Sireci, Hambleton, and Pitoniak (2004)—Direct Consensus method Legislation and professional standards No Child Left Behind Act (2001) requires states to set academic achievement standards for state educational accountability tests NCCA (2004) <i>Standards for the Accreditation of Certification Programs</i> includes expectations for standard setting	
2010 to Present	
Kaftandjieva (2010) <i>Methods for setting cut scores in criterion-referenced achievement tests: A comparative analysis of six methods with an application to tests of reading in EFL</i>	Identified 62 distinct standard-setting methods (see Appendix 1); many were developed for language tests used in Europe and Asia and method names may not be recognizable to U.S. psychometricians (e.g., the basket procedure).
Cizek (2012a) <i>Setting performance standards: Foundations, methods, and innovations</i> (2nd ed.)	The second edition of the volume on standard setting contains multiple chapters that address standard-setting methods, approaches, and issues.
Phillips (2012) <i>The benchmark method of standard setting</i>	Introduction of an empirically based approach to standard setting, benchmarked standard setting. See also Ferrara et al. (2021)
Mattar et al. (2012) <i>Reviewing or revalidating performance standards on credentialing examinations</i>	Introduction to standards validation as an alternative to traditional standard setting, signaling evolution in standard-setting design and practice See also Landl (2019) for another treatment of standards validation.
Cizek and Earnest (2016) <i>Setting performance standards on tests</i>	This updated second edition of the <i>Handbook of Test Development</i> retained a separate chapter on standard setting, acknowledging the role of standard setting in overall test design and development.

(continued)

Table 12.1 (continued)

Milestones	Significance
Lewis and Cook (2020) <i>Embedded standard setting: Aligning standard-setting methodology with contemporary assessment design principles</i>	Introduction to the embedded standard-setting approach, in which cut scores are established as part of the test development process; signals evolution in standard-setting design and practice
Reckase (2023) <i>The psychometrics of standard setting: Connecting policy and test scores</i>	This volume connected the psychometrics of standard setting to policy underlying the purpose of the specific standard setting.
Other standard-setting methods introduced	
Ferrara and Lewis (2012)—Item-Descriptor matching method	
Perie and Thurlow (2012)—Dominant Profile method	
Legislation and professional standards	
AERA et al. (2014) <i>Standards for Educational and Psychological Testing</i> includes three standards on standard setting (similar wording as in the 1999 edition)	
NCCA (2014) <i>Standards for the Accreditation of Certification Programs</i> includes expectations for standard setting	
Every Student Succeeds Act (2015) includes specific expectations for setting academic achievement standards (critical element 6.2)	
Domaleski et al. (2018), through CCSSO, creates <i>Establishing Performance Standards for School Accountability Systems</i>	

One driver of innovation in standard-setting methods has been the desire to improve the experience for panelists and ensure they can apply their expertise to make reasoned judgments following the guidelines within the method. Drawing on the extensive research in the field of standard setting and the authors' experience conducting these workshops, we recognize there are numerous influences on the judgmental process but no existing framework for organizing or modeling them. Therefore, we have developed a *cognitive and social model of standard setting*, which is detailed in the next section. We present that first because the remaining sections of the chapter discuss the aspects of this model and how the various influences (both desired and undesired) come into play during the workshop.

Historically, standard-setting methods have been classified as either test centered or test-taker centered to identify the focus of the judgmental task (Cizek, 2012c, p. 8; Jaeger, 1989). This has been a useful distinction because test-taker-centered methods require panelists to know the test takers and understand their knowledge, skills, and abilities and how they are taught, as well as the test content, whereas test-centered methods require panelists to bring their subject matter expertise about test content to the judgmental process. The research finding that panelists appear to understand test-taker-centered tasks better than test-centered tasks (Skorupski, 2012, p. 139) reinforces the distinction's usefulness. Hambleton and Pitoniak (2006, p. 440) recognized the need to expand this framework, given the increasing complexity of the design and scoring of educational achievement tests. They identified four categories, differentiated by the focus of panelist judgments: (a) item and scoring rubrics, (b) test takers, (c) test-taker work, and (d) score profiles. We agree with the distinc-

tions in both frameworks—that selecting a standard-setting method should take into consideration the types of judgments required of panelists and that the focus of these judgments should be aligned with the types of items on a test. We advance this thinking by reviewing cognitive-judgmental tasks required of panelists by various standard-setting methods.

To define standard-setting cognitive-judgmental tasks formally, we begin with a definition of *cognitive tasks*. According to Kester and Kirschner (2012),

Cognitive tasks are those undertakings that require a person to mentally process new information (i.e., acquire and organize knowledge/learn) and allow them to recall, retrieve that information from memory and to use that information at a later time in the same or similar situation (i.e., transfer). (p. 619–620)

According to this definition, the components of cognitive tasks are (a) acquire and organize new learning and (b) retrieve and apply that learning to complete tasks that require cognitive processing. Standard-setting *cognitive-judgmental tasks* are the specified decisions that panelists are required to make to recommend cut scores. This term, cognitive-judgmental task, highlights the interrelatedness and interactions among the demands placed on panelists when they undertake a standard-setting method to recommend cut scores: (a) cognitive processes, (b) judgmental processes, and (c) a problem-solving task, in the form of a decision to be made (i.e., the recommendation required by the standard-setting method).

The “cognitive-judgmental tasks are the distinguishing features of the various standard setting methods” (Ferrara & Lewis, 2012, p. 255). For most methods, the specified judgment fully defines the cognitive-judgmental task (e.g., estimate a probability or percentage in the modified Angoff method) and provides information to calculate cut scores. For other methods, the specified judgment and its accompanying thinking process are a step toward making an explicit decision, in the form of directly recommending a cut score (e.g., in the Bookmark and dominant profile methods). Most methods require consideration of additional information to make a judgment (e.g., performance-level descriptors [PLDs], descriptions of borderline test takers¹—those who represent the key differentiators between levels). In all cases, the cognitive-judgmental task is intended to elicit a thinking process to arrive at a judgment (i.e., make a probability, matching, signal detection, or value judgment).

A COGNITIVE AND SOCIAL MODEL OF STANDARD SETTING

Our model of standard setting subsumes three submodels: a panelist cognitive processing submodel, a group interactions submodel, and a workshop process submodel (see Figure 12.2). At the center is the cognitive-judgmental task within the panelist cognitive processing submodel. The arrows within the model identify the influences among these components. Finally, the model reflects that standard-setting workshops and panelist judgments take place within a larger policy and sociocultural context.

**FIGURE 12.2****The Cognitive and Social Model of Standard Setting**

Note. The model illustrates facilitator processes, group interactions, panelist cognitive processing, and workshop processes that influence cut score recommendations. Boxes represent processes and elements in the three submodels; arrows represent hypothesized directions of influence.

- Arrow 1: Facilitator influence on group behaviors and interactions; group behaviors that require facilitator intervention
- Arrow 2: Group interactions that influence individual panelist thinking and behavior; individual panelist behaviors that influence group interactions. The gray box around “Group Interactions” and “Panelists” indicates that panelists behave and act as both individuals and group members.

- Arrow 3: Facilitator influence on individual panelist thinking and deciding (or cognitive processing and decision-making)
- Arrow 4: Panelist behaviors, identities, and characteristics that influence individual panelist thinking and decision-making
- Arrow 5: Influence of standard-setting task features, overarching cognitive processes, heuristics, and biases on panelist cognitive processing and decision-making
- Arrow 6: Influence of other required conceptual understandings on panelist cognitive processing and decision-making
- Arrow 7: Reciprocal influence of panelist cognitive processing while learning required concepts and procedures
- Arrow 8: Influence of panelist cognitive processing and the cognitive-judgmental task on Round 1 cut score judgments
- Arrow 9: Reciprocal influence of panelist cognitive processing during group discussions of judgments and Round 1 feedback
- Arrow 10: Influence of panelist cognitive processing and the cognitive-judgmental task on Round 2 cut score judgments

In this next section, we describe each submodel. We begin with the panelist submodel because panelist thinking and deciding are central to the standard-setting activities.

Individual Panelist Cognitive Processing Submodel

The *individual panelist cognitive processing submodel* accounts for the method's cognitive-judgmental task and related general cognitive processing (i.e., judgmental task features, overarching cognitive processes, judgmental heuristics, and cognitive biases), as well as other required conceptual understandings. A panelist's cognitive processing includes all of these aspects. Responding to requirements of the standard-setting cognitive-judgmental task is influenced by the other two components. This submodel is the focus of this chapter.

Group Interactions Submodel

The *group interactions submodel* accounts for the social actors who participate in standard-setting workshops and their interactions among these social actors. This submodel is supported by social psychology theoretical and empirical literature on group interactions and decision-making. Early on, Fitzpatrick (1989) discussed two processes by which panelists may change their minds following group discussion in a standard-setting workshop: normative influences based on social comparison (Festinger, 1954) and learning of new information in social contexts (Burnstein & Vinokur, 1975). In addition to these social influence processes, we propose explicit consideration of the individuals involved in a standard-setting workshop: the panelists and the facilitator.

One component of the group interactions submodel is the panelists themselves. Standard-setting panelists may be broadly representative of stakeholders of the

assessment program, which implies some degree of diversity. In addition to this intentional diversity, panelists also bring varied personality characteristics, personal attributes, and points of view that may not be known during workshop planning. A second component of the group interactions submodel poses the influence of the panelist group on the standard-setting process. Panelist behavior and interactions are defined in small working groups, often organized as separate tables, rather than as coexisting individuals, and observable and inferable behaviors must be considered to understand their processes fully (Bonito & Sanders, 2011). The final component of the group interactions submodel is the workshop facilitator, who guides panelists through every step of the workshop as detailed in the “Workshop Designs, Processes, and Practices” section of this chapter. Because of space limitations, the group interactions submodel is not covered in detail in this chapter.

Workshop Process Submodel

The *workshop process submodel* describes three phases and five subsumed steps that are discernible in the agendas for most standard-setting workshops and methods, though the emphasis and amount of time allotted to any step can vary considerably. The three phases include preparation, Round 1 judgments, and Round 2 judgments. (Some workshops include more than two rounds.) Standard-setting workshop procedures generally follow similar steps and contain similar content and are customized for a specific method and workshop (see detail in the section “Workshop Designs, Processes, and Practices” later in this chapter).

Social and Political Context

These submodels (and the activities therein) exist within the larger social and political context, which is specific to each testing program. In this chapter, we focus on standard-setting practices within educational testing and credentialing testing. Although there are similarities in the design, execution, and evaluation of these activities, the social and political context is unique.

Educational tests are used to evaluate student achievement against performance standards as articulated through PLDs (see Huff et al., this volume). This may require setting a single cut score (e.g., pass or fail on a high school end-of-course examination) or multiple cut scores (e.g., to distinguish levels of performance). The results from these educational tests are used primarily for accountability purposes (as required under federal law); to evaluate school performance and improvement needs; to identify student groups that may require additional, specialized attention; and to measure achievement growth. Standard setting in education, therefore, represents high-stakes decisions for schools, districts, states, and, in some cases, students. These observations shared in this chapter with respect to educational testing are also relevant to setting standards for alternate assessments for students with significant cognitive disabilities (e.g., Elliott & Kettler, 2015) and for assessments of English language proficiency (e.g., Chalhoub-Deville & Deville, 2006). Both types of educational tests

are required for public accountability reporting, specifically for these unique student groups. Panelists for setting standards for these tests are expert and experienced in both the content standards and the unique learning needs and performance capabilities of these groups.

Credentialing testing covers examinations that are used to determine eligibility for licensure, certification, and certificates. The purpose of a passing standard typically is to determine whether a candidate (i.e., a test taker) has met a minimum standard for safe and effective practice within the profession. For that reason, most credentialing examinations result in either a “pass” or “fail” determination. The context of the standard setting, therefore, includes high-stakes decisions where the ultimate result will have implications for individual candidates’ current and future professional careers as well as the safety and security of the public. Additional stakeholders include employers and training programs. The practices (e.g., standard setting) of many credentialing programs are often reviewed by third-party accreditation organizations against standards demarcating acceptable practice.

Relationships Among the Submodels and Components

The 10 arrows shown in Figure 12.2 indicate influences between components in the three submodels. Some influences are unidirectional, as in the influence of facilitator processes on individual panelist cognitive processing (e.g., Arrow 3). Others are bidirectional, for example, the reciprocal adjustments between workshop facilitators and group behavior (Arrow 1).

Cognitive processing operates within each panelist and is not directly observable during a workshop. Panelist processing and decision-making are enacted in the three phases and five steps in the workshop process submodel. In the Learn step, influences on the panelist submodel function in both directions: As panelists learn about the cognitive-judgmental task and other required conceptual understandings, their cognitive processing develops, becomes more efficient, and, hopefully, conforms to the method’s intended cognitive-judgmental task. A similar developmental process holds true as panelists process insights and develop shared understandings during discussion of feedback, in the Listen and Interact step. Panelist processing and deciding also connects to the Decide steps. We hypothesize that this connection and its influence operate in one direction primarily, though there seems little doubt that many panelists continue to process their decisions after they have made them. In the meantime, group interactions are likely to influence individual panelist processing and decision-making, both while group interactions are occurring (e.g., discussions of feedback between rounds) and during subsequent independent thinking and deciding.

We have proposed this cognitive and social model of standard setting using theory, concepts, and empirical findings in cognitive and social psychology and standard-setting literatures. We now turn our attention to the center of the model and the central

focus in standard setting: panelists and their cognitive processing. To do so, we draw on the judgment and decision-making branch of cognitive and social psychology, which has been influential in economic decision-making and business management and perhaps is most closely associated with the work of Kahneman (e.g., 2011) and colleagues. The process of standard setting involves humans who are trained to use specific types of information to make decisions in order to recommend cut scores. However, human decision-making is susceptible to judgmental errors and biases. As we will show, the cognitive-judgmental tasks that define the most widely used standard-setting methods are functionally different and are susceptible in different ways to decision errors and biases. We begin with an overview of cognition in decision-making before defining and contrasting the cognitive-judgmental tasks for eight well-documented standard-setting methods. Later, we consider other factors that influence standard-setting decisions under different methods.

TAXONOMY OF COGNITIVE-JUDGMENTAL TASKS FOR STANDARD-SETTING METHODS

With that overview as background, we now introduce a taxonomy of cognitive-judgmental tasks for standard-setting methods that can help practitioners be clear about the cognitive-judgmental task they are asking panelists to undertake. We propose this *taxonomy of cognitive-judgmental tasks* to illustrate the similarities and differences among standard-setting methods in terms of the cognitive challenges they pose to panelists and provide examples from frequently used methods (see Table 12.2). In accordance with the focus of this chapter, we will not fully describe each of these methods. For additional detail on these (and other methods), the reader is referred to the original research on each method, as well as texts that cover multiple methods (see citations in Tables 12.1 and 12.2).

The hypothesized cognitive processes involved are determined and influenced by the features of the method's standard-setting task and the cognitive and other demands on panelists that we illustrate in this model. The cognitive-judgmental task defines each standard-setting method and is central to the cognitive-social model. The model illustrates the many cognitive and social influences on decision-making in a standard-setting workshop.

We have organized the taxonomy around four types of cognitive-judgmental tasks by drawing on findings in cognitive psychology and judgment and decision-making empirical literatures. These are:

1. *Probability judgments*: State a probability (directly or indirectly) or estimate a percentage as part of the process of recommending cut scores.
2. *Matching judgments*: Match test items, test-taker work samples, test-taker score profiles, or test takers themselves with achievement-level descriptors or descriptions of borderline test takers.

Table 12.2 Taxonomy of Cognitive-Judgmental Tasks With Key Elements of Eight Standard-Setting Methods (and Two Variations), Including Paraphrased Statements of Cognitive-Judgmental Tasks

(1) Probability judgments			
Angoff, modified			
Cognitive-judgmental task: Estimate the (a) probability that borderline test takers will respond successfully to each item or (b) percentage of borderline test takers who will respond successfully (Angoff, 1971; Plake & Cizek, 2012). Typical uses: Most widely used in credentialing testing; moderate use in K–12 educational testing			
Item formats: Dichotomously scored items	Data requirements: Item p values and impact data are not required, but panelists would review them if provided	Other required understanding: Test items Descriptions of borderline test takers	Cut score recommendations: Sum of item-level judgments ^a ; calculated by panelists or a psychometrician
Angoff yes/no			
Cognitive-judgmental task: Indicate which items you expect a borderline test taker to answer correctly—yes or no—where the expectation is a probability judgment or perceived likelihood (Angoff, 1971, p. 514; Impara & Plake, 1997). Typical uses: Most widely used in credentialing testing; moderate use in K–12 educational testing			
Item formats: Dichotomously and polytomously scored items	Data requirements: Item and impact data are not required, but panelists would review them if provided	Other required understanding: Test items and polytomous item score levels ^b Descriptions of borderline test takers	Cut score recommendations: Sum of item-level judgments; calculated by panelists or a psychometrician
Bookmark			
Cognitive-judgmental task: Place a bookmark at the first location in the ordered item booklet where borderline test takers have demonstrated achievement sufficient to be considered <i>Proficient</i> (<i>Basic, Advanced</i> ; Lewis & Cook, 2020). Alternative statement: The bookmark represents a judgment of the divide between items that a student at the threshold of a performance level (the minimally proficient student) should be able to answer correctly from those items that are not necessary to demonstrate mastery of at that performance level. Typical uses: Most widely used method in K–12 educational testing			
Item formats: Dichotomously and polytomously scored items	Data requirements: Dichotomous item and polytomous score level difficulty locations on an IRT scale, using a response probability criterion, ordered by difficulty	Other required understanding: Scale locations of dichotomous and polytomous items PLDs Response probability criterion	Cut score recommendations: Panelist judgment (bookmark placement); translated to score scale by a psychometrician

(continued)

Table 12.2 (continued)

Other probability-based methods The direct consensus (Sireci et al., 2004) and Nedelsky (Nedelsky, 1954; Zieky, 2001, p. 21) methods are included in the probability judgment category.			
(2) Matching judgments			
(a) Match items or test-taker work samples to PLDs			
Body of work			
Cognitive-judgmental task: Match test-taker work samples to PLDs (Kingston et al., 2001; Kingston & Tiemann, 2012). Typical uses: Most widely used in K–12 educational testing for performance and portfolio assessments			
Item formats: Polytomously scored test-taker work samples, including performance tasks and essay prompts, typically contained in a portfolio	Data requirements: All test-taker responses are scored and sorted from lowest to highest total scores (or vice versa); scores are not revealed to panelists	Other required understanding: Test-taker work samples, ordered by overall score PLDs	Cut score recommendations: Cut scores are the difference between average scores of work samples that are matched to each performance level; calculated by a psychometrician
Item-Descriptor Matching			
Cognitive-judgmental task: Step 1. Match the content knowledge, skills, and cognitive processes that each item requires (i.e., response demands) to the knowledge and skill capabilities in PLDs. Step 2. Find the location in the threshold region between two adjacent levels that best distinguishes the levels, this time by matching threshold region items to adjacent PLDs (Ferrara et al., 2002; Ferrara & Lewis, 2012). Typical uses: Used most widely in K–12 educational testing, sometimes with alternate assessments			
Item formats: Dichotomously and polytomously scored items	Data requirements: Item and polytomous score level difficulty locations on an IRT scale, using a response probability criterion, ordered by difficulty	Other required understanding: Scale locations of dichotomous and polytomous test items, ordered by difficulty PLDs	Cut score recommendations: Panelist judgment (location); translated to score scale by a psychometrician
(b) Match score profiles to PLDs			
Dominant profile			
Cognitive-judgmental task: Match score profiles to descriptors, then state their conjunctive and compensatory matching rules; for example, <i>Require a score of 3 on two tasks and at least a 2 on the other three tasks</i> (Cizek & Bunch, 2007; Perie & Thurlow, 2012, pp. 366–388; Plake et al., 1997). Typical uses: Field tested for National Board for Professional Teaching Standards certification assessments; used in credentialing testing sometimes as an adaptation of judgmental policy capturing (C. Buckendahl, personal communication, May 22, 2020)			

(c) Match test takers to performance level groups			
Borderline group			
Cognitive-judgmental task: Categorize individual test takers into clearly competent, clearly inadequately prepared, and on the cusp between competent and not competent status, based on PLDs (Cizek & Bunch, 2007, p. 113; Livingston & Zieky, 1982). Typical uses: Used for the Smarter Balanced K–12 educational testing program (Smarter Balanced 2015; 2017)			
Item formats: Test items are not examined, though test content is considered	Data requirements: Test scores are required to compute the cut score; panelists are unaware of test-taker scores	Other required understanding: Panelist judgments of passing/ borderline/ failing status of known test takers Descriptions of passing and failing test takers are not specified	Cut score recommendations: Average score of test takers classified as borderline; calculated by a psychometrician
Contrasting groups			
Cognitive-judgmental task: Categorize individual test takers into mastery/nonmastery or pass/fail status (Berk, 1976; Cizek & Bunch, 2007, p. 107). Typical uses: Used frequently in employment testing (C. Buckendahl, personal communication, May 22, 2020)			
Other matching-based methods The analytical judgment (Cizek & Bunch, 2007; Plake & Hambleton, 2001; Zieky et al., 2008) and integrated judgment procedure (Jaeger & Mills, 2001) methods are included in the matching category.			
(3) Threshold-signal detection judgments			
The performance profile (Morgan, 2004; Morgan & Perie, 2004, Table 2; Perie & Thurlow, 2012) and reasoned judgment (Roeber, 2002) methods are included in the threshold-signal detection category.			
(4) Value judgments			
Beuk (Beuk, 1984; Thompson, 2022), briefing book (Haertel, 2002; Haertel et al., 2012), Ebel (1972), Hofstee (Hofstee, 1983), judgmental policy capturing (Jaeger, 1995a; 1995b), and the structured judgment process (Jaeger, 1982) methods are included in the value judgment category.			

Note. IRT = item response theory; PLD = performance-level descriptor.

^aWhen panelists understand how cut scores are calculated, they can adjust item-level judgments to achieve a desired test cut score.

^bScore levels may be expressed as a rubric score (e.g., 1, 2, 3, 4) or rubric score-level location or threshold location on an IRT score scale.

3. *Threshold-signal detection judgments*: Discern when a score profile's indication of the requirements of one performance level shifts to the requirements of the adjacent performance level.
4. *Value and other judgments*: Make value and other judgments to recommend cut scores.

Probability Judgments

Many of the decisions we make in our lives are based on our beliefs about the likelihood of events and other outcomes. We express our beliefs using phrases like “I think that . . .,” “Chances are that . . .,” and so forth. We may or may not be completely

aware, when we make predictions and attach our judgment of the likelihood that the prediction will prove true, that we are making probability judgments. In standard setting, panelists are required to express these “subjective probabilities” (Tversky & Kahneman, 1974; see also Kahneman, 2011, p. 419) in the modified Angoff, Bookmark, direct consensus, and Nedelsky methods. Tversky and Kahneman (1974) and innumerable subsequent studies and research syntheses (e.g., Nickerson, 2004; Plous, 1993) concluded that “people rely on a limited number of heuristic principles which reduce the complex tasks of assessing probabilities and predicting values to simpler judgmental operations . . . [that can] lead to severe and systematic errors” (see Kahneman, 2011, p. 419).

Probability judgments are prone to judgmental errors that arise from cognitive biases. For example, people ignore base rates² (Kahneman, 2011, p. 88) when they judge the likelihood of a future event, they do not evaluate the quality of evidence they use to make these judgments, and they use representativeness³ (e.g., stereotyping; Kahneman, 2011, pp. 149–153) to make these judgments. Research also has shown that some situations tend to elicit nonprobabilistic mindsets (e.g., Rottenstreich & Kivetz, 2006) where people do not judge the likelihood of an event (i.e., its probability) and, instead, use intuitively generated, nonprobabilistic rules, heuristics, or rationales. For example, cognitive biases like “what you see is all there is” (WYSIATI⁴; Kahneman, 2011, pp. 85–88) and our need for coherence (Kahneman, 2011, pp. 75–76) can lead us to believe the explanatory stories we construct about the likelihood of a future event rather than evaluate the quality and relevance of available evidence as we make probabilistic and other judgments.

Panelists probably construct an internal representation of the knowledge and skills possessed by borderline test takers, based on a description that adds to the cognitive load of the probability judgment and, likely, the complexity of making probability judgments. This may lead panelists to use the substitution heuristic⁵ (e.g., Kahneman, 2011, p. 97) to reduce load and complexity. In one study, Baron and Kannan (2013) found that panelists may estimate high probabilities of correct responses for borderline test takers when they see the knowledge and skills measured by an item listed explicitly in the borderline test-taker description. In contrast, they may estimate a lower probability of a correct response for borderline test takers when they encounter items that measure knowledge and skills not explicitly listed in the borderline test-taker description.

Katz (2019) offered a framework of standard-setting panelist cognition for making probability judgments, specifically for the modified Angoff method. He built his framework on others’ studies of how people estimate numerical values (e.g., likely future stock values), preferences (e.g., which is the better of two products), and probabilities (e.g., the likelihood that someone is infected with COVID-19) using attributes of the situation and levels of the attributes. He illustrated the role that specific heuristics and biases can play in modified Angoff estimates. The framework acknowledges that people ignore information cues, place too much focus on some cues, and take shortcuts when they estimate.

Matching Judgments

People match focus entities (e.g., a salmon, a test item) to target categories (e.g., fish, easy items) using subjective judgments about the degree to which the focus entity is representative of an entity group and the features of the target category (Murphy, 2004, p. 373; Wills, 2013, p. 352). People use a variety of matching strategies, including “category-based induction,” to categorize and “make predictions about novel items” (Murphy, 2004, p. 243) and their category membership. Working in the opposite direction, people may use “property induction” (Hayes & Heit, 2013, p. 618) to infer properties from a category, such as knowledge and skill requirements in PLDs, to enable matching of test items and their response demands.

We hypothesize three subcategories of matching judgments in standard setting:

- Match items or test-taker work samples to PLDs or descriptions of borderline test takers (e.g., Body of Work or ID Matching methods)
- Match score profiles to PLDs or descriptions of borderline test takers (e.g., dominant profile method)
- Match test takers to PLDs (e.g., borderline method)

All three subcategories entail matching entities (i.e., items, work samples, and score profiles) to other entities (i.e., PLDs, descriptions of borderline test takers). Formal models of categorization may involve multiple competing processes, which have been shown to include probability matching (Wills, 2013, p. 352). While these three matching subcategories may appear to be unique, we hypothesize that cognitive processing is highly similar for all three and that matching focus entities and target entities is likely to require activation of similar declarative knowledge networks.

Threshold-Signal Detection Judgments

The concepts in signal detection theory reach back at least to the psychophysics research of Fechner in the late 1800s (Briggs, 2022, chap. 2; Swets, 1996, p. 7). Electrical and radar engineers developed the receiver (or relative) operating curve method in the 1940s to evaluate peoples’ diverse sensitivities to target stimuli (e.g., enemies on a battlefield). Detecting a signal amid noise is a main function of conscious attention. In psychology, the focus has been on perceptual detection of stimuli. We hypothesize that signal detection is the primary cognitive-judgmental task in the two methods in this section of the taxonomy (performance profile and reasoned judgment) and the secondary cognitive function in other methods (Bookmark, ID Matching, and dominant profile).

In standard setting, the signal is the detectable difference between two adjacent levels of performance or test-taker groups, indicated in items, score profiles, and scoring rubrics; the noise is competing and incomplete information, which obscures the information in the signal that is most useful in detecting a threshold. In detecting signals, panelists also consider, for example, the consequences associated with false-positive and -negative decisions, as in “If I recommend this cut score, then X percentage of test takers will fail.”

Nichols et al. (2010) proposed standard setting as a measurement process in which “the construct being measured is the panelists’ representation of student performance at the threshold of an achievement level” (p. 14). They hypothesize that panelists construct internal representations of a scale and a value on that scale (both are concepts in statistical signal detection theory) that indicates where the signal has changed from one category to another (e.g., *Nearing Proficiency to Proficient*, nonqualified to qualified). The predominance of signal detection in Round 1 for some standard-setting methods is likely reduced in subsequent rounds as a result of feedback and discussion.

Several of the standard-setting cognitive-judgmental tasks in other categories in the taxonomy contain an element of signal detection. For example, statements of the cognitive-judgmental task for the Bookmark method make the role of threshold-signal detection clear. In fact, it is not unreasonable to hypothesize that signal detection is part of all methods in the probability category of the taxonomy because all require making judgments about borderline test takers or the minimum threshold between adjacent performance levels.

Value Judgments

Value judgments involve “assigning a value (such as good or bad) to something” (Merriam-Webster, n.d.). *Psychology Wiki* elaborates: “A value judgment is a judgment of the rightness or wrongness of something, based on a particular set of values or on a particular value system. Value judgments are statements of subjectivity” (Psychology Wiki, n.d.). Some methods in this section of the taxonomy require percentage estimates and matching judgments. However, these judgments are made within a framework of value judgments.

Standard setting involves making judgments that are inherently value influenced, as in “Which cut score is the best or right score for these test takers and this test?” As the *Standards* state, “cut scores embody value judgments as well as technical and empirical considerations” (AERA et al., 2014, p. 101). However, methods in this category task panelists with making holistic cut score judgments based on the overall assessment and/or expected performance of test takers.

The proposed taxonomy is further exemplified in Table 12.2, which outlines how some common standard-setting methods serve as examples of each category. In addition to providing a description of the cognitive-judgmental task for each method, the table includes descriptions of how the method is commonly used, the item formats for which it is appropriate, the data required to implement the method as described, additional information panelists must understand to complete the cognitive-judgmental task, and how the cut score recommendations are derived from the judgments. Because of space limitations, the additional details are provided for those methods that are based on probability and matching judgments since these are most commonly used in current practice.

FACTORS INFLUENCING COGNITIVE PROCESSING IN STANDARD SETTING

Some psychological theories structure human decision-making as if people decide rationally because they seek optimal outcomes. A thoughtful look around the world suggests that this is not the case. The empirical and theoretical literature on judgment and decision-making (e.g., Kahneman, 2011; Kahneman et al., 1982; Plous, 1993) and business management textbooks based on this literature (e.g., Bazerman & Moore, 2013; Hastie & Dawes, 2010) emphasize the role of judgmental heuristics and cognitive biases in human thinking and deciding. More specifically, they illustrate that human thinking, judgment, evaluations, and decisions are strongly influenced by (a) heuristics that provide shortcuts for difficult (and not so difficult) thinking tasks, (b) biases that often are not part of our conscious awareness or recognized in executive functioning, and (c) other cognitive processes and factors. Some of these heuristics, biases, and other cognitive processes are applicable as panelists engage in the standard-setting cognitive judgmental tasks.

Simon's bounded rationality (Simon, 1956; Speekenbrink & Shanks, 2013, p. 688), where people satisfice by finding good-enough, rather than optimal, solutions, seems consistent with the characteristics of standard-setting cognitive-judgmental tasks. For example, panelists estimate probabilities and percentages, place bookmarks based on the probability of a correct response, align items or collections of evidence with PLDs, and so forth. While we have observed panelists working diligently to make reasoned decisions in standard-setting workshops, we also have observed them accepting the practical reality of making satisficing decisions. For example, panelists usually accept and are willing to work with empirical item difficulties even after estimating a different item difficulty (see Clauser, Mee, et al., 2009, 2013).

In standard setting, panelists follow the cognitive-judgmental task to make decisions about what cut score(s) to recommend. However, panelist cognitive processing is not solely influenced by the method's cognitive-judgmental task. Figure 12.2 shows how various factors, such as judgmental task features, overarching cognitive processes, judgmental heuristics, and cognitive biases that influence panelist processing and decision-making, interact with the demands of a method's cognitive-judgmental task. These factors, which can undermine the intent and valid implementation of a prescribed judgmental task, are described in this section.

Specifically, in this section of the chapter, we offer hypotheses about the influences of these factors on two of the categories within the taxonomy: probability judgments (i.e., Angoff and Bookmark methods) and matching judgments (i.e., Body of Work, ID Matching, Borderline Group, Contrasting Groups, and the Dominant Profile methods). These two categories include the most widely used standard-setting methods up to this time.

Our goal in proposing these hypotheses is to identify the heuristics, biases, and other cognitive factors that operate on decision-making in these methods and, therefore,

should be addressed in workshop design and panelist training. You will notice at least three things about these hypotheses. First, in a small number of instances where relevant research findings are available, we report the findings rather than generate new hypotheses. Second, our hypotheses indicate that, often, different standard-setting methods may be susceptible in different ways to influences of these factors. In other cases, a hypothesized influence may be similar across methods. While a reader may or may not find these hypotheses plausible, our goal is to stimulate thinking about judgment and decision-making in standard setting and susceptibilities of methods to specific types of judgmental errors. In a later section of this chapter, we provide considerations for panelist training and workshop facilitator monitoring in mitigating these undesirable influences on panelist judgments.

We now discuss the various factors that influence panelist cognitive processing in standard setting organized under the sections of judgmental task features, overarching cognitive processes, judgmental heuristics, and cognitive biases.

Judgmental Task Features

These are characteristics of the cognitive-judgmental task, such as cognitive load, cognitive strain, and cognitive complexity, that influence the cognitive challenges of the task.

Cognitive load and cognitive strain describe the demand on working memory or the level of effort required for a task. Such demands reduce memory capacity for new learning and decisions (see Kahneman, 2011, pp. 59–60, on cognitive strain; see Sweller, 1988, on cognitive load). Therefore, such factors may have an influence on panelist cognitive processing in probability and matching judgment methods where the panelists follow the cognitive-judgmental task by evaluating the knowledge and skill response demands for each item or piece of work and making the appropriate judgment. They must do this while keeping in working memory the description of the borderline test taker (or the expectations in the PLDs as in the Bookmark method) as well as their judgments about previous items to manage consistency. We hypothesize that this level of cognitive load (or strain) is likely to be higher in Round 1 as compared to subsequent rounds of judgments.

Cognitive complexity refers to the number and complexity of mental interactions required to make a decision (Bieri, 1955). Therefore, the cognitive complexity of a standard-setting judgmental task describes the number of factors that must be considered when making a judgment. In probability judgments, the cognitive complexity comes from having to integrate item knowledge and skill demands with features of the borderline test-taker description while maintaining consistency with previous judgments (i.e., tell a coherent story; see Kahneman, 2011, p. 87). In matching methods, complexity arises from having to identify item knowledge and skill response demands (also a challenge in probability methods). They then must align those demands with knowledge and skill expectations in PLDs or descriptions of borderline test takers, which defines minimal mastery of a content and skills domain. ID matching appears to require simply matching item response demands and descriptors, but no research has examined this

claim of simplicity yet. Empirical research illustrates that people use different strategies for matching entities. Integrating item and descriptor features is shown to be complex (see Katz, 2019, for a review of panelist cognition models). Cognitive complexity may be more challenging for the Body of Work method, where panelists must integrate their holistic judgments about the qualities of one or more pieces of evidence, and the dominant profile method, where panelists must analyze score profiles, integrate differences among similar profiles, and match those to descriptors. The complexity of matching known people (e.g., students, credential candidates) to a performance level may be the least cognitively complex matching task because panelists probably imagine one or more known people (or borderline test takers) with little specification of the basis for making those judgments. Research indicates that panelists seem to understand test-taker-centered tasks better than item-centered tasks (Skorupski, 2012, p. 139).

Some methods may lead to a propensity for algorithmic thinking where panelists develop mental rules to increase cognitive ease when making repetitive judgments. Specifically, panelists may begin the judgmental process with systematic, evidence-based analytic judgments (see Kahneman, 2011) but then progress toward more “automated” judgments to reduce cognitive load and strain. We hypothesize that the propensity for algorithmic thinking is increased when judgments are required for a large number of items (e.g., Angoff, Bookmark). An example of this is when panelists may make Angoff judgments quickly based on use item difficulty values (e.g., p values) without fully following the cognitive-judgmental task. Further, panelists may make automatic judgments for items that appear similar, influenced by the representativeness heuristic and halo effect (both of which are described later in this section), and may confirm snap judgments about items with little reflection. In matching methods, we have observed that panelists match sequences of items, one sequence after the other, rather than item by item, in an ordered item book (OIB) until they detect a change in ID matches. Panelists may use similar algorithms to reduce cognitive load (not to mention boredom) for other matching methods.

Overarching Cognitive Processes

Humans use processes such as framing effects and continuous monitoring to manage various types of cognitive tasks in our daily lives, but they can greatly impact our thought process. In standard setting, we hypothesize that panelists sometimes apply overarching cognitive processes such as framing effects to the standard-setting tasks.

Framing effects are seemingly inconsequential variations in a problem statement (e.g., how a cognitive-judgmental task is stated) that can lead to significant differences in decisions (Kahneman, 2011, p. 272; Tversky & Kahneman, 1981). Cognitive-judgmental task statements for probability methods such as “Would a borderline test taker respond correctly to each item on a test?” and “Place a bookmark at the first location in the OIB where borderline test takers have demonstrated achievement sufficient to be considered *Proficient* (etc.)” are stated unambiguously and likely would be interpreted in similar ways by most panelists. Cognitive-judgmental task statements for matching

methods should be familiar and even routine for teachers. For example, “Which PLD most closely matches the knowledge and skill response demands of this item?” (from ID Matching) is part of what teachers and professional preparation program trainers do when they break down the components of learning tasks for students as part of instructional planning. Still, panelists are likely to use some heuristics to reduce the difficulty of making the stated matching tasks, as indicated in two studies (Hein & Skaggs, 2009, 2010). When standard-setting facilitators state the cognitive-judgmental task unambiguously and repeatedly, the chance that panelists will succumb to framing effects and modify the problem statement is reduced.

Continuous monitoring and basic assessment process is a cognitive processing strategy where we pay automated, unconscious attention to aspects of a task to overcome dissonance and recover comfort (i.e., using automatic, quick, and easy decisions; Kahneman, 2011, p. 20). Standard-setting panelists are likely to feel some dissonance and discomfort as they make probability judgments for some items. They may feel uncomfortable when they believe that some items in an OIB are misordered, or when they judge item difficulties against what they understand about borderline test takers, or when they compare their judgments to empirical item difficulty, as is often practiced in Angoff method workshops. In matching methods, panelists may specifically monitor their judgments about the elements in the entities that they are required to match. They may monitor the consistency of current judgments with past judgments (i.e., to construct a coherent story; see Kahneman, 2011, p. 87). ID Matching workshop facilitators have observed that panelists report discomfort when they feel an item is “out of order”—that is, not in an expected location in an OIB. Some panelists may not be comfortable with matching items in the threshold region (i.e., items in the OIB that they perceive are located between two performance levels).

Judgmental Heuristics

Heuristics are mental shortcuts humans take to simplify a judgmental process. We have observed panelists use several heuristics such as substitution, availability, representativeness, and recognition as they engage in the cognitive-judgmental tasks required by the standard-setting method.

Substitution is used when we replace a challenging judgmental task with a simpler heuristic question and then map the judgment about the simpler question back to the target question (Kahneman, 2011, p. 97). In probability judgments, for example, panelists may substitute the complex judgment—“Can Grade 6 borderline test takers be expected to solve for x in $2x = 5$?”—with a simpler judgment such as “Can Grade 6 borderline test takers be expected to solve for x in simple equations like this one?” In matching methods, panelists may use a variety of substitution judgments when matching entities becomes particularly difficult. For example, they may find ways to simplify their judgments about matching diverse pieces of evidence to PLDs in the Body of Work and dominant profile methods. In

ID Matching, panelists may designate items to the threshold region between adjacent performance levels simply to reduce the cognitive strain of making a definite ID match, with the intention to make more definitive decisions later in the judgmental process.

When working with scales and values, we are prone to intensity matching and values translation. This may occur when panelists judge the intensity or amount on an underlying scale (e.g., a probability or percentage, degree of match) and translate it to standard-setting judgments (Kahneman, 2011, p. 94). In probability methods, panelists may calibrate their judgments about borderline test takers by estimating, for example, that borderline test takers would be able to respond successfully to an item sometimes, which might suggest a lower probability, or most of the time, which might indicate a higher probability. In matching methods, panelists may use an internal scale of the closeness of matches between entities to reduce cognitive strain and then translate those judgments to the specific requirements of the Body of Work, ID Matching, and other matching methods. In addition, panelists may rely on threshold-signal detection first and then match entities rather than implement the specified cognitive-judgmental matching task.

We use the availability heuristic when we judge the probability or frequency of a class or event based on the ease of bringing instances and occurrences to mind and disregarding other evidence (Tversky & Kahneman, 1974). In probability methods, panelists may make judgments by calling to mind a test taker they know rather than based on the borderline test-taker description. This hypothesis also represents the substitution heuristic. In matching methods, panelists may match collections of evidence, items, score profiles, and known people to descriptors because they can recall such instances easily, rather than a deeper, more detailed consideration.

We use the representativeness and recognition heuristics when we judge the probability that an entity matches another entity or belongs in the same group as other entities, based on how much they resemble recalled prototypes or other members of the group, while disregarding other crucial judgmental information, as in stereotyping people (see Tversky & Kahneman, 1974). Recognition is a faster process based on instantaneously perceiving an entity as an example or not an example of a group (see Gigerenzer & Goldstein, 1996). In probability methods, panelists may make judgments for some items that are similar to other items in terms of knowledge and skill response demands. (This is an illustration of a positive heuristic effect that we might call efficiency, unless panelist recognition judgments are inaccurate.) Panelists may give more importance and expect all test takers to respond correctly to items that they recognize in their own area of specialization (e.g., literature, geometry) more often than items from other specialization areas. In matching methods, panelists may match collections of evidence, items, score profiles, and known people to descriptors as an approximation, as in “This match is probably close enough.” Research suggests that we can expect panelists to use a variety of matching strategies (Kahneman et al., 2021) unless the facilitator specifies the matching process.

Cognitive Biases

Finally, cognitive biases can be errors in human thinking that can impact how we interpret information and make decisions. We hypothesize that a number of cognitive biases, such as confirmation bias and anchoring and adjustment bias, can impact how panelists engage in the cognitive-judgmental tasks required by the standard-setting method. Some of these cognitive biases are discussed here.

Overconfidence bias occurs when we have high confidence about the accuracy of inaccurate judgments. The impact of this bias is most extreme in tasks of great difficulty (Lichtenstein et al., 1982, pp. 314–315). Further, people typically have great confidence in judgments that they base on heuristics (Slovic et al., 1982, p. 472). In probability methods, panelists may be overly confident about their superficial judgments. For example, panelists may respond “yes” with assuredness to an item that requires, for example, knowledge and skills that are included in PLDs but not in the borderline test-taker description. When making matching judgments, panelists may feel sure of matches between item knowledge and skill demands and the knowledge and skill expectations in PLDs, despite inadequate understanding or consideration of the demands and expectations of the two entities to be matched.

The *WYSIATI effect* (Kahneman, 2011, pp. 85–88) occurs when we base judgments on what we can represent in working memory without evaluation of the quantity or quality of the evidence. Panelists may make probability judgments based on attention only to selected knowledge and skills in the borderline test-taker description. Or they may fail to extrapolate beyond the borderline test-taker description to cover the specific knowledge and skill response demands. In matching judgments, panelists may evaluate collections of evidence, item knowledge and skill response demands, and score profiles based on limited consideration of those demands that are easy to call to mind, such as surface features of the items (e.g., vocabulary requirements) or the knowledge and skill requirements in the PLDs.

Confirmation bias happens when we locate and use information (e.g., recollections) to preserve a belief and disregard disconfirming information (see Ross & Anderson, 1982, p. 149). In probability methods, panelists may make judgments about borderline test-taker responses to items based on their individual beliefs about borderline test takers—that is, not the shared description—and their judgment of the cognitive challenges in responding to an item (i.e., the affect heuristic); they may support these estimates in subsequent rounds of judgments by selecting only supporting views offered by other panelists. In matching methods, panelists may weight features of collections of evidence, item knowledge and skill response demands, and score profiles and skill expectations in descriptions of levels of performance to justify the matches they prefer.

When the *affect heuristic* is operating, we allow likes and dislikes to determine our judgments rather than evidence-based analytic judgments (see Kahneman, 2011, p. 103). In probability methods, panelists may alter their judgments for some items to achieve a desired cut score (or alter an undesired cut score in subsequent rounds), rather than implement the intended cognitive-judgmental task. Standard-setting facilitators have observed that panelists tend to prefer and even work toward cut scores

that are two thirds of the total possible test score (see Davis-Becker et al., 2011). In matching methods, panelists may match collections of evidence, item knowledge and skill response demands, and score profiles with PLDs based on their likes and dislikes for particular pieces of evidence, items, content area subdomains they consider too difficult or easy, specific score profiles, or desire for a specific location of a cut score.

We employ *anchoring and adjustment bias* when we estimate an initial value and then make inadequate adjustments toward accuracy (Tversky & Kahneman, 1974, pp. 427–430). In both probability and matching methods, panelists may constrain probability judgments for some items in Round 1 based on their judgments to previous items, perhaps because they appear similar in knowledge and skill response demands. In addition, their Round 2 judgments may remain anchored to Round 1 judgments, despite contradicting insights offered by other panelists during feedback and discussion.

The *halo effect* occurs when judgments of one feature of an entity influence judgments about other features. People cannot easily evaluate individual features of people or objects fully independently of their evaluations of other features; as a result, they produce correlated ratings (Plous, 1993, p. 45). Horn effects produce the opposite of halo effects. Primacy, recency, and other ordering effects influence the strength of recall in working memory of multiple entities. The contrast effect can lead to inordinately higher judgments of a slightly better entity after a string of mediocre entities and vice versa (see Daly & Dickson-Markman, 1982; Plous, 1993, pp. 42–44). Panelists may make probability judgments for some items based on their previous judgments of items that appear to be similar in terms of knowledge and skill response demands. The influence of the halo effect appears similar to the effects of the representativeness and recognition heuristics, even though they have been researched separately in the judgment and decision-making literature and thus may appear to be different cognitive processes. Similarly, panelists may match pieces of evidence, item knowledge and skill response demands, and score profiles to PLDs based on their previous judgments that appear to be similar in terms of knowledge and skill response demands.

Therefore, panelists may be influenced by the order in which items are presented. Some panelists have reported that they work their way through all items and then review and change judgments for some earlier items, whereas others indicate that their comfort and understanding of the task increases as they work further through the test (i.e., they have more confidence in later judgments than in earlier ones).

WORKSHOP DESIGNS, PROCESSES, AND PRACTICES: MITIGATING UNDESIRABLE COGNITIVE AND SOCIAL INFLUENCES STANDARD-SETTING WORKSHOP DESIGN AND EXECUTION

The cognitive and social model of standard setting (Figure 12.2) proposes a comprehensive view of the standard-setting process and sources of influence on panelist judgment and decision-making. As shown in this model, the outcome of

standard-setting activities is influenced by a number of factors, many of which are determined during workshop design and execution. Earlier, we described the workshop process submodel (Figure 12.1), which explicates steps that are designed to immerse panelists in the standard-setting process of a specific standard-setting method; help them develop shared understandings of the required concepts, criteria, and procedures; and lead them through two or more rounds of making standard-setting judgments. In this section, we review the key decisions related to the design and execution of standard-setting workshops and propose strategies that standard-setting designers and facilitators can build into training with the goal of debiasing panelists. We base these strategies on what we have learned through our review of the cognitive-judgmental tasks within common standard-setting methods and the potential for cognitive biases and heuristics to impact how panelists apply the tasks.

Workshop Design

The design details of any standard-setting study are specified through a series of decisions made during the design phase. However, designers and facilitators may make adjustments during execution of the workshop. These decisions reflect all aspects of the cognitive and social model of standard setting because they include selection of the method (and the corresponding cognitive-judgmental task), selection of the panel, and design of the process.

A standard-setting *designer* makes key design decisions as to how standard(s) will be set. A standard-setting *facilitator* executes the standard-setting workshop and works directly with panelists. In some cases, the same person may serve these two roles, but for the purposes of this chapter we describe the responsibility of each separately. In this section, we outline key design decisions including selecting the standard-setting method, content or work samples to be used in the standard setting, empirical information to inform the process, the expert panel, and the meeting mode.

Selection of a Method

Method selection begins with identifying options that are feasible, based on the characteristics of the testing program (e.g., item formats, psychometric analysis), availability of required elements (e.g., test-taker work samples, test-taker performance data), and the appropriateness of the method's cognitive-judgmental task. Our analysis of cognitive processing requirements and cognitive-judgmental tasks of different standard-setting methods (see Table 12.2) suggests potential challenges for justifying selection of some methods. For example, the judgment and decision-making literature indicates that people generally do not make accurate probability judgments (e.g., Murphy, 2004) and percentage estimates (Gigerenzer & Hoffrage, 1995, as cited in Larrick, 2007, p. 325). In addition, some methods, such as Angoff, entail relatively complex cognitive loads. The famously provocative "fundamentally flawed" quote (Shepard et al., 1993, p. 77) refers

to the cognitive complexity of Angoff probability judgments (see also Pellegrino et al., 1999). In addition, as the field evolves toward writing technical reports that are oriented toward claims, evidence, and validity arguments (e.g., Ferrara et al., 2023; see also Kane, 2013), supporting the selection of some standard-setting methods may become even more problematic. Therefore, choosing a method that minimizes cognitive complexity, cognitive load, and other cognitive-judgmental task requirements may have to supersede past practice.

Selection of Test Content or Work Samples

The specifics of the selected method dictate what type of content needs to be a part of the standard-setting process. We use the term *content* to refer broadly to items, test form(s), work samples, or scoring rubrics. The test content reviewed in a standard-setting process should be selected so that the findings can be generalized to other forms of the test and other test-taker groups. Standard-setting studies typically focus on one form of a test and the resulting cut score(s) are equated to other forms. In some cases, test forms are quite long and the task of reviewing and judging an entire test form can become tedious.

Various studies (e.g., Coraggio, 2008; Ferdous, 2005; Kannan, Sgammato, & Tannenbaum, 2015; Kannan, Sgammato, Tannenbaum, & Katz, 2015) have evaluated the reasonableness of using a subset of items to set cut scores using an Angoff method. Results from early simulation studies (Coraggio, 2008; Ferdous, 2005; Ferdous & Plake, 2005, 2007) support the use of subsets of items. Resampling of operational standard-setting data was used to determine that approximately 45 items are sufficient to obtain generalizable cut scores (regardless of the length of the full test; Kannan, Sgammato, Tannenbaum, & Katz, 2015). This finding was then confirmed in an operational study where the results from two panels (one evaluating a 45-item subset and the other a full-length test) were comparable (i.e., within one standard error; Kannan, Sgammato, & Tannenbaum, 2015).

For item-mapping methods like Bookmark and ID Matching, a single test form may not cover the entire score scale with sufficient differences in item difficulty to facilitate judgments (Lewis et al., 1996). Therefore, creating an OIB may require sampling additional items from the bank to faithfully represent increments on the score scale, fill in large gaps between item scale locations, and reduce clustering of item locations, especially in ranges of the scale where cut scores could be located. This makes for a longer judgmental process (i.e., more items to review) but ensures panelists can make a cut score recommendation at the precise location on the score scale that corresponds with their expectations.

Other methods require panelists to set expectations for performance by matching work samples to PLDs (e.g., Body of Work, Judgmental Policy Capturing, and the Analytical Judgment methods). Although each of these methods is different, they all require study designers to preselect work samples for review. The work samples should

have been consistently scored and have good person fit (Kingston & Tiemann, 2012). Reviewing scoring rules/guidelines as well as work samples enable panelists to (a) understand the knowledge or skills required to achieve a given score for methods such as the extended Angoff (designed specifically for polytomous items), and (b) be able to match work samples to PLDs based on the scores on a rubric in methods such as Analytical Judgment.

Selection of Empirical Information as Feedback to Panelists

Standard-setting designers must also determine what empirical information will support panelists in their judgmental process. We identify three types of feedback that may be presented to inform panelists judgments: results from their judgments, item difficulty, and impact data. A later section on workshop execution details how feedback should be presented in a standard-setting workshop.

JUDGMENT RESULTS AS FEEDBACK After each round of judgments, facilitators have the opportunity to help panelists see how their judgments translate into a recommended cut score and how their judgments compare to those of others from the panel. Reckase (2001) referred to this as “process feedback” (p. 165) because it may encourage panelists to reconsider their judgments and increase the likelihood of convergence of their recommendations. This may include providing panelists (a) their individual recommended cut scores, (b) the range and average of panelists’ recommended cut scores, and/or (c) a full distribution of all panelists’ recommendations.

ITEM DIFFICULTY AS FEEDBACK In some standard-setting methods, panelists are asked to either explicitly (e.g., Ebel) or implicitly (e.g., Angoff, Bookmark) evaluate the difficulty of items or tasks by estimating probabilities or percentages as part of the cognitive-judgmental task. The empirical item difficulty may be presented as part of the materials (e.g., within an OIB in the Bookmark method) or provided later in the process (e.g., Angoff) for panelists to evaluate their judgments and guide refinement of judgments in later rounds. This feedback may be presented as item p values, IRT scale difficulty locations, or average score (for multipoint items). Reckase (2001) also classified this as process feedback. Reckase and Chen (2012) offered other, complex representations of item difficulty information (e.g., by test-taker score, by content area). It is important that the facilitator ensures panelists understand how to interpret difficulty information and incorporate this information into the cognitive-judgmental task as they make their decisions.

IMPACT DATA AS FEEDBACK Most standard-setting methods focus on setting expectations that represent the expected knowledge and skills of borderline test takers. However, providing impact information (e.g., pass rates, percentages of test takers classified within each performance level) can serve as a reality check (Green et al., 2005; Reckase & Chen, 2012) and help to assess the reasonableness of these recommendations.

Reckase (2001) referred to this as “normative feedback” (p. 163). Impact data are presented either after each round of standard setting or just before the final round. If available, the estimated impact of recommended cut scores can be evaluated by comparing to the impact from external benchmarks (e.g., state, national, and international tests; see Ferrara et al., 2021).

When data from operational administration are not available, one option is to provide historical impact data. However, historical data may represent a different exam (e.g., different content framework or format; Reckase & Chen, 2012). Another option is to examine the impact data from a similar exam (e.g., same or similar population and content focus).

In some cases, prior to the standard-setting meeting, the policy body may meet to discuss practical expectations for the standards to be set. This discussion may go as far as to set expectations for a range of standards or impact that would be tolerable, based on the information available (e.g., performance expectations, historical data). If available, these tolerance ranges may be provided to standard-setting panelists, in the form of target cut scores or benchmarks (see Ferrara et al., 2021) to help inform their judgments.

Empirically based approaches to standard setting (e.g., Ferrara et al., 2021; McClarty et al., 2013; O’Malley et al., 2012) are unique in that impact data are central to framing the judgmental task for panelists in the form of target cut score ranges. We opened this chapter by recognizing that standard setting is policymaking. Some designers take the point of view that impact data are relevant to policy decisions and should not be in the hands of content experts who are standard-setting panelists (e.g., Ferrara et al., 2021). When using an empirically based approach, impact is central to the cognitive-judgmental task and therefore must be reliable and well understood.

INFLUENCE OF DATA ON PANELISTS’ IMPLEMENTATION OF THE COGNITIVE-JUDGMENTAL TASK The research in this area is very clear about the value of data. While it can help to increase convergence among panelists (Margolis & Clauser, 2014) and increase panelists’ confidence in their judgments, it also influences their judgments (Brandon, 2004; Clauser et al., 2013; Impara & Plake, 1997; Margolis & Clauser, 2014; Mee et al., 2013; Skorupski & Hambleton, 2005). Specifically, panelists substantially modify their judgments irrespective of whether the data are accurate (see Clauser, Mee, et al., 2009; see the WYSIATI effect in the previous section). Similarly, when the estimated impact is very different from what a panelist would expect, it will likely drive the direction of adjustments to their judgments in the subsequent rounds of the standard setting (e.g., see the affect heuristic; and anchoring and adjustment bias).

Overall, presenting any type of performance data to standard-setting panelists requires caution and thought. First, designers should consider the relevance of the data to the intended interpretation and use of the cut scores. Knowing that panelists trust data even if they are inaccurate, it is important that the data serve as a reliable estimate of item difficulty or impact on the target test-taker population. If the only available

data are based on a different group of test takers or from a small sample of the target population, standard-setting designers should question the value of providing this information. Second, the ability of panelists to comprehend and interpret the information should be considered. Some item-level data are more straightforward than others. For example, a p value is more directly interpretable than IRT difficulty estimates (i.e., b values), and especially for polytomously scored items. Finally, policy makers or study designers may not support providing this information (Hambleton & Pitoniak, 2006), since the introduction of such information may alter panelists' judgments to the point where they no longer focus on the target cognitive-judgmental task. Therefore, standard-setting designers should consider the possible sources of this information and how it may help in the standard-setting process while enabling panelists to remain focused on the cognitive-judgmental task.

Expert Panel Formation

Standard setting is a judgmental process. Therefore, selection of a representative sample of appropriately qualified experts to carry out these judgments is critical to the overall validity argument for standards recommended in a workshop (Raymond & Reid, 2001). More specifically, because standard setting should be managed as a convergence process, diverse points of view and independent judgments are the key to achieving the most appropriate group recommended cut scores. Galton demonstrated the importance of these two features by observing expert farmers guessing the weight of an ox at the West of England Fat Stock and Poultry Exhibition at Plymouth, England.⁶ He observed that the *vox populi* (i.e., the median; Galton, 1907, p. 450) was within 1% of the correct weight while the individual estimates were up to 4% distant from the correct weight. The median recommended cut score in a standard setting is the best or most appropriate indication of a group's recommendation because it reflects the best combined judgments of all of the expert panelists and adjusts for highly discrepant judgments. Surowiecki (2005) resurrected Galton's observation and popularized the term *the wisdom of crowds*, which helps illustrate the importance of diversity and independence in standard-setting judgments.

PANEL COMPOSITION Based on the intended score interpretations (i.e., claims to be made) and uses (i.e., decisions to be made), standard-setting designers can identify qualifications for individuals to serve as subject matter experts. The definition of a subject matter expert can differ based on the context and purpose of the examination (e.g., entry level vs. advanced certification; Cizek & Bunch, 2007). At a minimum, individual panelists should have content area expertise (Hambleton & Pitoniak, 2006; Raymond & Reid, 2001) and be familiar with the target test-taker population to envision how a test taker would interact with test content. In educational testing, a standard-setting panel for an educational assessment may be composed of content experts such as teachers (who focus on the target content area and test-taker population) and nonteacher

educators (e.g., content specialists, administrators). In credentialing, a standard-setting panel is typically composed of veteran practicing professionals, recently credentialed professionals, and educators/trainers. Some panelists may consider themselves specialists (e.g., they hold the general credential but work within only one sector of the defined field) but are expected to be able to make judgments about all knowledge and skill expectations for new practitioners. In both education and credentialing, the panel should represent most (if not all) major subsets of the larger test-taker population.

For some contexts, non–subject matter experts who have a familiarity or a vested interest (Kane, 2001) with the target test-taker population may be included in the panel. They may be members of the public or those who have a vested interest in the decisions to be made based on the outcomes of the tests (Kane, 2001). Examples include parents of children taking the educational assessments, professionals who work collaboratively with those who hold the credential being sought, or members of the public. However, the inclusion of nonexperts has been questioned (Plake, 2008) because they are likely to lack the specific content knowledge and familiarity with the test-taker population to develop the shared understanding required to complete the judgmental task as intended and recommend defensible cut scores.

Panel diversity varies based on the type of program and may include personal characteristics (gender, race, ethnicity, or age) and professional factors (years of experience, credentials, type of employer, job role, and geographic location). In education, designers also should consider the diversity of the test-taker population who will take the assessment (e.g., general education, advanced classes, English language learners, students with disabilities) and the types of students represented by each subject matter expert. In credentialing, the panel should also represent the diversity of professional practice, including area of focus, professional responsibilities, and populations served by potential panelists.

Panel diversity may also include the perspectives (and possibly goals) that panelists bring to the standard-setting activities. For some panelists who are educators, the standard setting may have a direct impact on their own students or their school or district (i.e., in school and district public accountability reporting). In credentialing, some practitioners may feel inclined to set higher standards than necessary to limit competition within the field and hold candidates to a higher standard, whereas educators may feel inclined to set lower standards to increase the likelihood that their students will earn the credential (Buckendahl & Davis-Becker, 2012). All of these can result in misclassifications and violate the expectations in the *Standards* (AERA et al., 2014; see Standard 11.16).

Before selecting a panel, standard-setting designers are encouraged to set targets for the representativeness of the panel (e.g., Cizek, 2022; Hambleton et al., 2012) that reflect the characteristics of the larger test-taker and candidate populations. This requires casting a wide net to recruit experts that represent various strata of test takers and candidates. Based on the influence of group interactions within the cognitive and social

model of standard setting, we recommend looking beyond these traditional markers of surface-level diversity (e.g., adequate representation of race and gender) to consider deep diversity (Harrison et al., 1998), which includes heterogeneous attitudes, beliefs, and values that would be appropriate to represent in the panel. While it is likely not feasible to obtain information about these deep diversity characteristics from panelists ahead of recruitment, the degree to which deep diversity is achieved could be evaluated using questionnaires about the attitudes, beliefs, and values of panelists and evaluating those against the values believed to matter most for achieving performance standard recommendations based on diverse points of view.

NUMBER OF PANELISTS But how many panelists are enough? There is no set number for all standard-setting contexts. Standard-setting designers should include enough panelists to (a) achieve a reasonable representation of relevant expertise in the field, (b) yield small enough cut score standard errors to support the interpretation of cut scores, (c) enable full group and subgroup collaboration, and (d) include diverse opinions so that one perspective does not dominate panel-level discussions. Panels of 15 to 20 experts typically are recommended for state-level educational assessments (Hambleton et al., 2012) to ensure panel diversity and representativeness. In practice, 10 to 15 panelists have been found to yield acceptable standard errors (Raymond & Reid, 2001) and can be more manageable during panel-level discussions. Standard-setting designers should balance the need for enough panelists to ensure diversity and manageable size to be able to elicit all points of view. In credentialing, panel sizes of 10 to 15 panelists are more typical for large-scale programs (e.g., national licensure programs such as nursing, architecture, engineering). For smaller credentialing programs (e.g., highly specialized certification such as specialized technology fields, medical subspecialties), fewer experts may be available within the broader population and therefore smaller panels of 7 to 8 often are used in practice. The recent trend in standard setting for educational achievement tests is toward smaller panels of 8 to 10, primarily because recruiting teachers out of classrooms for multiple days can be challenging. Multiple, parallel, independently operating panels can enhance the generalizability of recommended cut scores and will often produce consistent results (e.g., Tannenbaum & Kannan, 2015). Some workshops include the use of a single panel with multiple subgroup tables for discussion. This enables richer discussion, more participation by each panelist, and comparisons of cut scores across subgroups to estimate cut score standard errors and evaluate consistency without having to run concurrent parallel panels. Generalizability analyses can be applied to evaluate a variety of assumptions about numbers of panels, panelists, and items to be used in a standard-setting study. For example, Hurtz and Hertz (1999) used a generalizability study to determine the optimal number of panelists necessary for standard-setting studies. In evaluating eight occupational licensing examinations, they found that 10 to 15 panelists would be optimal, based on the reduction in expected standard errors.

Remote Versus In-Person Workshops

Traditionally, most standard-setting workshops involved face-to-face meetings. However, some programs successfully conducted virtual standard-setting processes even before remote meetings were commonplace (see Katz et al., 2009; Schnipke & Becker, 2007; and Shaw, 2007, for some early implementations of virtual standard-setting meetings.) The Smarter Balanced Assessment Consortium (2015) was the first high-stakes educational program to implement a fully online process to gather crowd-sourced Bookmark judgments from over 2,000 educators from a number of states.

Advantages of virtual standard setting largely are logistical (Schnipke & Becker, 2007) because they are cost-efficient (no requirements for travel, meeting space, or meals) and only require participation (not travel) time (e.g., Katz et al., 2009). In turn, programs may be able to recruit larger, more representative panels for virtual meetings. Comparative research on in-person versus virtual standard-setting workshops generally indicates similar recommended cut scores (Harvey & Way, 1999; Katz & Tannenbaum, 2014; Kollias, 2018) and reports of positive experiences from participating panelists (Katz et al., 2009; Kollias, 2018).

However, some concerns remain about conducting a high-stakes process in this manner. First, virtual meetings leave more opportunities for panelists to be distracted and less engaged than in-person meetings. Although facilitators can monitor for engagement (e.g., track input such as comments and questions) and use encouragement strategies, less group collaboration may impact the panel's ability to develop a shared understanding of the task and expectations on which to base their judgments. Second, working face to face provides more opportunities for a facilitator to evaluate panelists' understanding of the task (e.g., evaluating body language) and offer additional explanation and training (e.g., one-on-one conversations). Third, distributing secure test content outside a secure meeting room increases the risk of compromise. Such risks are being increasingly managed with improvements in virtual collaboration tools and remote meeting technology. As virtual meetings become more commonplace, these concerns may be reduced as a result of familiarity with this format and improved virtual meeting technology that allows increased flexibility for addressing the needs of meeting participants.

Judgmental Rounds

Most standard-setting workshops are designed as an iterative process where panelists make judgments, receive feedback on their judgments and possibly additional empirical information, and then revise their judgments accordingly. Most standard-setting designers would advocate that multiple rounds of standard-setting judgments enable panelists to review and revise their judgments after going through the process entirely (i.e., Round 1), learning how their judgments are transformed into a cut score, considering how their judgments compare to those of the panel, and reviewing empirical information. However, there is debate as to whether more than two rounds are necessary. Some advocate that additional rounds allow facilitators to layer in feedback (e.g., results

and process feedback provided first, followed by any empirical or normative feedback), whereas others suggest that a third round simply reduces variability in the results due to continued discussion while adding significant time and expense (Cizek, 2022).

Validation Framework to Guide Workshop Design

In concluding this section on workshop design, we turn our attention to validity evidence that is collected throughout the workshop and used to form validity arguments for the defensibility, generalizability, and intended interpretations and uses of cut scores. Building off previous guidance offered by Hambleton and Pitoniak (2006) and Kane (1994, 2001), we propose a framework of expectations and supporting evidence aligned with the claims presented earlier in the chapter that:

1. The cognitive-judgmental task (inherent in the standard-setting method) is a critical aspect of standard setting and should be central to the design, preparation, execution, and evaluation of the workshop.
2. In addition to the cognitive-judgmental task, there are other influences on panelist judgment and decision-making in standard setting. Some are design features and are desirable; some are not.
3. Standard-setting results should reflect a well-executed process that was led by experts who helped panelists make their judgments avoiding undesirable influences.

In Table 12.3, we describe the validity expectations and suggested documentation for each type of evidence: design, preparation, decision-making, and outcomes evidence. Because validation begins with design and design of the workshops influences the recommended cut scores, the expectations laid out in this framework should be considered in making the workshop design decisions.

Workshop Process

In this section, we focus on workshop processes (i.e., workshop process submodel in Figure 12.2). In addition, we review how final cut score decisions are made and how the entire process is evaluated and documented. Facilitator processes in the group interactions submodel are implicit in each of these steps.

Getting Oriented: Building Familiarity With the Test and Performance Expectations

Several activities within most standard-setting workshops are devoted to orienting the panelists to the standard-setting context and forming some “key conceptualizations” (Cizek & Bunch, 2007, p. 48). Orientation typically includes activities such as familiarizing panelists with the test and discussing expectations for performance on the test (e.g., PLDs). Orientation activities typically are conducted before training panelists in the standard-setting method’s cognitive-judgmental task.

Table 12.3 Framework to Guide Workshop Design and Gather Validation Evidence to Support Claims about the Interpretation of Cut Scores

Validity Expectation	Suggested Documentation
Design Evidence	
The study design aligns with the purpose and characteristics of the test and cut score(s) to be set.	
1. The standard-setting method and its cognitive-judgmental task are suited to the format of the test, expertise of the panelists, and the intended interpretation and use of test scores.	- Rationale for the selected standard-setting method and how the cognitive-judgmental task is appropriate for the panelists and intended interpretation and use of test scores.
2. Empirical information presented during standard setting (e.g., external benchmarks and target cut scores, item difficulty, performance distributions) is consistent with the standard-setting workshop design and method.	- Description of the empirical information including the sample of test takers represented and when it was collected. - Details as to when and how the empirical information was presented during standard setting, including instructions provided to panelists to guide interpretation and inform judgments.
3. The panel collectively represents the range of expertise needed to inform the cut score recommendations.	- Panelist qualifications such as employer, position, years of experience, geographic location, and populations served.
4. Standard-setting activities (i.e., training, judgment activities, feedback), ways of integrating expert judgment, empirical information, and discussion are specified in the workshop design.	- Details about the standard-setting plan that includes the inputs to, and collection of, judgments used to determine the recommended cut score(s).
Preparation Evidence	
Panelists are adequately prepared to make the necessary judgments.	
5. Panelists developed a shared understanding of the item response demands and expectations for each performance level.	- Details about the review of PLDs and/or the development of threshold PLDs. - Panelist evaluation responses indicating they had a sufficient understanding of the expectations for each performance level and/or the threshold performance expectations.
6. The training adequately prepared panelists for the standard-setting task, including following the cognitive-judgmental task and addressing potential heuristics, biases, and other factors that can distort decision-making.	- Details about the training activities including topics covered and specific instructions provided to panelists including what to think about and what shortcuts to avoid. - Panelist evaluation responses indicating they felt adequately prepared to follow the cognitive-judgmental task.

(continued)

Table 12.3 (*continued*)

Validity Expectation	Suggested Documentation
Decision-making Evidence	
Panelists make standard-setting judgments following the standard-setting design and plan.	
7. Panelists applied the method's cognitive-judgmental task as intended, including consideration of additional feedback information that was provided.	- Panelists' evaluation responses indicating they followed the cognitive-judgmental task during each round of judgments.
8. The process provided opportunities for panelists to receive and discuss meaningful feedback on their judgments and revise their judgments, if warranted.	- Panelists' evaluation responses indicating that the feedback and discussions were valuable to inform their judgments.
9. Workshop facilitators managed processes without unduly influencing judgment and decision-making about cut score recommendations.	- Panelists' evaluation responses indicating that they have confidence in their recommended cut scores.
Outcomes Evidence	
The results show consistency in panelist expectations and the results are reasonable. ⁷	
10. The results indicate the panel's shared understanding of the knowledge and skill expectations for each performance level.	- Empirical information on the similarity in recommended cut scores among panelists (e.g., range, standard error).
11. The results indicate that panelists were consistent in their application of the cognitive-judgmental task.	- Empirical information that shows consistency between panelists' judgments and other measures of the item response demands (e.g., targeted performance level, empirical item difficulty).
12. The results are reasonable, based on external information or review by stakeholders.	- External evaluation of results that indicate reasonableness which may be empirical (e.g., comparison to historical results, results from another measure, results from another standard setting method) or subjective (e.g., review by policy body or subject matter experts).

FAMILIARIZING PANELISTS WITH THE TEST Various documents may be used to familiarize panelists with the test, the types of assessment activities (i.e., items), and the relative emphases placed on content strands within the test. These documents range from high-level descriptions of test content to more detailed test specifications or sample test forms for panelists to review or take (Cizek & Bunch, 2007). Whether panelists take the entire test or a selection of items, they then can discuss how the tested content matches the test specifications (Morgan & Michaelides, 2005). This enables panelists to develop a shared understanding of what the test measures. During this discussion, the facilitator's responsibility is to focus discussion on the *actual* tested content, clar-

ify any misperceptions about difficulty or fairness of the test, and remind the panelists that their task is to recommend cut scores on the test as it is presented to them, not to evaluate the content of the test.

Education standard-setting panelists may have some familiarity with the test but it is important to review this information to ensure everyone has the correct understandings. Conversely, participating in a standard setting may be a credentialing panelist's first experience in working on a test. Therefore, training for a credentialing standard setting usually involves a significant amount of time to orient panelists to the test's purpose, design, format, and general development process, as well as the purpose of standard setting in this process.

UNDERSTANDING AND DEFINING EXPECTATIONS Cut scores are set on tests to enable interpretation of performance in relation to expectations for leveled categories. It is important that standard-setting panelists understand the knowledge and skills expected at each performance level and the key differentiators between adjacent levels.

In credentialing testing, there are usually two performance categories, representing qualified and nonqualified candidates. Therefore, the focus of expectations is on the point of differentiation between these two levels, or the candidate who is on the borderline (i.e., minimally qualified, minimally competent). Panelists can develop a shared understanding of this minimum level of expectation by developing or reviewing the description of the borderline candidate. Expectations should be framed around anticipated job responsibilities for an entry-level professional, rather than what is emphasized in an educational program or experience opportunity (e.g., an internship).

In educational testing, PLDs and their labels represent the state's educational aspirations for its school-age children. The cognitive-judgmental task for most of the probability and some matching methods focuses on borderline test takers and may require the development of borderline PLDs. Range PLDs (Egan et al., 2012) define the expectations, within a performance level, of what individuals in a performance level should know or be able to do in a test content area (Cizek & Bunch, 2007). Cut scores reflect the minimum of knowledge and skills required to enter that performance level or to be licensed or accredited in a field (e.g., bare minimum knowledge and skills to be licensed as a teacher—not an expert teacher, but someone who is qualified enough to receive the keys to the classroom). Therefore, developing well-articulated PLDs is one of the most critical steps in arriving at reasonable cut scores. This importance has been particularly recognized in recent years (e. g., Bejar et al., 2007; Egan et al., 2012; Hambleton et al., 2012; Huff & Plake, 2010; Huff et al., this volume; Luecht, 2020; Perie, 2008).

It is now more common for these expectations (e.g., borderline test taker, PLDs) to be developed by separate panels prior to the standard-setting workshop because they are used in other test development activities (Bejar et al., 2006, 2007). Developing

descriptors ahead of a workshop can reduce panelist meeting time and expense because reviewing and internalizing descriptors can take less time than generating them. However, we have observed that going through the development process helps panelists internalize these expectations as they debate the expectations for a given level.

Learn: Training, Modeling, and Practice to Achieve Competence in Implementing the Cognitive-Judgmental Task

Standard-setting panelists are recruited because they possess content expertise and may represent a constituent stakeholder group. However, they cannot be expected to have experience with the chosen standard-setting method. Therefore, building in sufficient time to train panelists in the standard-setting method is critical so that they may appropriately carry out the cognitive-judgmental task to recommend a cut score (Cizek & Bunch, 2007; Hambleton et al., 2012). We define training as (a) presentation of concepts and the cognitive-judgmental task, (b) modeling of judgments and decisions, and (c) guided practice and focused feedback in implementing the intended cognitive-judgmental task.

Panelists should receive step-by-step instructions on the materials they will use and the factors they must consider as they complete and record their judgments (Hambleton & Pitoniak, 2006). First, panelists should be trained to focus on the correct target for their judgments (e.g., knowledge and skills of borderline test takers vs. the entire performance level) to properly implement the intended cognitive-judgmental task. Second, panelists should be explicitly trained in implementing the intended cognitive-judgmental task for the chosen standard-setting method. Third, they should learn about the heuristics, biases, and other negative influences that may arise for the selected method. Finally, after the cognitive-judgmental task is clearly described and modeled, panelists should have the opportunity to practice (e.g., Plake, 2008) and receive guided feedback. This practice activity allows panelists the opportunity to solidify their understanding of the cognitive-judgmental task and the descriptions of the borderline test takers developed/reviewed in the training.

The materials used for practice (e.g., test items, test-taker responses, scoring keys and rubrics, descriptions of borderline test takers) should be similar to those panelists would use in the actual task. To avoid biasing subsequent independent judgments, there should be no overlap of items or test-taker responses used for practice with those that will be used in the actual rounds of judgment. Facilitators can uncover any misunderstandings about the intended cognitive-judgmental task or underlying biases during the practice discussions. We know from several studies (e.g., Davis-Becker et al. 2011; Hein & Skaggs, 2009) that some panelists may use the substitution heuristic (Kahneman, 2011) in undetectable ways to simplify their judgmental task. Facilitators can use these practice discussions to reiterate the purpose of the standard-setting study and refocus panelists if they see panelists straying from the intended cognitive-judgmental task.

Typically, panelists are asked to declare their readiness to proceed at the end of training using a self-report survey (i.e., evaluation). Panelist readiness also can take the form

of a quiz to evaluate their understanding of the intended cognitive-judgmental task. Self-report evaluations typically include statements about participants' understanding of the assessment and its purpose, the standard-setting process, the clarity of the borderline test-taker descriptions, the training and modeling provided in the cognitive-judgmental task, sufficiency of practice opportunity, and their overall comfort and readiness to proceed to implement the intended cognitive-judgmental task. Several authors provide sample evaluation forms that can be customized for any standard-setting workshop (e.g., Cizek, 2012b; Cizek & Bunch, 2007; Hambleton et al., 2012; Zieky et al., 2008). Effective training is essential to support the validity of the entire standard-setting process (Morgan & Michaelides, 2005) and the resulting cut scores. Yet, to our knowledge, no research has directly addressed the effectiveness of training on standard-setting panelists' ability to implement the cognitive-judgmental task while minimizing the influence of biases and unintended influences.

SOME PROPOSED TRAINING STRATEGIES FOR DEBIASING In an earlier section, we identified cognitive processes, judgmental heuristics, and cognitive biases that may influence the degree to which panelists follow the cognitive-judgmental task for some methods. In Table 12.4, we propose training strategies to reduce the deleterious effects of these biases and influences. Some proposed strategies are generalized from empirically supported training interventions. Others involve modeling cognitive behaviors, providing examples of thinking errors, and guiding panelist practice in overcoming judgmental errors. Our proposals are intended to help facilitators guide panelist thinking and decision-making—that is, to nudge them to make judgments and decisions with minimal interference from ineffective heuristics, biases, and other sources of errors. At the end of this chapter, we recommend research on the efficacy of these training strategies specifically in standard-setting situations and for specific standard-setting methods.

Feedback and Discussion

Typically, standard-setting processes include at least two rounds of judgments, with feedback and discussion between rounds. Impact data (i.e., normative feedback about test-taker performance) can influence panelists' cut score recommendations either directly or indirectly in methods like benchmarked standard setting (Ferrara et al., 2021). When there are more than two rounds of standard setting, Reckase (2001) advised the following: introduce criterion-referenced (e.g., item difficulty) feedback after the first round, followed by normative feedback (e.g., impact data) after the second round, with panel results provided at the end of each round. This enables panelists to refine their understanding based on criterion-referenced aspects (such as item difficulty) first, without the compelling influence of normative feedback, which is irrelevant to the fundamental cognitive-judgmental task.

One final form of feedback occurs naturally as panelists share viewpoints with each other between rounds. During discussions, panelists may explain their think-

Table 12.4 Proposed Proactive Training Strategies to Reduce Deleterious Effects on Panelist Judgment and Decision-Making of Judgmental Heuristics and Cognitive Biases (or “Debiasing”)

Overarching Cognitive Processes
Framing effects: State the cognitive-judgmental task exactly as panelists are expected to think and decide, ensure that panelists understand how they should and should not think, provide ample practice opportunities, and reinforce panelist understandings by asking them to restate and explain the statement.
Continuous monitoring and basic assessment process: Encourage panelists to self-monitor their thinking and decision-making as they implement the cognitive-judgmental task. Encourage panelists to raise questions and ask for guidance if they become uncomfortable with a part of the standard-setting process or a decision.
Overconfidence bias: Raising panelist awareness of the accuracy-confidence disconnect and reminding them to check and question their thinking and decisions may help to mitigate this bias. Personalized performance feedback on inaccurate or unfounded judgments and the “consider the opposite” strategy (Lord et al., 1984) have been shown to reduce overconfidence.
Judgmental Heuristics
Substitution: Ask panelists to restate the intended cognitive-judgmental task statement regularly. Discuss the importance of implementing the intended cognitive-judgmental task and avoiding substitution and other ways in which other panelists may work around the stated cognitive-judgmental task.
Intensity matching and values translation: There may be no effective way to train panelists to improve inconsistent and inaccurate translations of intensities from one scale (e.g., item response demands categories) to another (e.g., probabilities of a correct response). It does seem likely that a facilitator could ask panelists to rethink a judgment that is overheard as part of the monitoring process.
Availability: Reminding panelists that the ease of recalling category examples to mind does not always comport with the range of possible examples. Nudging them to think about other possibilities may help somewhat. In addition, encouraging panelists to listen to other panelists’ examples and taking the outsider view (i.e., considering broader implications rather than focusing only on the immediate situation) may be effective in calling to mind a wider range of possibilities.
Representativeness: Encouraging panelists to be disciplined and consider all response demands of items, requirements of performance-level descriptors (PLDs), characteristics of borderline test-taker descriptions, qualities of test-taker work samples, and achievement of known test takers may improve their matching judgments, but not probability judgments.
Cognitive Biases
WYSIATI effect: Raising awareness of this bias and encouraging panelists to consider all response demands of items, requirements of PLDs and borderline test-taker descriptions, qualities of test-taker work samples, and abilities of known test-takers may reduce this bias.
Confirmation bias: Training panelists to look for disconfirming as well as supporting evidence may be the most effective way to mitigate this bias.

Affect heuristic: Making panelists conscious of this heuristic, how it may influence their judgments (e.g., selecting a desired cut score rather than a supportable one), and nudging them to stay true to the intended cognitive-judgmental task may be the most effective intervention.

Halo and other effects: Mitigating the influence of adjacent and nearby items, work samples, and score profiles on a current judgment may not be feasible. In addition, it is likely that the contrast effect also may operate and perhaps cannot be mitigated. Raising awareness and urging discipline in making judgments and decisions may be the only recourse.

Anchoring and adjustment bias: Raising awareness of underadjustment in relation to Round 1 cut scores that serve as anchors for Round 2 judgments may free panelist thinking to deviate from their Round 1 decisions. However, significant deviation from Round 1 or from externally benchmarked anchors is inconsistent with the goal for subsequent standard-setting rounds (i.e., convergence of panelist judgments) and for benchmarked standard setting (i.e., retaining target cut scores or making only small adjustments to the anchors). Personalized performance feedback on inaccurate judgments may mitigate inadequate adjustments.

ing and consider others' explanations for their judgments. Social comparison (Festinger, 1954) may influence panelist thinking and judgments in subsequent rounds. Likewise, information sharing among panelists can lead panelists to adjust their judgments (e.g., persuasive arguments theory, Burnstein & Vinokur, 1975)⁸ and serves as feedback. The facilitator may provide guidance on persistent misunderstandings of concepts, the process, or indications of biases. Feedback obtained during discussions may also have substantial influence on the judgments made by panelists, as suggested by convergence of panelist judgments over rounds and reported in workshop evaluation surveys.

Postworkshop Activities and Documentation

FINAL CUT SCORE DECISIONS Standard-setting results (i.e., cut score recommendations) are determined based on the final standard-setting judgments. As an initial step in consolidating the results, standard-setting designers and/or facilitators can examine the results and explicitly describe the recommendations of the panel based on all the information collected during the workshop. In addition, standard-setting leaders can review workshop evaluation results and individual panelist recommendations for evidence that they followed the cognitive-judgmental task. If there is reasonable evidence to suggest that a panelist did not follow the intended cognitive-judgmental task (e.g., based on observations from the facilitator), standard-setting leaders may decide to exclude those judgments when calculating final cut score recommendations (i.e., "adjustments to participants"; see Cizek, 1996, p. 17). Taking such action is not intended to influence the overall recommendation in any particular direction or artificially decrease the standard error of panelist recommendations. Rather, this strategy enhances the defensibility of cut scores by using only those judgments that appear to follow the intended cognitive-judgmental task.

The final cut score recommendations are calculated based on the specific method. In many cases, the recommended cut score may be calculated as an average or median of

the panel's recommendations, which is typically presented within a range of cut scores that reflects the variability in recommendations across the panel. The size of the range is determined by the standard error (more variability = larger standard error). These results are then presented to the authoritative body/organization responsible for selecting the final cut score. Additional context may be provided to help policy makers interpret the results of the standard setting, such as estimated impact, historical impact, or comparison to other related measures. Buckendahl et al. (2005) described a process in which the estimated impact from the recommended cut scores (on a new statewide assessment) was presented in comparison to the previous state assessment and the state-level results from the National Assessment of Educational Progress (NAEP). Policy makers are advised to select the final cut score from within the recommended range given the defensibility of the standard-setting process and the validity evidence that supports the results.

In rare cases, an authoritative body will set the final cut score outside the recommended range. Although not often documented or shared, this typically occurs in one of two situations. The first is when a program is making a significant change to test design, structure, content, or format and the accompanying cut score represents a significant increase in expected knowledge and skills and a significant decrease in the pass rates. In such cases, a policy body may implement a phased approach, where a lower cut score is set as an interim step with the plan to increase the cut score (to the recommended level) over time. Policy bodies also may set a cut score different from the panel recommendation if they feel the panel did not provide them with a reasonable recommendation. This type of heavy-handed action may seem similar to a judge setting aside a jury's decision to enforce a different verdict in a courtroom setting. A policy body will consider such actions only if they have strong evidence based on observed conversations within the panel (e.g., collusion to advance a particular agenda beyond the intended focus of the standard setting) or empirical evidence indicating the cut score is not reasonable (e.g., expected impact of a 20% pass rate when similar measures have a 60% pass rate).

STANDARD-SETTING RESEARCH: CURRENT FINDINGS AND FUTURE DIRECTIONS

We conducted an extensive review of the empirical research literature on standard setting. We focus in this section on investigations into panelist experiences. In the broader review, we identified four areas of research on standard setting. These areas are:

- comparisons among standard-setting methods. Studies in this group compare two or more standard-setting methods, often focusing on the cut scores that are ultimately recommended.
- investigations of specific standard-setting methods. Studies in this group focus on a particular standard-setting method and common modifications to, or

assumptions about, a particular method. Studies proposing new methods with outcome data also are included in this group.

- explorations of panelist experiences. Studies in this group are concerned primarily with standard-setting panelists, what they think about as they make standard-setting judgments, and the effects of panelist characteristics on their judgments and decision-making processes.
- general issues in standard setting. Studies in this group address broader issues in standard setting that apply to different methods and contexts such as different modes (e.g., face to face or virtual) or how standard setting fits within the broader assessment field.

Given our emphasis on panelist cognitive processing and judgment and decision-making, we focus on the research in the third group above: explorations of panelist experiences. More specifically, we review findings from research that complement our proposed cognitive and social model of standard setting (Figure 12.2) and focus on what panelists think about when they participate in a standard-setting workshop. We organize this review into two sections: studies that examine (a) panelists' internal thinking about various components of the standard-setting process (reflecting the individual panelist cognitive processing submodel) and (b) external factors that are hypothesized to influence panelist thinking (reflecting the social and political context and the group interactions submodel). Our workshop process submodel is addressed implicitly because researchers frequently gather data from panelists about their experiences at key points during workshops through surveys or interviews. The review concludes with an explicit discussion of how these research findings relate to the model. Following the review, we suggest areas where further research is needed to better understand panelists' thinking and experiences during the standard-setting process.

Research on Standard-Setting Panelist Cognition

Research on Panelist Thinking in Standard-Setting Workshops

Research on panelist thinking during standard-setting workshops is concentrated among variations of the Angoff and Bookmark methods, which require panelists to employ probability judgments. Some research has examined how panelists conceptualize borderline test takers in these methods. Although this does not constitute a cognitive-judgmental task, panelist thinking about borderline test takers (and potential operation of heuristics and biases when doing so) has important implications for how panelists navigate the decisions they make.

PANELIST THINKING IN ANGOFF METHOD VARIATIONS Using focus groups, Ferdous and Plake (2005) investigated differences in panelist thought processes, based on panelists' propensity to provide systematically high, moderate, or low item performance estimates, using the modified Angoff method for fifth-grade reading and mathematics

assessments. They found that panelists who provided systematically high item estimates (resulting in higher proposed cut scores) thought about PLDs and their own students when making decisions. Panelists who provided systematically low estimates of borderline test-taker performance (resulting in lower proposed cut scores) also considered the policy impacts of cut scores in accordance with federal accountability requirements in *No Child Left Behind* (2001).

Skorupski and Hambleton (2005) examined panelist thought processes using questionnaires at key points in an Angoff yes/no standard-setting workshop for an English as a second language test. They focused specifically on the reading and speaking sections of the test. Panelists, all of whom were teachers, completed questionnaires immediately following the workshop welcome and orientation, the yes/no method training session, discussion of test content and PLDs, Round 1 judgments, discussion of feedback on Round 1 judgments, and following Round 2 judgments. Data from the welcome and orientation questionnaire revealed that some panelists did not understand the purpose of the standard-setting session; some believed they would be reviewing or scoring test items. Following their Round 1 judgments, panelists reported various strategies for making yes/no judgments, including considering how a reading item's difficulty could be affected by an associated reading passage and selecting "yes" when in doubt about borderline test takers, in both reading and speaking. Panelists generally reported that feedback between Rounds 1 and 2 was more helpful for the reading section than for the speaking section. Finally, following Round 2 judgments, panelists reported a greater focus on test content for the reading section than in Round 1 and reported not changing decisions between rounds for the speaking section.

Hansen et al. (2013) explored panelist experiences in an extended Angoff method workshop for three versions of a state's alternate science assessment for students with significant cognitive disabilities. Each assessment version differed in cognitive demands. The extended Angoff method was modified further by application of the mean estimation procedure, where panelists estimated average item scores for a hypothetical large group of borderline test takers (Loomis & Bourque, 2001). Following training, panelists in this workshop created PLDs for each version of the assessment before making their standard-setting judgments. They reported challenges with this process. For all three versions, panelists reported challenges in differentiating among high, medium, and low levels of performance. Several unique challenges emerged in crafting PLDs for the least cognitively complex version of the assessment, including "keeping 'low' definitions in positive terms" and being unsure "if enough science content was included" (Hansen et al., 2013, p. 309). For the more cognitively complex version of the assessment, panelists reported struggling to determine whether students at a low level of performance should be taking a less complex version (and vice versa for high levels of performance). Following their first round of judgments, panelists' greatest concern was that their judgments would be substantially different from the rest of the group. This concern dissipated after group discussion and the second round of judgments. Most panelists were confident in their judgments and applications of

the standard-setting procedure following the second round. Panelists also reported an array of factors important to their judgments, including the PLDs, group discussion, and perceptions of item difficulty.

Clauser et al. (2013) investigated panelists' use of different kinds of performance data in standard setting for medical licensure tests. In two modified Angoff workshops, the authors provided some panelists with limited performance data between rounds (i.e., the percentage of test takers selecting each response option) and other panelists with more extensive feedback (i.e., the response option information and test-taker performance on each item in deciles). They found that when panelists were provided more extensive data, their Round 2 judgments were more highly correlated with empirically estimated conditional item probabilities for borderline test takers than the judgments of panelists who were provided with limited performance data. However, they found no differences in how the different types of data impacted the cut scores that were ultimately recommended.

In an Angoff yes/no application for a licensure test, panelists recommended cut scores in three prespecified pass/fail conditions (Condition 1: where no target criterion was specified; Condition 2: with a 50% criterion; and Condition 3: with a 70% criterion). The Angoff yes/no judgmental task was stated as "Will a borderline test taker respond correctly to this item?" (In Conditions 2 and 3, the statement included "More than 50% of the time?" or "More than 70% of the time?") The average panelist cut score recommendations in Conditions 1–3 were, respectively, 60%, 50%, and 70% yeses, suggesting that when a criterion was specified, panelists may have altered their item-by-item judgments, on average, to approximate the specified criterion (R. Tannenbaum, personal communication, April 23, 2020). Framing effects, an overarching cognitive process, explain what may have operated here. The result also suggests that compliance was in operation (defined as "a change in a person's behavior in response to a direct request," (APA, n.d.).

PANELIST THINKING IN THE BOOKMARK METHOD Dawber et al. (2002) used survey and think-aloud procedures to probe panelist bookmark placement strategies and considerations for high school examinations. Across rounds, panelists commonly reported placing bookmarks through identification of a promising interval of items and selecting among the items in the interval or identifying a single promising item and "focus[ing] on that item and the preceding items" (Dawber et al., 2002, p. 36). They also found that panelists considered their own professional experiences with students, content standards, and PLDs in initial bookmark placements and expanded this list of considerations to include empirical item difficulties (when provided) and group discussion in their second round of bookmark placements.

Hein and Skaggs (2009) found that panelists in traditional and single-passage Bookmark⁹ standard settings struggled with selecting a single item and OIB page on which to place their bookmark. They also reported that several panelists deviated from the method's intended cognitive-judgmental task, particularly in the traditional Bookmark

condition. Like Dawber et al. (2002), they report that some panelists identified a range of items for bookmark placement and struggled to settle on a single item. Some panelists also reported calculating their bookmark placements mathematically, based on the point in the OIB where a particular percentage of content standards were reflected in the items. These qualitative reports complement the findings of other empirical work (e.g., Davis-Becker et al., 2011; Clauser et al., 2017) that suggest that panelists use alternative strategies to place bookmarks (i.e., they use the substitution heuristic). Hein and Skaggs (2009) found that panelists persisted in the use of alternative strategies even when redirected to the intended cognitive-judgmental task, defending their strategies as the pursuit of “adequate justification” for their bookmark placement (p. 219). These findings suggest that panelists may have engaged in algorithmic thinking, seeking rules to lead to what they considered the best bookmark placement.

In an investigation of a Bookmark standard setting for an education leadership exam, Cravens et al. (2013) reported that panelists found PLDs helpful in guiding their judgments, but relied on these descriptions less as they progressed through each round of bookmark placement. The authors suggest this may be due to increased panelist confidence and internalization of the PLDs over the course of the workshop. Panelists also reported appreciation of guiding questions provided during the process to keep the focus on the criterion-referenced nature of the task:

(a) What behaviors must a principal exhibit to achieve a rating of *at least highly effective* [i.e., a 4; italics in the original] on this item? and (b) What makes it more difficult to achieve a rating of *at least highly effective* on this item than on all previous items in this book? (Cravens et al., 2013, p. 134; italics in original)

Panelist thought processes also are addressed implicitly in several other studies. For example, Davis-Becker et al. (2011) found that, in a Bookmark standard setting, panelists placed their bookmarks in similar positions for a randomly ordered OIB and a difficulty ordered OIB, suggesting that panelists may be paying more attention to the percentage of items captured by their cut score rather than difficulty of content and relationship to PLDs. Clauser et al. (2017) obtained similar findings when they compared panelist bookmark placements in OIBs that were designed to target different levels of ability.

Similar findings also have been observed for the response probability (RP) criterion in the Bookmark method. Karantonis and Sireci (2006) suggested that the commonly used RP 67 is helpful in assisting panelists in conceptualizing mastery of test content. However, the selection of an RP criterion may have implications for proposed cut scores. Hambleton and Pitoniak (2006) suggested that, theoretically, different RP criterion should lead to equivalent performance standards, even if they result in different bookmark placements by panelists. However, some research disputes this theoretical principle. Wyse (2011) sought to investigate circumstances under which the use of different RP criteria would lead to the identification of identical cut scores and found that this is very unlikely to occur in practice. Baldwin et al. (2020) examined differences

in proposed cut scores when panelists were randomly assigned to consider response probabilities of .67 or .80 for identical tests. They found that panelists placed book-marks in similar locations in both conditions. This led to a higher cut score in the RP 80 condition, which resulted in a higher than projected failure rate.

PANELIST THINKING ABOUT BORDERLINE TEST TAKERS In two separate Angoff studies for fourth-grade reading and high school mathematics tests, where initial borderline test-taker definitions of varying specificity were provided, Giraud et al. (2005) investigated (a) correspondences between teachers' descriptions of *Barely Proficient* or *Barely Master* test takers and (b) factors they identified during training that might make assessment activities easy or difficult for these students. The fourth-grade reading panelists were provided with a relatively broad definition for a *Barely Proficient* student, while the *Barely Master* definition provided to the high school mathematics panelists was more specific. They found that panelists generated more varied descriptions of borderline test takers when the facilitator provided a less specific initial definition.

Panelists may conceptualize the behaviors of more than one hypothetical borderline test taker. Hein and Skaggs (2010) examined teachers' conceptualizations of classrooms of borderline students using the single-passage Bookmark and Angoff yes/no methods. Panelists reported difficulty with the prescribed cognitive-judgmental task for both methods, which involved imagining "an entire classroom made up of only barely proficient students" (Hein & Skaggs, 2010, p. 43). Panelists in the single-passage bookmark condition were instructed to place their bookmarks at the point where two thirds of the class would succeed on the item; panelists in the Angoff yes/no condition were instructed to select yes if they believed that at least two thirds of the class would succeed on an item. In both methods, panelists reported struggling not to think about their own classes, which are not composed solely of *Barely Proficient* students. They reported several alternative strategies, the most prominent for the Angoff yes/no method being that panelists thought about the borderline students within their own classrooms. Panelists using the single-passage bookmark method tended to focus on a specific borderline *Proficient* student from their own class and then imagine a classroom composed of other, similar students.

Research on Factors Hypothesized to Influence Panelist Thinking

Although not every component of our proposed group interactions submodel is addressed in the research literature (for example, readily accessible research on standard-setting facilitation is particularly sparse), topics such as panelist identity and group interactions have been explored to some degree. Some research also has examined the impacts of social and political contexts on panelist thinking.

PANELIST IDENTITY Busch and Jaeger (1990) found small, statistically significant differences in panelist judgments following group discussion in a modified Angoff standard setting for the National Teacher Examination in North Carolina. Specifically, public

school teachers tended to revise their judgments in the direction of teacher educator panelists. In the Angoff and Hofstee methods, Wayne et al. (2008) reported differences in recommended cut scores among panelists with different experiences (i.e., communication experts, program directors, postgraduate trainees, or hospital patients) for a medical communications exam. In contrast, Wyse (2018) did not detect significant differences in Angoff judgments across panelist professional roles for 14 medical imaging credentialing exams carried out over 15 years. He also explored potential impacts of examination development experience (e.g., prior standard setting, serving as an item writer or reviewer) on recommended cut scores and, again, did not find statistically significant effects. Cravens et al. (2013) found convergence in judgments across principals, supervisors, and teachers when implementing the Bookmark method for a principal evaluation tool.

Other studies present panelist effects related to content expertise, and for the most part suggest that content expertise does influence panelists' standard-setting judgments. An earlier study by Plake et al. (1994) did not find systematic differences in Angoff cut scores recommended by content specialists versus nonspecialists in various subjects on the College Basic Academic Examination. However, more recent studies in the medical field report substantive differences in judgments related to content knowledge. For example, Verhoeven et al. (2002) found that item writers recommended an Angoff cut score 12.4% higher than recent graduates for a medical school progress examination in the Netherlands. Evaluating expertise by asking panelists to complete test items, Verheggen et al. (2008) found that knowing the answers to undergraduate psychiatry items was associated with providing a higher Angoff cut score for most panelists. Margolis et al. (2016) also found that answering an item correctly was associated with higher Angoff judgments in medical licensure. Clauser et al. (2017), also in medical licensure, reported that panelists tended to judge items covering content that was unfamiliar to them as more difficult than items covering familiar content.

Research on impacts of standard-setting panelists' social identities is less common. Caines and Engelhard (2012) explored relationships among panelists' personal characteristics (i.e., race/ethnicity and gender), teaching contexts (i.e., school socioeconomic status and region), and recommended cut scores in modified Angoff standard settings for mathematics and English language arts assessments. They did not find race/ethnicity or gender to exert a substantial effect on panelists' recommended cut scores. However, they found significant impacts for school socioeconomic status (captured through upper, middle, and lower designations of students receiving free and reduced-price lunch in the district) and region (i.e., five geographic areas across the state). Specifically, teachers from schools in areas with low socioeconomic status recommended lower cut scores. Although region also appeared to influence teachers' judgments, it is difficult to interpret this substantively because the identity of the state in which the study was carried out is not provided. It is also possible that school socioeconomic status and region are correlated.

GROUP DISCUSSION Researchers have approached the topic of group discussion from several perspectives, examining both its content and its effects on recommended cut scores. In a research simulation of a modified Angoff standard setting, Novakovic (2008) found that mock panelists for a Teaching Exercise and Fitness certification test did not make statistically significant adjustments to their judgments following group discussion, a clear illustration of anchoring and adjustment bias (Kahneman, 2011).¹⁰ Panelists did self-report that the discussion influenced their decisions; this discussion appears to have been confirmatory for most participants. Some panelists did report experiencing peer pressure to modify their judgments to conform to the group. These panelists also reported that the introduction of empirical performance data into a subsequent round of judgments undermined their confidence. Clauser, Harik, et al. (2009), using a medical credentialing examination in the United Kingdom, showed substantial impact on the variability among panelists' estimates of borderline test takers after discussion of Round 1 results.

Several studies examine the content of group discussions in standard setting. In a study linking scores from two United Kingdom English language assessments of the Common European Frame of Reference (CEFR) using the basket standard-setting method¹¹ (Council of Europe, 2009; also see Kaftandjieva, 2010). Papageorgiou (2010) developed a nuanced account of group discussion by coding specific topics of conversation. Three coding categories relevant to panelist decision-making emerged, each of which contained several subtopics: the CEFR language proficiency standards, test takers, and the standard-setting panelists. When discussing the CEFR standards, panelists identified problems with the framework as well as difficulties they encountered throughout the standard-setting process, such as conceptualizing a borderline test taker rather than a test taker with clearly sufficient knowledge. The test-taker coding category included test-taker performance, the target test-taker definition provided by the CEFR performance levels, and explicit reference to borderline test takers who just passed one of the English language exams. Finally, the panelist code encompassed panelist confidence, references to specific test takers the panelists knew, panelist expectations for their students, and standard-setting feedback and consequences. Panelists most frequently discussed test-taker performance and target test-taker descriptions.

Deunk et al. (2014) brought discussion contents and effects together in their study of a Bookmark standard setting for reading and mathematics assessments in the Netherlands. The authors found that panelists did alter their bookmark placements following group discussion, although not in a consistent direction. Their content analysis of group discussion transcripts revealed five categories of panelist discussion: item content, school contexts, scores, the standard-setting meta task (i.e., the standard-setting process itself), and other topics not related to the standard-setting task. Surprisingly, some panelist groups did not discuss item content at all. In general, mathematics panelists spent more time discussing content than English panelists did. The degree to which the facilitator participated in, or guided, the discussion is not addressed.

POLICY AND SOCIOCULTURAL CONTEXTS Research on workshop contexts investigates the broader settings in which standard-setting panelists carry out their work. These include the policy landscape surrounding the standard setting and even the role of the assessment itself. Some of these investigations are quite specific; that is, carried out within a single standard-setting workshop. Others try to capture broader contexts using surveys. In Figure 12.2, we conceptualized the context as the larger container, political and social context. We provided a brief introduction to these factors as pertaining to the purpose of the test and intended use of test scores, which would reflect the cut scores to be set.

At a broad level, research sheds some light on aspects of the standard-setting design that may go unnoticed in individual standard-setting studies, for example, when designers favor a specific standard-setting method or use different descriptions of borderline test takers across contexts. In a survey of U.S. state assessment directors, Kannan (2014, 2016) reported that the Bookmark method appears to be the most widely used standard-setting method within K–12 state assessment. A majority of states also incorporate PLDs into their standard-setting processes. However, one state reported panelist difficulty in focusing solely on the PLDs without considering the policy implications of their task.

More specifically, the use of specific language can influence judgments given how terms are perceived, possibly because of the personal and professional implications of the standard-setting outcomes. In a survey of teachers, Burt and Stapleton (2010) examined how performance level labels can vary in evaluative connotations for teachers. Evaluative connotation refers to “the personal meaning individuals associate with a word” (Burt & Stapleton, 2010, p. 30). They found that different labels did in fact evoke different evaluations and judgments about mastery. For example, teachers judged the terms *Limited Knowledge*, *Basic*, and *Apprentice*—all used by different states to represent a generic *Basic* level—quite differently in terms of teacher evaluative connotation and mastery. Specifically, *Apprentice* was evaluated significantly more positively (i.e., reflecting a higher level of mastery) than both *Basic* and *Limited Knowledge*, and *Basic* was evaluated significantly more positively than *Limited Knowledge*.

More recently, O'Donnell (2020) surveyed teachers and parents regarding their perceptions of various performance-level labels used in middle school assessments across several states. Participants rated labels for encouragement (i.e., not potentially disparaging to students) and clarity and found differences in these ratings across different labels. For example, among the labels representing the lowest levels of performance, teachers found the labels *Standard Not Met* and *Did Not Pass* to be clearer than *Minimal* or *Below*.

Other research has focused specifically on standard setting outside the United States. Ferdous and Buckendahl (2013) collected data on panelists' thinking in an Angoff yes/no workshop for English and mathematics in a sub-Saharan Africa country. Panelists completed questionnaires at various junctures during the standard setting: after training, after Round 1 judgments, after feedback, and after Round 2 judgments. Panelists reported general comfort with the standard-setting process and confidence

in their judgments throughout the workshop. For Round 1 judgments, English and mathematics panelists reported thinking about students in their classes and PLDs and indicated generally that they did not provide judgments based on a desire to set high or low expectations for schools. Panelists were mixed in their perceptions of the utility of feedback and did not appear to make as much use of feedback as panelists from U.S. standard settings typically do. Panelists in this study also did not explicitly reference policy structures as influential in their decision-making.

Pitoniak and Yeld (2013) described challenges in the implementation of pilot and operational Angoff standard settings for National Benchmark Tests in South Africa. Panelists expressed concern throughout the process that any standards that were set might adversely affect Black students in historically underresourced schools. This led to a high level of anxiety throughout the process and may have negatively impacted panelist engagement in the task, as evidenced by repetitive questions about the process and some lack of attention to feedback provided between rounds of judgment. These observations led to revision of procedures between the pilot and operational studies. The authors suggested that pilot workshops are essential for standard setting in new contexts.

Summary and Connections to the Cognitive and Social Model of Standard Setting

The research we have reviewed on panelists' standard-setting experiences highlights the relevance of the cognitive and social components of the model of standard setting. Several studies present conclusions supporting the explicit consideration of panelist thinking and the components of the individual panelist cognitive processing submodel. Perhaps most important, we find that panelists' faithful and intentional application of the cognitive-judgmental tasks for variations of the Angoff and Bookmark methods—or any method—cannot be taken for granted. Some studies provide clear evidence of panelists' deviation from a method's intended cognitive-judgmental task and application of alternative decision-making strategies. Perhaps the clearest example of this is the use of algorithmic thinking to create rules for bookmark placements based on item proportions as a hypothesized explanation for the findings of Clauser et al. (2017), Davis-Becker et al. (2011), and Hein and Skaggs (2009). Other studies shed light on instances of potential deviation from a method's intended cognitive-judgmental task that may require further examination and explanation. For example, panelists in several studies (e.g., Dawber et al., 2002; Hein & Skaggs, 2010) reported thinking about their own students when making judgments, which raises concerns about the influence of the availability heuristic. Even in cases where panelists do not directly report difficulty carrying out prescribed standard-setting judgments, other data sources such as panelist surveys or interviews may indicate otherwise (e.g., Novakovic, 2008). These findings are consistent with Katz's (2019) framework of standard-setting panelist cognition for making probability judgments. Hein and Skaggs's (2009) finding that panelists used such strategies in the pursuit of "adequate justification" for their recommendations

(p. 219) is interesting to consider because it suggests that panelists may perceive alternative decision-making strategies as more defensible than faithful application of the cognitive-judgmental task prescribed by the standard-setting method. These findings are particularly noteworthy given the popularity of these methods.

Research also highlights the importance of considering the social components of standard setting represented in the group interactions submodel. Findings concerning the impact of group discussion on panelist decision-making are mixed, with some research suggesting that panelists report discussion to be more influential on their thinking than empirical data (e.g., Novakovic, 2008). Other research finds inconsistent changes in panelist judgments following group discussion (e.g., Deunk et al., 2014). The impacts of panelist professional identities is somewhat ambiguous, with earlier research (e.g., Busch & Jaeger, 1990; Wayne et al., 2008) finding differences in recommendations based on professional role that do not emerge in more recent studies (e.g., Cravens et al., 2013; Wyse, 2018).

It is also worth considering information that is not present within this review. The studies discussed here mostly concern probability judgments. We have found no research that explicitly examines panelist thinking or experiences in the other categories of the taxonomy. Thus, the ways in which panelists may struggle with or adapt matching, threshold detection, and value judgments in relation to the individual panelist cognitive processing submodel are largely unknown. There is also much that is unknown about the interplay of the components of the group interactions submodel. For example, we could locate only a single study that explicitly focused on panelist social identities (Caines & Engelhard, 2012). We could find no research that examines workshop facilitation. Research from judgment and decision-making and social psychology literatures supports these submodels. Further research is needed to examine their manifestation and influences in different standard-setting contexts. We propose what the beginning of such a research agenda might look like in the next section.

Standard-Setting Questions: A Proposed Research Agenda

Papageorgiou and Tannenbaum (2016) provided a comprehensive research agenda to support standard setting. They argued that “standard setting should be an integral part of the validity argument” (p. 109) rather than responding to allegations about its arbitrariness. Their research agenda was organized around substantive and procedural components of standard setting and borrowed extensively from Plake (2008), who proposed a research program that challenges standard-setting assumptions and practices.

We call attention to research questions derived from the cognitive and social model of standard setting proposed in this chapter. A comprehensive research agenda that addresses all parts and processes of the model would be massive. Therefore, the research agenda we propose here is only a starting point. Our recommendations focus on the influences of heuristics and biases on the cognitive-judgmental task and interpersonal interactions and highlight additional questions as recommended topics for future investigations.

Research Questions on Heuristic, Biases, and Other Influences

Within this chapter, we have integrated theories as to how particular heuristics and biases might be operationalized in various standard-setting methods. These hypotheses represent how we connected the research on judgment and decision-making with standard-setting processes and experience facilitating standard-setting activities. Within this section, we present a set of research questions that would help test these hypotheses and develop solutions to mitigate any negative impacts.

1. How does each heuristic or bias affect panelist thinking and decisions in different standard-setting methods? Which methods are most susceptible to the use of, or impact from, heuristics or biases? Specific examples of this research question include the following:
 - In which methods are panelists likely to use substitution?
 - When panelists are provided several sources of information to consider, do they rely on selected pieces more than others (e.g., use of availability and WYSIATI)?
 - Do panelists bring in additional memories or information while making their judgments?
 - How do panelists use the representativeness and recognition heuristics for efficient decision-making? How might these contribute to judgmental errors?
 - In what ways do anchoring and adjustment bias affect judgments in Rounds 2 or 3?
 - How pervasive are the effects of the affect heuristic in standard setting? Do they operate more or less for specific methods?
2. What are the sources of cognitive complexity and cognitive load for each standard-setting method?
3. Are particular groups of panelists more likely to use heuristics or biases (e.g., more or less experienced)?
4. What facilitation strategies, such as debiasing, can minimize the impact of heuristics and biases on panelist judgments?

Research Questions on Interpersonal Influences in Standard Setting

Although empirical evidence indicates that panelist judgments shift following group discussion, little research focuses on interpersonal interactions among panelists and between panelists and workshop facilitators (cf. Fitzpatrick, 1989). The group interaction submodel highlights likely influences regarding these interactions, as well as various aspects of panelists' social identities. The field could benefit from research concerning the following.

1. To what extent can standard setting be conceptualized as a group task and how might concepts from group work research (e.g., coordination, group member misbehavior; Barron, 2000; Kolb, 2016; Rico et al., 2008) appear in standard-setting workshops?

2. How do panelists' social identities (e.g., gender, race, profession) impact their participation in standard-setting workshops and influence the cut scores that they recommend?
3. To what extent is deep diversity (Harrison et al., 1998) achieved in standard-setting panels and how do personal beliefs and values impact panelist participation in standard-setting workshops and influence the cut scores they recommend?
4. What facilitator competencies and areas of expertise are most important for effective standard-setting facilitation?
5. How do facilitator actions influence panelists' engagement in a standard-setting method's cognitive-judgmental task?

Other General Research Questions

Once results from studies that address these research questions emerge, we can adjust standard-setting practices and or envision methodologies that will enable panelists to follow the cognitive-judgmental task with minimal negative influences. We also will be able to debate more general questions such as:

1. Should we continue to use traditional standard-setting methods given their susceptibility to heuristics and biases that undermine the fidelity of their cognitive-judgmental tasks? What judgmental methods could we use instead?
2. We have argued that the fidelity by which cognitive-judgmental tasks are implemented matters in making validity arguments about the suitability of a method and defensibility of performance standards generated by those methods. How much does method fidelity influence the acceptability of recommended cut scores?
3. How can we revise popular standard-setting methods to reduce cognitive complexity, cognitive load, and susceptibilities to the negative effects of judgmental heuristics and cognitive biases?
4. Many of the studies that we have discussed are single studies. Given the "replication crisis" in psychology, medicine, and other fields (see, for example, Camerer et al., 2018), where findings from studies are replicated at disturbingly low rates, can standard-setting findings be replicated? Under what conditions? To what degree do panelist effects, facilitator influences, and the policy and political environment influence standard-setting recommendations?
5. How can we triangulate standard-setting research findings using methods such as think-alouds, surveys, and interviews other than those used in the original studies?

CONCLUSION AND EVOLUTION OF STANDARD SETTING

We began this chapter with three claims. We proposed the following:

1. The cognitive-judgmental task (inherent in the standard-setting method) is a critical aspect of standard setting and should be central to the design, preparation, execution, and evaluation of the workshop.

2. In addition to the cognitive-judgmental task, there are other influences on panelist judgment and decision-making in standard setting. Some are design features and are desirable; some are not.
3. Standard-setting results should reflect a well-executed process that was led by experts who helped panelists make their judgments, avoiding undesirable influences.

To support these claims, we began at the center of the model and presented the taxonomy of cognitive-judgmental tasks. We then presented a list of positive and negative influences on panelist judgment and decision-making, including judgmental heuristics, cognitive biases, and other factors. We related these influences on the submodels in the overall model and provided suggestions as to how standard-setting facilitators can manage such influences during the standard-setting process and document validity evidence to this effect. Finally, we will highlight findings from standard-setting research that connects directly to these topics and make suggestions as to how these influences can be explored in future research.

State of the Art and Practice: Innovation and Inertia

Standard setting is evolving (e.g., Ferrara, 2022). At the same time, its practice remains essentially unchanged (Davis-Becker, 2022). What do we see for the near future of standard setting? We propose that recent innovations represent evolution in thinking about standard setting and some practice of standard setting (Ferrara, 2022; see also Luecht, 2020). The innovations included the following.

First are the innovations in standard-setting workshop design, including selecting a method with an appropriate cognitive-judgmental task, accounting for the implications in two proposed models of standard setting—the cognitive and social model we have proposed here and a psychometric model of standard setting proposed by Reckase (2023)—and remote standard setting workshops (Kanistra, 2022; Kollias 2018).

Second, there is an increasing influence of policy during standard setting, including conceptualizing standard setting as a lever to pursue policy aspirations for student achievement and for specification of minimal competency for new professionals, and Benchmarked Standard Setting approaches (Ferrara et al., 2021).

Third is the increasing prevalence in the use of principled assessment design, including writing PLDs as a first step in assessment design (Bejar et al., 2007; Huff et al., this volume, Luecht, 2020), selecting an appropriate method (Ferrara et al., 2023), articulating content standards and PLDs vertically (Cizek & Agger, 2012), pursuing item-PLD alignment (Ferrara, 2017), standards validation (Landl, 2019; Mattar et al., 2012), and embedded standard setting (Lewis & Cook, 2020).

Embedded Standard Setting as an Example of Innovation

Lewis and Cook (2020) have proposed embedded standard setting as an approach to standard setting that integrates identifying cut scores into a principled item development

process and as preferable to setting standards after operational administration. They describe the process and argue for its logic this way.

When item writers develop items that are designed to measure the KSAs associated with specific performance levels, then the second fundamental task that . . . standard-setting panels perform—making item-level judgments that operationalize the KSAs and allow them to be translated into appropriate cut scores—has also been fulfilled, again with more thought, transparency, and rigor than can typically occur during a relatively brief standard-setting workshop. (Lewis & Cook, 2020, p. 9)

And, more succinctly, “the practice of principled assessment design renders traditional standard-setting methodology redundant at best and contradictory at worst” (p. 8).

Specifically, this approach proposed by Lewis and Cook (2020) determines cut scores based on the targeted alignment to PLDs. Further, this approach seeks to minimize the impact on cut scores of items whose empirical scale locations do not align with their targeted PLDs (R. Cook, personal communication, May 11, 2022). Gaertner and Powers (2021) conducted a simulation study in which they compared 13 statistical and procedural methods for calculating cut scores to minimize bias and variability in cut scores. They found that the embedded standard setting weight method, which chooses a cut score to minimize distances between item-PLD misalignments, worked well when there was item-PLD mismatch (any amount: low, medium, or high) and some (a medium amount) of imbalance in the difficulty of the items. Of course, embedded standard setting can be completed only when IRT item parameters are available, usually after analysis of a field test or operational administration, when item scale locations are available, empirical item-PLD alignments can be determined, and cut scores can be applied.

Following the main premise in this chapter, embedded standard setting can be conceptualized as combining the cognitive judgments, which typically are part of standard setting, within the test development process and then conducting the empirical aspect of standard setting (i.e., calculation of recommended cut scores, evaluating validity evidence) after data are available. The goal of both traditional standard-setting processes and embedded standard setting is to maximize item–PLD alignment for a test form. The process can be applied to entire item banks, although cut scores should be based on selections of items that match test form blueprints.

A Recent Trend

Recently, standard-setting leaders and state departments of education have had difficulty in recruiting panelists for standard-setting workshops for state assessment programs. This difficulty has arisen even when recruiting for panels as small as 10 to 12 participants. This is quite different from the early 2000s, when it was relatively easy to fill out panels of 25 to 30 participants. Fifteen to 20 years ago, the then-new No Child Left Behind requirement that all states test students in Grades 3–8 and high school was controversial and performance standards were worrisome to states.

That newness probably stirred statewide and local interest—sometimes expressed as outrage—which motivated educators to participate in state assessment standard settings, to learn what standard setting was about, and, perhaps, to protect against what they considered unreasonably high performance standards. We personally observed school principals and district assistant superintendents attending standard-setting workshops and openly encouraging panelists to propose low cut scores. More recently, new state assessments and performance standards seem to be accepted as routine, which may reduce the willingness of local educational leaders to allow teachers to leave their classroom for two or more days to participate in standard-setting workshops.

Inertia in Standard-Setting Practice

Despite this list of innovations, inertia is another way to describe standard-setting practice over the past several decades. Although new methods are introduced every few years (see Table 12.1), many practitioners still rely on methods that were first described in the 1970s. This lack of change in practice is not unique to standard setting and can describe much of the larger testing industry. For example, Hambleton (1989) described the IRT work of Lord from the early 1950s, with some of the first large-scale applications occurring much later, in the early 1980s.

This inertia is somewhat understandable. First, many of the “new” methods are variations on presentation or judgmental guidance of existing methods. Second, the high-stakes nature of many testing programs discourages setting designers from implementing any operational changes. Third, many programs are seeking, or seeking to maintain, approval by an external organization (e.g., U.S. Department of Education peer review, third-party accreditation) and wish to use operational practices that have been previously approved by these organizations.

CLOSING

Whether you view standard setting as a rigorous integration of art and science or a necessary evil, it is a significant enterprise in educational and credentialing testing. The measurement community’s recognition of its importance has evolved from its first mention in the second edition of *Educational Measurement* in 1971 to its prominence in the early 21st century. It took only 50 years to get here. The importance of standard setting requires that we strive continuously to improve our methods, conceptualizations, and practices. We have attempted to meet that requirement in this chapter. We encourage our colleagues who are standard setters to continue their improvement efforts as well. And we hope that the cognitive and social model of standard setting, the taxonomy of cognitive-judgmental tasks, and the research agenda topics we have proposed here stimulate researchers to recognize the rich opportunities that standard setting provides for research topics.

ACKNOWLEDGMENTS

Steve Ferrara was the inspiration, driving force, and team leader for the development of this entire chapter. He was excited to share these ideas with the measurement community and inspire future debate and discussion around standard setting. We wrapped up the final draft of the chapter and were all excited to celebrate . . . except Steve, who was ready to work on the next research paper! Up until his passing, he was full of ideas, inspiration, and appreciation for this professional community. We are grateful for the opportunity to collaborate with Steve and hope everyone appreciates his ideas shared in this chapter.

The authors also wish to thank a number of our colleagues and friends who helped us during the development of this chapter. First, we want to thank the editors, Linda Cook and Mary Pitoniak, for the invitation to create this chapter and the support during the process. Second, we want to thank our reviewer/collaborators, Barbara Plake, Ellen Forte, and Jim Pellegrino, who provided guidance in shaping our work and communicating a clear message. Third, we want to thank other colleagues who contributed ideas and reviews based on their experience and expertise: Chad Buckendahl, Brian Clauser, Rob Cook, Jamie Dunleavy, Voula Kanistra, Charalambos (Harry) Kollias, Dan Lewis, Marianne Perie, and Mark Reckase. Finally, we want to thank the graphics team at HumRRO for their help in developing our visual model of standard setting: Constance Denning, Ryan McGrath, Haeley Phan, and Stephanie Means.

NOTES

1. In standard setting, the term “Borderline Examinee” is more commonly used. However, we have used “Borderline Test Taker” to be consistent with the terminology used throughout the volume.
2. For example, as in the “Tom W’s Specialty” experiment (Kahneman, 2011, pp. 146–148): Tom is described to resemble stereotypes of nerdy engineers and computer scientists (not to leave out psychometricians and statisticians); experimental subjects select those graduate specializations as most likely for Tom even though higher probability guesses—that is, specializations with higher enrollments and base rates—are humanities and education.
3. Similarities in evidence, with disregard for the veracity of the evidence.
4. We make decisions based only on those ideas that we can activate in working memory, which can lead to biased and suboptimal judgments.
5. Replacing a difficult question or cognitive task with a simpler one and then applying the judgment to the original question or task.
6. Voting and Supreme Court decisions are processes in which consensus (i.e., an agreement held by all or most) is sought, though usually not achieved. Juries arrive at verdicts by consensus, though television shows and movies suggest that it often is a wearing-down process rather than true agreement. We recognize that Galton’s (1907) observation was about accuracy. In our view, reasonableness

and acceptability of the group median cut score is analogous conceptually to accuracy.

7. Although there is no way to judge cut scores as correct or incorrect, “reasonable” means the cut scores (or resulting impact) would be judged as fair or appropriate by informed stakeholder groups.
8. Persuasive argument theory refers here to effects on panelists when they receive insights and other information from other panelists, not that panelists are explicitly trying to persuade other panelists.
9. In the traditional Bookmark method, items are ordered by difficulty, disregarding passage item sets. The single-passage Bookmark method is a variation applied to reading assessments with reading passages and intact item sets. Separate OIBs are created for each passage and item set in an effort to reduce the cognitive complexity of the task (Skaggs et al., 2007).
10. People estimate or accept an initial value, then make inadequate adjustments toward accuracy.
11. This is a standard-setting method, similar to Body of Work and ID Matching, in which panelists put test items in “baskets” that correspond to one of the CEFR achievement levels relevant to the test in question.

Reporting Scores and Other Results

April L. Zenisky

University of Massachusetts Amherst

Francis O'Donnell

NBME

Ronald K. Hambleton

University of Massachusetts Amherst

When most people who are not test developers think about tests and measurements, it is not models or theories that typically come to mind. It is test scores and how they have been presented and explained that is memorable and often consequential. Basic questions often asked, such as “Did you pass?,” “How’d you do?,” and “What does your score mean?,” speak to the impact that tests and test results have for stakeholders and where these users’ primary interests reside. Tests, by and large, fulfill a specific purpose for specific users, and there are actions and choices to be made on the basis of the scores, such as advancement down a career path, needing to take a review course or sign up for tutoring, or applying—or not—for admission to certain institutions. For these reasons, it is critical that test takers and other score users understand what the results mean relative to whatever actions may be available given the validated interpretation(s) and use(s) of the results.

Reporting test results is thus perhaps the single most important point of interaction between the testing agency and users of test scores, and, as the old saying goes, “You never get a second chance to make a first impression.” A well-designed and carefully crafted report of test results should support stakeholders by first communicating information about performance and, second, providing evidence to support whatever action(s) follow from that report of performance. In contrast, a poorly designed or confusing report does not lend itself to accomplishing an informational or actionable purpose and, in discouraging understanding of results, also can foster skepticism and/or distrust in a test.

GOALS FOR THE CHAPTER AND ADVANCE ORGANIZER

In this chapter, the intent is to provide readers with a broad theoretical context for understanding reporting and reporting choices and to draw on the growing body of research on reporting test results that is relevant to practical problems. To be clear, the approach here is less on prescriptive findings from prior studies and more on offering general trends where appropriate, tempered by the guidance for report development teams to engage with users whenever possible, to the extent possible.

The chapter begins with an overview of frames and perspectives for reporting, acknowledging that reports come in various sizes, shapes, and forms, and there are several conceptual approaches to reporting that are reflective of specific stakeholders’ interests and needs. Reporting efforts and report design approaches must be explicitly and directly tied to validity, meaning they must—first and foremost—support the intended interpretations and uses of test results. From there, the focus will turn to defining reporting in terms of several key dimensions, including the unit of analysis for reporting results, assessment contexts, report contents, mechanisms for reporting, and the context of reporting efforts within broader reporting systems.

Then, a seven-step model for reporting based on a synthesis of the work done by Hambleton and Zenisky (2013) is introduced to present the report development process

in light of the literature in this area, and an updated checklist for designing reports is provided. Topics of interest in this section include some reflection on the interdisciplinary nature of reporting and what can be learned from other fields, the need for documentation such as user guides alongside reports, and the need for ongoing research on reporting. From there, the chapter concludes with attention given to challenges and opportunities in reporting, such as next-generation assessments, subscore reporting, technology-based reporting, advances in data visualization, and reporting in a formative context.

CONTEXT FOR REPORTING AND RESEARCH

Over the years, I have been struck by the contradiction between the efforts and successes in producing sound technical assessments, drawing samples, administering the assessments, and analyzing the assessment data and the effort and success in disseminating the assessment results. (Hambleton, 2002, p. 193)¹

The body of research on educational and psychological measurement largely came into being in the 20th century. During that time, most of the more well-known tests were, as an unofficial rule, both norm referenced and multiple choice, and the focus of the measurement field was largely on advancing the technical, behind-the-scenes statistics and procedures to develop tests and validate proposed uses (see Clauser, 2019, for a history of classical test theory; see also Clauser et al., this volume, for a history of educational measurement). Communication with users has not always been prioritized as a matter of theory *or* practice, nor was the compilation of evidence establishing the potential score interpretations as reliable and valid themselves, separate from scores.

In reflecting on the history of *Educational Measurement* as a volume chronicling key elements of this field, it is worth noting that results reporting only gained its own chapter in this edition. This is not to say that reporting has been deliberately or consciously neglected in the editions curated by Lindquist (1951), Thorndike (1971), Linn (1989), and Brennan (2006). It has been discussed briefly in prior editions: Indeed, for example, in the 1951 edition, Mosier's chapter on "Batteries and Profiles" (Mosier, 1951) provided some guidance on the elementary principles of profile construction as

a graphic representation of a set of test scores for a single individual in which the tests are represented by ordinates spaced along the horizontal base line and the magnitude of each score is represented by plotting the point at the appropriate height on that ordinate. (p. 795)

In the 2006 edition, Cohen and Wollack noted that reporting is "clearly essential to test validity," but at the time it was "only just beginning to receive rigorous attention" (p. 382). Now, the time has come.

Reporting test results is a topic that cuts across psychometrics and many additional fields, including communications and marketing, graphic design, cognitive science, and information processing. In the same way that tests and testing practices have evolved, and stakeholder interest in and use of reports has changed along with how stakeholders

consume and use data more generally (Zenisky & Hambleton, 2012b), the way this profession has handled reporting has necessarily changed and is still evolving. No longer are reports simply data dumps with the goal to get as much information as possible onto a single page, and the literature on reporting is now much more substantial than even in the early 2000s.

A number of historical events and movements have also contributed to greater awareness of the impact of results reports. Reflect for a moment on several of the tests, testing programs, and assessment-related initiatives that have appeared over time at the forefront of the public consciousness involving tests: the introduction of Army Alphas and Army Betas for military selection in the early 20th century (Waters, 1997); the rise of the SAT (formerly Scholastic Aptitude Test) with the objective to level the playing field for college admissions (and waves of pushback to the use of standardized tests for that purpose) (Lemann, 1999); the publication of *A Nation at Risk* during the Cold War (National Commission on Excellence in Education, 1983; the standards-based revolution and accompanying transition from norm- to criterion-referenced testing (Hamilton et al., 2009); the No Child Left Behind Act of 2002 in the United States and the accountability imperative of testing affecting most schools and its subsequent reauthorizations (Linn et al., 2002); the rising interest in national and international comparisons afforded by assessments such as the National Assessment of Educational Progress (NAEP), the Programme for International Student Assessment (PISA), the Progress in International Reading Literacy Study (PIRLS), and the Trends in International Mathematics and Science Study (TIMSS) (Fischman et al., 2019); and the evolving “opt-out” movement in many places (Kirylo, 2018). What is undeniable through reflection on these (selected) watershed moments in the history of assessment is the social impact of test results and how communication of results and the context for those results can both reflect and refract historical shifts in society. However, it is equally important to note that the quality of the reporting of results across these initiatives is variable: Typically, the data that are gathered lend themselves more easily to summative statements about proficiency on a relatively general or global level, and many reporting efforts falter when it comes to providing actionable guidance for intended users of such data, particularly when it comes to instructional uses.

Indeed, at present, stakeholders are often more skeptical consumers of data and seek additional information whenever possible, leading to something of a tension between what stakeholders want and what interpretations the psychometric models strictly support. In this way, testing agencies must thread a needle of reporting transparency, quality, and quantity that speaks to the very fundamentals of test development and validation where, it is our belief, results reporting should be among the very first considerations. Results reports are often the final and most public-facing aspects of any assessment system. But, rather than being left to something that is handled late in the development process, within the context of a principled approach to assessment design, reporting must be prioritized as part of assessment development and validity considerations to inform all the decisions that follow.

What Is a Results Report?

The topic of reporting begins easily enough with a paper document, often a single page, printed double-sided, that provides test results for one individual. Figure 13.1 provides an example based on a fictitious K–12 testing program. This kind of report is broadly representative of what an individual might receive after taking a college admissions test, a standardized educational assessment, a credentialing test, or a psychological test battery. The information communicated on the individual score report in each of those areas can be tailored to the recipient, but the commonality is an accounting of the performance of a single individual on a test taken. The actual results included can be represented in a wide range of ways, such as with numbers, text/labels, and graphics, and the primary aim of this document is to be informative at that individual level (“Here’s how you performed”). In some testing contexts, paper reports have increasingly given way to electronic versions of the same information. These are sometimes accessed via email or, increasingly, a secure login to a reporting portal of some kind, but the reported information remains generally the same for individuals regardless of report delivery mode. Such reports can also be formatted for printing if that is an anticipated action users will take.

For some individual reports, it should be noted that the report not only serves the function of reporting status, but also offers prediction and/or guidance for next steps. This is perhaps most common in educational assessment, but is also found in reports

FIGURE 13.1
Simplified Sample of a K–12 Results Report

for other contexts where test users need help in identifying areas for improvement (for example, failing candidates in credentialing). This element of reporting can use subscore reporting techniques to identify areas of relative strength and weakness; in addition, rule-based/logic triggers (or, increasingly, artificial intelligence) can be implemented to evaluate response data and specify actionable next steps on a report. An example of this is a reading test that, as part of the reported results, provides a Lexile level to an individual and then suggests texts by name that are level appropriate (see Figure 13.2), or a mathematics assessment that reports relative weaknesses and structures reporting of such skills with links to specific online math lessons. Such connections, when included in reports, offer direct actions to the test taker and/or other users that take some of the guesswork out of what comes next, which is especially valuable when the report targets a test taker or families, who may well benefit from direct scaffolding in the area of “next steps.”

Group reports are also an essential part of the reporting landscape, and the format and audiences for those are more varied than for individual reports. It is when results for groups of test takers start being aggregated that the extent of the *who* and *what* of group reporting comes into view, and the idea of what a “report” is starts to expand exponentially. Consider the *who* of reporting for a moment: In an educational/K–12 setting, a group could, for example, consist of:

- a subset of students in a classroom, selected purposefully by a teacher or instructional administrator;
- all students in a classroom;
- selected students within a grade level grouped by some socioeconomic or demographic quality;
- all students in a grade level within one school in one district;
- all students in a grade level in multiple schools within a district;
- all students in a grade level within a state or territory; and/or
- all students in a grade level within a country.

These various groupings are not of equal interest to all users of assessment results. What a classroom teacher will focus on in a group report is necessarily quite different from what a school or district administrator will look at, which is different again from what

Your Reading Level: 1340L Current Reading Range: 1240L – 1390L		The best way to improve your reading level is to read books in your range. Consider the suggestions below.
Book	Author	Level
Hope For Animals and Their World	Jane Goodall	1240L
Stories Well Told: Science Fiction	Valerie Bodden	1340L
Core Four	Phil Pepe	1390L

FIGURE 13.2
Sample Report Section With Lexile-Based Book Suggestions

administrators in a state or provincial office of education consider most important. Although the idea of group reports is simple in that a group report is most basically some kind of aggregation of individual performance results, it broadly encompasses many different groups of individuals, data about their performance, and levels of communicating results.

Similar kinds of conceptualizations of what is a “group” for reporting can be applied to other testing settings. For example, in credentialing, a group could be all test takers testing at a certain test center within a defined testing window, all test takers from a certain institution or training school within a year, or all test takers grouped by a socio-economic or demographic quality within a year—these are dependent, again, on the audience and the planned use of the data.

Because of the many possible group selections for aggregate reports, group reporting is increasingly occurring (or at least originating) as a function of database queries rather than static report documents. To a point, dependent on the user group and the intended use(s) of group-level data, the process of accessing aggregate test results involves using interactive, web-based tools that tend to reflect a continuum of analysis (Zenisky & Hambleton, 2012b). This continuum spans from tools that provide results that are purely descriptive in nature to those that function more akin to a statistical analysis package to carry out original analyses, including significance testing. Examples of the former include the data tools for many U.S. states, such as Massachusetts (<http://profiles.doe.mass.edu/statereport/mcas.aspx>), Florida (<https://edstats.fldoe.org/SASPortal/main.do>), and Texas (<http://texasassessment.com/administrators/>). The International Data Explorer tool is the premiere example of the latter class of online assessment results tools because it is a “one-stop shop” for access to results from PISA, PIRLS, TIMSS, and the Programme for the International Assessment of Adult Competencies (<https://nces.ed.gov/surveys/international/ide/>). This portal, which mirrors that of the NAEP Data Explorer (<https://nces.ed.gov/nationsreportcard/data/>), permits users to run simple or complex descriptive results and carry out analyses of performance data with respect to innumerable additional variables gathered through participant and educator surveys. Results can be run to produce tables as well as highly customizable graphics.

Conceptualizing Reports and Reporting

Know the communicative purpose of the display and do not try to do too much.
(Wainer et al., 1999, p. 304)

A critical aspect of reporting that must be raised at the outset of this discussion concerns the idea of *effectiveness*. Much of the research and discussion that focuses on results reporting aims to support the development of “good” reports, but the quality of a report is a concept that deserves some reflection. What is an effective report? Ryan (2006) established a report itself as a form of communication, and a starting place to answer this question can be traced back to several key advances in the results reporting literature. First, the work of Wainer in focusing on visual displays of quantitative data (e.g., Wainer, 1992, 1997a, 2005, 2009; Wainer et al., 1999) is especially

instructive in that it draws across disciplines to formulate broad principles that apply to individual and group reports alike, such as creating visuals that are high in information and low in adornment, labeling clearly and fully, and using spacing to aid perception.

This line of research advanced by Wainer and others calls on those responsible for developing reports to think critically about the intended story of each data display as well as the nature of the data being presented. There are numerous examples in Wainer's writings of cases where graphics (assessment related and otherwise) were revised to show a very different story, one that was obscured by the original data presentation. Building on Wainer's work on graphical presentation and its considerable implications for results reporting of assessment data, then, effective—in part—draws on adhering to basic principles of communication and cognitive processing to create reports that are purposefully crafted to communicate specific information.

The foundational work on quality reporting done by Jaeger (Jaeger, 2003; Jaeger et al., 1993) likewise laid the groundwork for differentiation of reporting by audiences. By referring to "NAEP's audiences" (in the context of the NAEP) and reframing school report cards with the intended recipient in mind, reporting has effectively had to shift from one size fits all to a model that acknowledges and responds to the informational needs and interests of users of test data. This is a perspective that has rightly permeated current thinking about reporting and provides a conceptual basis for reporting efforts that are informed by research with various articulated user groups.

Figure 13.3 provides an updated perspective on Jaeger's (2003) nine tables offering a road map for audience-specific research activities for report development. The premise of Jaeger's (2003) work was that there are some key questions that should be asked of each stakeholder group, to learn not only what is of interest to them, but also how such information could and should be provided to them. And, with each stakeholder group, there are different methodologies available to report developers for the purpose of investigating those key questions, and those methods, naturally, provide quantitatively and qualitatively different data. Figure 13.3 links the main considerations in the design of research on reporting: For agencies that engage in these questions, it may be helpful to frame the work to be done relative to these considerations and build out the work relative to the priorities and available resources of a testing program.

Indeed, Jaeger's (2003) contributions, including the differentiation of users (and the accompanying need to probe and understand reporting interests of different groups), provide a direct line to another key advance in conceptualizing quality reports, which is the presentation of general models for report development and evaluation (Hambleton & Zenisky, 2013; Zapata-Rivera, 2011; Zenisky & Hambleton, 2012a, 2015). With regard to model-based approaches to report development, the focus on audiences and users as something to be articulated and respected propagated a shift in the process of report development, where Hambleton and others suggested that reports should evolve through audience-specific research and development, and reporting aims are discussed and user input is solicited at multiple points, to inform report development from conceptualization to implementation and maintenance. This advance helps to

FIGURE 13.3
A Road Map for Audience-Based Research

Note. Adapted from *NAEP Validity Studies: Reporting the Results of the National Assessment of Educational Progress* (Working Paper 2003-11), by R. M. Jaeger, 2003, U.S. Department of Education, Institute of Education Sciences.

ensure that a key dimension of how report quality is defined is informed by direct communication with and solicitation of input from the intended users.

Another fundamental source for informing a working definition of an *effective* report is drawn from Hattie's approach working with educators, under the umbrella of his "Visible Learning" initiative (Hattie, 2009, 2010). In the realm of results reporting, much of Hattie's work has sought to elevate the importance of the audience and supporting stakeholders in using assessment data. The lessons of his research on learning, achievement, and results reporting transcend their original context to apply to all of the reporting contexts relevant here. In Hattie (2010), 15 principles for establishing the validity of results reports are enumerated, grouped in topics including validity of reports, sources of validity evidence for reports, and design principles for reports. Among these principles are the ideas that reports should have a specific theme and be designed to address specific questions posed by the stakeholder and that, from a conceptual point of view, reports should be conceived of as actions, not screens to print. These are critical principles that, similar to the ideas in Wainer's work, speak to the notion of what effective is that will guide this chapter.

Reporting and Professional Standards

The *Standards for Educational and Psychological Testing* (American Educational Research Association [AERA] et al., 2014), offers an additional lens for evaluating report effectiveness for the contexts described in Figure 13.4: educational assessment, workplace testing and credentialing, and psychological assessment. The *Standards* are presented in clusters, and two clusters specifically address results reporting: one focusing on reporting and interpretation and another on test takers' rights to fair and accurate reports. The first standard from the first cluster is the most emblematic of the kind of recommendations provided:

FIGURE 13.4

Overview of Assessment Contexts for Reporting, per the *Standards for Educational and Psychological Testing*

Note. Information is drawn from *Standards for Educational and Psychological Testing*, American Educational Research Association, American Psychological Association, and National Council on Measurement in Education, 2014.

When test score information is released, those responsible for testing programs should provide interpretations appropriate to the audience. The interpretations should describe in simple language what the test covers, what scores represent, the precision/reliability of the scores, and how scores are intended to be used. (AERA et al., 2014, p. 119)

With sentences such as “provide interpretations appropriate to the audience” in the text of the standard and “reports and feedback should be designed to . . . minimize potential negative consequences” in the accompanying commentary, the *Standards* offers reporting ideals in ways that are necessarily broad to account for guidance that spans highly varied testing purposes. Examples of how those ideals might be achieved are discussed, but the specific approaches in the examples are options rather than requirements, in alignment with the thinking that there is no one-size-fits-all report design that will succeed in every testing context.

Within the two clusters, there are standards addressing the need to ensure the validity of automatically generated interpretive text (Standard 6.11) and select performance labels that support intended inferences without being stigmatizing (Standard 8.7; e.g., O’Donnell & Sireci, 2021). There are numerous performance-level labels in use, as illustrated by the word cloud in Figure 13.5 based on O’Donnell’s (2020) review of labeling practices for statewide assessments in the United States (larger text represents more frequent use of a word). There are also standards for more procedural aspects of reporting, including report delivery and handling material errors. Beyond the standards in those clusters, O’Donnell and Zenisky (2020) identified 36 standards (AERA et al., 2014) that apply to results reporting, many of which are mentioned later in this chapter along with standards from the National Commission for Certifying Agencies (2014), which are similar but geared toward credentialing.

FIGURE 13.5
Performance-Label Word Cloud

The International Test Commission's Guidelines on Test Use (International Test Commission, 2013) are also instructive here: While some of those guidelines offer assistance in the selection of tests and test administration, Section 2.7 focuses on interpretation with 12 substandards pertaining to generalization of scores, reliability and validity of results and implications for meaning, and minimization of bias and social stereotyping that may negatively impact individuals and groups. Section 2.8 of these ITC guidelines further relate to communication of results, addressing privacy concerns and providing guidance about communication strategies that take audience interests into account. Overall, the guidelines from AERA et al. (2014) and other groups place validity and understanding one's audience front and center, promoting the idea that an effective report is one that guides users toward valid interpretation and uses, leaving it up to developers to find the exact content and design features that will be most successful in that task.

From Score Reporting to Results Reporting

Historically, the topic of communicating test results has been referred to as score reporting and, indeed, scores (primarily overall scale scores) were the main or only data contained on reports for many years. Over time, however, there has been a clear shift in most large-scale testing programs where what is being communicated to audiences is substantively different. Much of what is found in present-day reports extends well beyond simple scores to include achievement levels (e.g., *Pass, Not Yet Meeting Expectations, Proficient*), information to support comparisons to relevant groups (e.g., percentile ranks, reference group descriptive statistics), and numerical or categorical subdomain feedback. Other results sometimes included are item-level performance data, where item-level results can be provided for individual test takers or groups of test takers, and growth results (Zenisky et al., 2019), which use test scores from previous administrations to project test performance in the future.

Although it is certainly true that most of the data presented on current reports are scores or derivatives of scores, the shift in language being advanced here—from “score report” to “results report”—supports a more inclusive perspective. This change in emphasis is intentional in that it reinforces a more expansive approach to representing test performance. The task explicit in this shift is to consider and explicitly prioritize ways to communicate test information that are richer and more engaging. For example, there is growing research on interactive reporting tools such as dashboards, discussed later in this chapter.

Our recommendation, reflected in the terminology shift, is to approach the task of reporting assessment results as sharing multiple pieces of information with unique value rather than treating data other than the overall score as secondary in importance. This line of thinking may help develop reports that not only fulfill informational purposes and contribute more meaningfully to reporting systems, but also guide users to what comes next on the basis of the results, aligning with the third of Hattie and Timperley's (2007) reporting questions: Where to next?

PERSPECTIVES ON REPORTING FRAMES AND VALIDITY

Clear and useful score reports support users in making appropriate score inferences and have an important role to play as part of efforts to explain the validity argument for a test to key stakeholders. (Hambleton & Zenisky, 2013, p. 479)

Reporting as Validity in Action

Validity is the most essential consideration in the process of developing and evaluating tests. In turn, how test results are interpreted and used is central to how validity is defined in the AERA et al. (2014) *Standards* because validity there is understood as “the degree to which evidence and theory support the interpretations of test scores for proposed uses of tests” (p. 11). Interpretations and uses are also key to the argument-based approach to validation (Kane, 2006, 2015), which provides a practical framework aligned with the *Standards*. Following this approach, at the outset of test development, test developers must first create an interpretation and use argument (IUA), listing all proposed interpretations and uses along with the reasoning for each, and then proceed to a validity argument, which involves a strategic evaluation of the claims and assumptions in the IUA. The development of an IUA, then, can provide a clear evidentiary basis for reporting (Ferrara & Lai, 2016).

Similarly, based on the *Standards* (AERA et al., 2014), test developers are asked to articulate all intended interpretations of results for specified uses (Standards 1.0, 1.1, 11.1) and later gather and evaluate validity evidence for each of those interpretations (1.0, 1.2, 1.11–1.25, 11.1). Intended interpretations and uses are mentioned in standards regarding scores (5.1, 5.4), precision (2.0), norms (12.5), and various other topics. A smaller number of standards focus on ensuring that those intended interpretations come to fruition when reports reach their audience:

Standard 3.1: Those responsible for test development, revision, and administration should design all steps of the testing process to promote valid score interpretations for intended score uses for the widest possible range of individuals and relevant sub-groups in the intended population. (p. 63)

Standard 13.5: Those responsible for the development and use of tests for evaluation or accountability purposes should take steps to promote accurate interpretations and appropriate uses for all groups for which results will be applied. (p. 211)

This notion of effective reporting is in line with a view of validity heavily informed by the work of Messick (1989), with an emphasis on consequences and use. Reporting is essential to validity because it is the means through which intended interpretations are realized, and this is critical to interpretation, particularly in terms of the intended (and unintended) consequences of testing (per Messick, 1989). The greater focus on *intended* rather than *actual* interpretations in the AERA et al. (2014) *Standards* is likely because the former are needed to start building an IUA and are available earlier in the test development process. However, the interpretations made by users on the basis

of reports should also be a major component of validity evidence. If a report fails to guide users toward the validated interpretations for an assessment, the chances that the assessment program will meet its goals are greatly diminished, regardless of how much evidence exists in support of ideal, but unrealized, interpretations. Ryan (2006) also espoused this connection between validity and interpretation, suggesting that elements or features of reports that foster or lead to unsupported interpretations have a corrupting effect on validity. (See also Lane & Marion, this volume.)

Tannenbaum (2019) described this issue in terms of alignment: “A score report that is not well aligned with the test is of little value; similarly, a score report that is well-aligned, but not communicated to users in a way understandable to them is of little value” (p. 9). This is a critical point that speaks to an important dimension of effective, in that a report without alignment or meaning is essentially devoid of consequence and occupies space without adding value. To ensure alignment, Hambleton and Zenisky (2013) proposed explicitly linking validity evidence and the purpose of a test to the contents of results reports and subsequently investigating the characteristics and information needs of the intended audience to determine how to best present that content (all steps of the Hambleton and Zenisky model are described in a later section). A common thread among Tannenbaum (2019) and Hambleton and Zenisky (2013) is the view that effective reporting is critical to validity, and ensuring that reports can be interpreted as intended to fulfill specific purposes is as important as having other sources of validity evidence.

Several authors have proposed alternate notions to better situate reporting as part of the validation process, recognizing its critical role. These include the following:

- The validity of reports: the notion that reports deserve their own validity arguments (Hattie, 2010);
- User validity: the perspective that the conceptualization of validity from the AERA et al. (2014) *Standards* should be expanded to include a user-centered source of evidence based on the accuracy and effectiveness of interpretations based on test output (MacIver et al., 2014);
- Report interpretability: the view that the interpretability of reports should be considered an aspect of validity (Van der Kleij et al., 2014); and
- IUA source materials: the view that reports and other technical documentation of tests are source material for the IUA for an assessment (Ferrara & Lai, 2016).

O’Leary et al. (2017) expanded on those ideas, proposing an approach that aligns with the unified conceptualization of validity (Messick, 1989). Instead of discussing new types of validity, O’Leary et al. (2017) recommended expanding the five sources of validity evidence—content, response processes, internal structure, relations to other variables, and consequences—to include interpretability: evidence focusing on the “adequacy, accuracy, and effectiveness of user understanding of scores and the consequences of testing” (p. 20). Further, they proposed that evidence based on interpretability and evidence based on consequences be treated as having equal importance as

the four other sources, which traditionally have only yielded evidence in support of possible interpretations.

Alternatively, the five current sources of validity evidence could be adapted to encompass results reports more explicitly. Tannenbaum (2019) provided several ideas of how this might happen. Evidence based on test content, which is usually about the relationship between the content of the test and its target construct, could also include evidence that the content of the report is well aligned with the content of the test. Evidence based on response processes, which focuses on how well the test elicits the strategies or cognitive processes that are key to the construct, could incorporate evidence that users visually navigate the report as intended, spending more time on the areas the design of the report was meant to highlight.

Evidence based on internal structure is typically about how well the relationship among items or portions of a test reflect its target construct and the extent to which those relationships stay consistent across subgroups of test takers. When applied to reporting, this source could involve gathering evidence of how well report users understand the ways in which different parts of the report relate to one another (e.g., how a sentence about precision should inform conclusions based on a graph with content area results). It would also be relevant to evaluate how different groups within the target audience interpret and use the information reported (e.g., groups from different socioeconomic backgrounds, test takers scoring below and above a passing score).

Gathering evidence based on relations to other variables in the context of evaluating results reports is more complex. Traditionally, this type of evidence comes from analyzing the relation between test scores and other measures. To evaluate reports, Tannenbaum (2019) suggested investigating the match between students' competency as communicated on their score report and as evaluated by teachers, noting that convergence would be confirmatory evidence and discrepancy would be more challenging to interpret (it could reflect differences in what was tested compared to what teachers considered in their evaluation).

Finally, validity evidence based on consequences of testing has a strong connection to reporting. The interpretations individuals make and any actions they take in response to results reports are a direct consequence of testing. So are potential misinterpretations, inaction, and undesired actions. This type of evidence, which could employ multiple methods, should shed light on the extent to which reports are interpreted and used as intended based on reasonable expectations or the IUA for a test.

Whether testing organizations plan test development and validity research in alignment with the argument-based approach to validity or a framework such as principled assessment design, described next, effective reporting should be treated as essential to validity and given due consideration.

Reporting and Principled Assessment Design

Principled assessment design (PAD) refers to several approaches, including evidence-centered design (Mislevy & Haertel, 2006) and assessment engineering

(Luecht, 2013), intended to offer a more integrated pathway for designing or improving assessments and building validity arguments. Huff et al. (this volume) offer a comprehensive overview of the framework, detailing how—in contrast to more conventional methods that may lead to siloed activities—it employs strategies to ensure coherence “from construct definition through task development and score inference” (p. 447).

Both PAD and the argument-based approach to validity reflected in the AERA et al. (2014) *Standards* rely on the explicit articulation of ideas to guide the design and validation process. However, while the argument-based approach calls for the articulation of proposed interpretations and uses of assessment results (along with their rationales), PAD requires integrated documentation and articulation of the assumptions and decisions related to *all* aspects of test design and validity research. This focus on approaching the assessment cycle in a more unified way is ideal for reporting work, which in the past seemed to be treated as an afterthought in the test design process (Katz, 2019).

PAD is a promising framework to help those involved in test development meet present-day challenges, including greater distrust and scrutiny of assessments and the increasingly common expectation that one assessment may serve multiple purposes (Huff et al., this volume). In practice, approaching results reporting in the context of PAD may take many forms. It may involve creating a prospective score report early on to promote discussions about what information the assessment should provide (Slater et al., 2019; Zapata-Rivera et al., 2012), using the prospective score report to clarify the claims to be made about test takers (Zieky, 2014), and changing test design specifications to align with the desire to report specific information, such as subscores (Sinharay et al., 2019).

What is common across these examples, and central to PAD, is the idea that reporting considerations are a key component of assessment design—not a step to be taken when other important test design decisions are already finalized. In such an unfortunate scenario, the report must conform to those established test design decisions, which may not be aligned with the information needs of report users. PAD offers an approach for considering test content, format, and reporting in tandem, making it more likely that results reports will be effective in promoting validated inferences. This idea of articulating reports and their purposes in advance might be viewed as backward design, in the sense of starting with the product and working through the process early on to get to that place in the end, but such an approach is quite forward thinking and in effect prioritizes understanding and actions associated with reports before it is too late to change course.

Reports as Data Stories

One of the ways of making statistical results more meaningful to intended audiences is to report the results by connecting them to numbers that may be better understood than test scores and test score scales. For example, to relieve the concern many persons had about flying after the TWA crash a few years ago,

the airlines reported that there is a single plane crash every 2,000,000 flights. In case the safety of air travel was still not clear, the airlines reported that a person could expect to fly every day for the next 700 years without an accident. Probably some people felt more confident after hearing these statistics reported in this way. Knowing that the probability of being in a plane crash is less than .0000005 may not be so meaningful. (Hambleton, 2002, p. 194)

Building on the approaches to validity and PAD referenced here, a key idea to raise at this point is that of the *data story*, where results reporting can be conceptualized as a coherent and planned approach to communication about assessment data, rooted not only in the validity of the inferences being made but also in the validity of the communication about the data. Data story is a term that has emerged from business and marketing settings in recent years to describe a highly coordinated strategy for talking about data in various nonassessment contexts, but, given the nature of data in reporting, there is a natural relevance to this topic in educational and psychological testing. The basic concept of a data story is that it is a thoughtful and intentional approach to sharing data that brings together data visualizations and compelling narratives, targeted to specific audiences, that aims to help intended users of the data understand the data and take action where appropriate (Hooper, 2021). It is not simply a matter of better (or different) graphics, but rather an orientation on the part of report developers to identify a story to be told with data and then use tools such as visualizations and one or more narrative patterns to explain something about the data (and why the data matters), in the context of a specific vehicle for communication (e.g., a results report, a presentation, or an online reporting tool).

Bach et al. (2018) defined a narrative—in this data story context—as giving shape to the *events* in a data story, following a specific narrative pattern. The pattern(s) that underlie any data story can vary from context to context, and the choices made are predicated on a narrative's intent. Narrative intent is an important idea here, in that it reinforces the purpose of the communication effort and can be linked to the context of assessment through articulation of both (a) test purpose and (b) report purpose. Examples of intents that might underlie data stories from the data story literature could include enlightening audiences, evoking emotional responses, spurring action, and questioning beliefs and behaviors. It is not hard to move from these general intentions to the aims of results reporting with respect to these intents.

To select and use any narrative pattern, the author must have a story idea, an idea of the intended audience, and an intended effect such as sympathy, action, information, or explanation (Bach et al., 2018). Conceptually, this links quite closely to the layers of reporting put forth by Behrens et al. (2013), in which three layers of reporting were articulated. Layer 1 corresponds to information communication (in effect, the “what” of reporting, asking, What is the story to be told?), while Layer 2 is couched in social activity (How are people approaching the story and who is the audience for the story?). The third layer of Behrens et al.'s (2013) approach aligns to societal transformation

(asking, What is the moral of the story?)—in effect, the intended outcome, or the *why* of the act of data communication.

Drawing on visualization and data story work, as well as arts and literature, there are several ways to think about narrative patterns. One overarching narrative strategy that has been identified in this area is explanatory versus exploratory orientations (Thudt et al., 2018). This has been discussed in the context of results reporting by Zenisky and Hambleton (2012b) relative to digital reporting efforts. Explanatory reporting efforts are predicated on the report developer's conscious and explicit choices about content, appearance, and interpretation support, while exploratory efforts typically align to interactive tools that offer users flexibility and personalization of the experience of the data story. Most traditional results reports in use for educational assessments in the early 21st century follow the explanatory narrative strategy, while publicly available anonymized databases on state websites draw on the exploratory model, with drop-downs and selection boxes that allow for customization.

Another narrative pattern to consider in the context of reporting involves prediction and how users might be presented with formative results to guide future action. Prediction, as a reporting aim, draws on the past to identify next steps. Thus, reports that address this aim may use data that might be presented in a static way using an explanatory strategy to set the stage for the results and include an exploratory component that offers the user the opportunity to navigate through to identify areas of strength and weakness and connect the results to specific actions.

At a similarly straightforward level, another approach to narrative patterns is to think of some narratives as linear (following a highly temporal or sequential route, such as the Harry Potter books tracing Harry's path from preadolescence to adulthood in the wizarding world) while others are nonlinear (such as the television show *Lost*, with the story told using flashforwards, flashbacks, and even sideways/parallel paths; or *The Godfather Part II* film, which juxtaposed events in the lives of the Corleone patriarch and his son to unfold both stories semisimultaneously). In the context of results reports, the analogue to a linear narrative pattern is the body of work that is produced to communicate the long-term trend results for NAEP (National Center for Educational Statistics, 2013). The overarching data story in long-term trend results is based on data that are linear in nature, with many visualizations used that aim to illustrate the performance of test takers over time.

Exploratory or explanatory and linear or nonlinear are not, however, the only narrative patterns that can be used for data stories. Bach et al. (2018) identified five different groupings of narrative patterns based on broad intent. These groupings are provided in Figure 13.6.

In reflecting on these groupings and the specific patterns within each one, it is important to note that any data story may well use more than one of these techniques to accomplish different intentions within the same document. For example, on a typical individual student results report for K–12 assessment in the United States, narrative patterns that can be spotted relatively quickly might include familiarization

Patterns for argumentation

These serve the intent of persuading and convincing the audience. Examples of these patterns are compare, concretize, and repetition.

Patterns for flow

These patterns serve the intent of structuring a sequence of a message or argument, setting the order, rhythm, and pace of the story. Examples here are reveal, slowing down, and speeding up.

Patterns for framing the narrative

Patterns here serve the intent of controlling how facts and data are perceived and understood. Examples of framing narrative patterns are familiar setting, make-a-guess, defamiliarization to challenge expectations/convention breaking, silent data, and physical metaphors.

Patterns for empathy and emotion

These serve to engage the audience with the content of the data story. There are overlapping narrative patterns here (reveal, slowing down, speedup, and concretize). There are also some novel patterns as well, such as breaking the fourth wall, humans behind the dots, and familiarize.

Patterns for engagement

This category serves the intent of connecting the audience with a story, to make them feel part of it and perhaps even offer them some control. Specific tracks that can be taken here include the use of rhetorical questions, call-to-action, make-a-guess, and exploration.

FIGURE 13.6

Narrative Patterns for Reporting Data Stories

Note. Adapted from “Narrative Design Patterns for Data-Driven Storytelling,” by B. Bach, D. Stefaner, J. Boy, S. Drucker, L. Bartram, J. Wood, P. Ciuccarelli, Y. Engelhardt, U. Köppen, and B. Tversky, 2018, in N. Riche, C. Hurter, N. Diakopoulos, and S. Carpendale (Eds.), *Data-Driven Storytelling* (pp. 107–133). CRC Press. <https://doi.org/10.1201/9781315281575-5>

(using the student’s name in personalizing the report), compare (to compare the student’s observed score to a class, school, district, and state), and physical metaphors (with stoplight displays or pie charts to illustrate mastery of subdomain skills). This is quite common: Bach et al. (2018) commented on a number of use cases where multiple narrative patterns are used in data stories, pulling examples from different media sources.

The literature on results reporting itself offers a number of additional narrative patterns. One such approach is *question and answer*, where the flow of the report document is sectioned by a series of questions formulated by the report authors to reflect common questions from intended users, with answers provided. Another approach is reflected in the traditional individual results report that presents a high-level overall result, followed by a progressive “drill-down” to more granular series of data points. In this case, the pattern of the data story moves in a linear fashion on the basis of the granularity of the data (from least to most), typically drawing in some comparisons and making some inferences highly concrete. The report might then conclude with a call to action (in a section entitled “Next Steps”). Figure 13.7 highlights the narrative patterns used in the sample report presented at the beginning of the chapter.

Empathy: Familiarize
Introducing the test and learning standards in the context of Alex's education, making them more relevant and relatable

Flow: Repetition
Using repetition to emphasize Alex's overall score

Argumentation: Compare
Showing Alex's performance in relation to three groups, reinforcing the overall result

Argumentation: Concretize
Showing both the score scale and Alex's score graphically, making them more meaningful

Flow: Reveal
Throughout the report, presenting information gradually (from broader to more specific) for better flow

Framing the Narrative: Convention Breaking
Adding a "warning" symbol to the Below Mastery result, drawing attention to it

Engagement: Call to action
Explicitly referring to "next steps" to promote action

Engagement: Rhetorical Questions
Posting and addressing questions that report users might have about the results

FIGURE 13.7
Simplified Sample Report With Annotations Highlighting Narrative Patterns

Hattie's (2010) work on the validity of reports likewise offered some guidance that aligns well with the idea of results reports as data stories. Principle 3 ("Readers of reports need a guarantee of safe passage") and Principle 4 ("Readers of reports need a guarantee of destination recovery") align to the underlying concepts of Bach et al.'s (2018) patterns for flow. Principle 5 ("Maximize interpretations and minimize the use of numbers") is a way into patterns for argumentation, and critically, Principle 8 ("Each report needs to have a theme") brings us full circle on the very idea of data stories and intent: defining the aim of the report and articulating the structural and communication techniques that can be employed to achieve the intent of a specific data story, for specific user groups.

The value of the data story and narrative pattern framework lies in the premise that reporting in educational and psychological testing is an intentional act of communication about data, and the approaches to conceptualizing and organizing the stories discussed here, drawn from outside measurement, have significant interdisciplinary value. Across assessment contexts and reporting settings, there are many data stories to be told (at both individual and group reporting levels) and many ways to accomplish the communication of assessment data. Under this paradigm, report developers must look at the data story of the report as a coherent whole, as well as how distinct report elements contribute to the story in a purposeful and organized way.

ESTABLISHING REPORTS, REPORTING SYSTEMS, AND REPORTING CONTEXTS

There is no one-size-fits-all design for what constitutes a "good" score report. Tests and test purposes are different, and users' data needs vary. No one magical visual display will make test results understandable to all users, and—sadly—there

is no one perfect line of text that illuminates what standard errors are and why they matter. (Zenisky & Hambleton, 2015, p. 586)

In considering the breadth and depth of what reporting is more fully, it may be helpful to extend the metaphor of the data story to assist in defining critical reporting dimensions and aspects. Specifically, the questions of *who*, *what*, *where*, *when*, *why*, and *how*, long associated with journalism, can serve as something of an organizing framework for conceptualizing and disseminating results reports broadly in the context of assessment, in line with the data story metaphor.

Who?

The first of these organizing questions is *who*. In results reporting, there are in effect two very significant ways to address this fundamental point in report development. One of these involves the subject(s) of the report, in terms of whose results are being reported. Quite simply, a report can be crafted to describe the performance of one (a single individual) or many (more than one). From the perspective of developing a report, this first aspect of *who* concerns the unit of analysis for the report—individuals or groups (and how group membership is operationalized for the purpose of the report).

From that natural division arises the second way to address the *who* of reporting, which is the intended user. Reports are developed to describe the performance of an individual or a group on a specific assessment, and building on that, individual and group reports are typically developed for different intended audiences (to fulfill different reporting aims—the *why* of reporting).

The most detailed reports for individual test takers are typically disseminated to the test takers themselves and, depending on the testing context, others close to them in the social space, such as family members and educators. Indeed, reports for individuals are typically more relevant for test takers and their own families and for the test takers' instructors. In the context of credentialing, individual reports are provided to the test takers themselves, and the considerations of reporting are differently nuanced between the personal and the professional uses (O'Donnell & Sireci, 2019).

As the social distance from the test taker grows, the nature of the substantial detail around the performance of the individual can change. In the example of certification and licensure, individual results at the global level of pass or fail may be transmitted to a local or national governing body for record keeping and maintenance of professional standards, but the focus in this group-level report to this user group is not instructional or formative, and as such, subdomain results or other score breakdowns may not be of primary interest for these particular users. (Detailed results exploring comparisons between test-taker subgroups will be of interest, but such data are typically summarized and anonymized for governing body uses [record keeping, monitoring, and public communication].)

To that end, results for groups of test takers can be constructed to reflect groups of hyperlocal interest (such as a class, grade level, or school) all the way to aggregations

for national and/or international comparisons. School and district personnel may use group-level reports to identify academic strengths and weaknesses within classes, schools, and districts, and at the larger scale (such as states) statistical power can be used to help identify broader trends in student performance over time (Zenisky & Hambleton, 2015). Reporting units of interest can be based on geography (such as class, school, district, state) or other relevant demographic variables (e.g., race/ethnicity, language status, individualized educational plan status). Thus, results reports for groups can be reported on the basis of groupings constructed to reflect geography, demographics, and/or other dimensions of interest. The users of various group reports can be close (as in educators and coaches) or more removed (such as policy makers, the general public, and the media). The more removed such users are, the larger the aggregation (typically), and the purpose becomes more policy oriented in nature.

Though sometimes it is the individual score report that garners much of the interest in terms of reporting research, a great deal of foundational work on reports and reporting quality occurred within the context of evaluating NAEP group-level results (Zenisky et al., 2016), where research focused on interpretation of the reporting scale (Beaton & Allen, 1992; Hambleton, 1998, 2002; Hambleton & Meara, 2000). Other work prioritized audience-specific differentiation (Forte Fast & Tucker, 2001; Jaeger, 2003; Levine et al., 1998; Simmons & Mwalimu, 2000), displays for state results and other subgroups (Hambleton & Slater, 1997), market-basket reporting (Mislevy, 1998; National Research Council, 2001), and digital reporting strategies (Zenisky & Hambleton, 2007; Zenisky et al., 2009). All of these efforts have contributed in significant ways to the present understanding of report development processes and report evaluation procedures.

What?

Test scores are elusive. Even the popular percent score scale that many persons think they understand cannot be understood unless (1) the domain of content to which the percent scores are referenced is clear and (2) the method used for selecting assessment items is known. (Hambleton, 2002, p. 194)

The *what* of reporting, naturally, is about the contents of reports. Fundamentally, this is a question about data and what data elements are being communicated. It is a broad question, not only incorporating the specific results reported but also encompassing the presentation and interpretation supports (text and visual design) that play a critical role in shaping how results are communicated via reports.

As an activity that occurs part and parcel in the progression of test development, reporting encompasses the process by which data about human knowledge and skill (as measured by an instrument of some kind) are conveyed to intended users (Zenisky, 2015). In this way, the answer to the *what* of reporting is not simply a matter of scale scores, performance levels, and average scores for reference groups, but rather can perhaps be better thought of as a reflection on the key components of a report, in the sequence of the data story, referenced earlier.

In any data story, context is important, and a first way to address *what* in reporting involves the larger backdrop of the assessment context and what information broadly matters given the assessment being reported. For the purpose of results reporting, there are several key settings for reporting that are directly relevant, as previously presented in Figure 13.4: educational testing (summative and formative), workplace testing and credentialing, and psychological assessment. Each of these types of assessments accomplishes different measurement goals, and accordingly, the reports for each vary significantly in terms of their content because the underlying data and use for each differs from one another, in important and meaningful ways.

Reporting is not just about scores and data, but rather begins conceptually with information and communication. Whether the aim is content knowledge at an endpoint or at places along an educational path, demonstration of mastery to enter a profession, or an indicator of status relative to a psychological construct, these conceptualizations help to focus the reporting activity and ultimately the report product that is composed of scores and other results.

Some of these types of reports serve primarily to report an informational purpose, while others are developed with the intent to guide specific actions, and importantly, this often connects back to the purpose of an assessment. For many summative assessments in the educational context, the main reporting aim is status, and that is therefore reflected in the statement of purpose, though there may be a secondary nod to next steps in the statement of report purpose and in the report itself. In certification and licensure, the assessment purpose is to determine qualification to hold a specific credential, so reporting there prioritizes that information, though an exception here can be for failing candidates. At the discretion of a testing agency, candidates who do not pass may receive some guidance about relative strengths and weaknesses, from which the candidates can infer what might be valuable to focus on during future test preparation efforts. Formative assessment, as well as diagnostic assessment, both function at something of a crossroads in this regard. The typical aim of formative and diagnostic assessments is to inform instruction and identify areas of need, so while the reports contain information and the user of the report may or may not act on that information, the intent of the report is to provide actionable next steps. In this respect, the extent to which the aim of a report is fulfilled is up to the user.

To that end, briefly, a typical report begins with introductory content of some kind, to set the stage for the data being communicated. The nature of this introductory content may vary considerably, from individual reports to group reports, and depending on the audience. It may be as simple as a title that is descriptive of the results and some method of documenting whose results are contained within the report (as in the name of a specific individual or the parameters for inclusion in a group report, relative to geography, demographics, or other considerations). Some individual reports will go further in this regard, however, with text that describes the purpose of the assessment as well as the purpose of the report.

Another dimension of introductory content may include a statement to the effect of what is assessed, aligned to the purpose of the assessment. This should offer some broad contextual information as to the nature of test content and what is assessed. As reported by Zenisky and Hambleton (2015), a noninclusive list of examples of the descriptive elements of reports may include information such as:

- test name and/or test logo
- test date
- report title
- report purpose
- test purpose
- introductory statement from testing agency or governing body personnel
- individual reports: header space with identifying details such as name, address/school, group membership or status (individualized education plan, language, etc.)
- group reports: header space with identifying details for reported group(s) including demographic, geographical, and/or other grouping variable specifications
- details for external links to additional resources, such as curriculum materials and interpretive guides
- information about the location of frequently asked questions documents or other resources for score inquiries
- guidance on test score use/links to interpretive guidance
- glossaries of terms

The next section of most score reports is the high-level, overall, or primary results. On an individual results report, most agencies provide the overall scale score and—where appropriate—the performance level associated with that score. The formatting of these results can vary considerably, where different agencies may use different visual strategies to communicate the overall results data for one or more content areas, such as typography and font size, but also tables, bar graphs, and/or line graphs. For group reports, the overall data may be presented in a summary form, using a table or a graphic structure to communicate specific points about the data. The high-level results, whether on an individual or a group report, in the general case typically provide the results that align best to the primary purpose of the assessment. Below is a nonexhaustive list of types of scores that can serve as the basis of the scores reported (Zenisky & Hambleton, 2015). Some of these types of scores are more common in some testing applications than others:

- raw scores
- scale scores
- percentage correct
- percentiles
- stanines

- grade equivalent
- *T* scores
- performance classifications (e.g., *Advanced*, *Proficient*, *Basic*, and *Below Basic*)
- subtest or subdomain scores
- item-level scores
- student score growth

As part of the overall results, many individual reports will include additional contextual data in the form of comparisons to relevant reference groups. For educational tests, this typically means that the results for the individual student of interest may be presented alongside average scale score results for similar test takers in relevant geographic units (class, grade, city, state, country) or demographic groupings. Though many tests in the early 21st century are criterion-referenced and the primary interpretation advanced by agencies is performance relative to standards or benchmarks, these pseudo-norm-referenced comparisons are common, and often even expected. Many report users desire information about how the subject of an individual report is doing relative to others, even if little or no data about the distribution of performance are provided. It should be noted that in recent years, educational assessments have moved away from norm-referenced to criterion-referenced tests, but some form of normative data as described here is still present on many results reports. A number of examples of individual student reports can be found on the current websites for U.S. state education departments, as well as within Goodman and Hambleton's (2004) paper.

The next section(s) of many reports offer finer grained results. It is in this section of reports that, when these data are provided, report users begin to understand their performance on a test and why they achieved the score or result that they did. These finer grained results are what users look to in order to improve. The typical format of these results is the presentation of subscores, but this is a challenging topic for psychometrics because of the issues of dimensionality and the reliability of subscores and similar subdomain-level results. Most summative assessments are simply not built to offer high levels of reliability at the subdomain level, because they are intended to offer reliable results at the overall level given their articulated testing purpose and do not contain sufficient items to attain psychometric reliability for subsets of items. This is an active area of psychometric research (see Sinharay et al., 2019, for a thorough review of the considerations and issues), but a few recommendations from Sinharay et al. (2019) include the following:

- When possible, approaches such as evidence-centered design or assessment engineering are preferable where subscores are to be reported to address issues around the relative distinctiveness of the subscores since they conceptually support differentiation, because content blueprints alone may not avoid high correlations among subscores (Sinharay et al., 2007);
- Reported subscores should exhibit psychometric properties of adequate, reliability, validity, and distinctiveness;

- Agencies may wish to consider using weighted averages or augmented subscores for diagnostic purposes, rather than subscores to address the quality considerations of reliability, validity, and distinctiveness;
- When sufficient items are present for subscore reporting, subscores can be reported on the scale score metric for a test, and subscores can be equated so that interpretation of subscores can be interpreted and used consistently over forms;
- The quality of subscores aggregate over test takers can be useful but should be evaluated for indicators of quality (reliability, validity, and distinctiveness); and,
- The expectations around subscore quality for large-scale summative assessments can and should be applied for formative assessments.

It should be noted that many reports do include some form of subscore or subdomain results to provide a minimum of guidance for test takers, particularly those who obtained lower scores and who may seek information on how to improve. An additional set of recommendations around making choices as to which subscores to use and when from Sinharay et al. (2019) are as follows:

- Reporting of observed subscores may be reasonable if the subscore is reliable and dimensionally distinct.
- If evidence for subscores does not support their reliability and distinctiveness, then no amount of statistical adjustment can address fundamental limitations of the scores, and thus reporting of subscores cannot be justified.
- If subscores are moderately reliable and moderately correlated, then statistical adjustment may help.

Whereas simple subscores are easy to compute and are easily understood, Sinharay et al. (2019) do provide a comprehensive list of techniques to compute and adjust subscores, as referenced above, which can be drawn on to address the unreliability and lack of distinctiveness problems. These include augmented subscores and weighted averages, Yen's Objective Performance Index (Yen, 1987), the use of cognitive diagnostic models, multidimensional item response theory (IRT) models, and scale anchoring (Beaton & Allen, 1992). It is also certain that as data mining and data analytics work advances, so too may new methods for subscore reporting emerge.

Clearly, this topic, as an issue of psychometrics and operational practice, is not a settled matter. Large-scale assessments rarely, if ever, meet the numbers of items needed to obtain high values of traditional reliability in subscore reporting. For example, Sinharay et al. (2019) suggested that a threshold of 0.8 for reliability (based on Nunnally, 1978) is reasonable, and to get there might require 20 items. This raises philosophical issues of (a) what constitutes quality in subscores (when viewed through the lenses of reliability, validity, and distinctiveness and how those are defined) and (b) potential for harm (what are the consequences of reporting subscores that do not meet such thresholds/definitions of quality?).

Detouring briefly to group-level reports, formats typically include list-style reports of individual performance or reports that highlight summative statistics that describe

performance in aggregate. It is important to note that as a matter of good practices, the *Standards* (AERA et al., 2014) do suggest that contextual information is critical for reporting on groups, especially when reporting on group differences. For example, Standard 12.17 suggests that reports should include relevant contextual information to support meaningful and appropriate interpretations. Noted here as well is a hybrid approach to group reporting when such results are accessed online. Often such reports are targeted to instructional users and mix levels of aggregation. For example, a class-level report for a teacher may have class-level aggregated results but also display a roster-type view. In that roster view, a teacher might want to carry out certain functions, such as sorting a student list according to performance on the assessment, or click on individual student names and see more detailed individual results. The final section of a report often includes some kind of concluding information and/or guidance for next steps. Once a recipient of a report has that report in hand (physically or viewing onscreen), many reports conclude with a brief section on what might be next for the user, particularly in the context of the individual reporting. Such report sections might offer some kind of summary about performance and links to various types of resources available locally or online. The idea is that once the report document has provided some information about the performance of a test taker, the stakeholder may, for example, want to find out more about the test and use the overall and subdomain results to collaborate and develop a plan for next steps and potential improvement. Similarly, this concluding section of reports might also have links to other external documents, such as frequently asked questions where stakeholders can access additional information. Whatever such documentation is linked to from a report, whether it be lesson plans, other instructional materials, or guidance of an administrative or informational nature, it should be noted that it is incumbent on the report agency that is promoting those materials—by means of such links—to articulate the purpose of such materials; establish standards for their quality, accessibility, and usability; and provide users with logical connections to align results with provided materials, where appropriate.

Concentric Circles of Results

One visual way to consider the *who* and *what* of reports, spanning the range of individual and group reporting efforts previously discussed, is shown in Figure 13.8. This idea of the concentric circles of interest in assessment results emerges from the audience-specific considerations and research road map illustrated in Figure 13.3, and as such, Figure 13.8 further provides a general framework for thinking about the progression of audience and results. It is important to understand that not all circles of interest are necessarily applicable for all tests. Beginning at the center of Figure 13.8, the results reported are at the most local and personal level—the individual test taker. A report at that level is crafted with the test taker as the reporting unit of interest, developed for the test taker (and perhaps their family, depending on testing context), and the report contents are scores and other forms of results, often linked to targeted or specific next steps of some kind. Moving outward, the next circle of results is intended at the level of

Who?

FIGURE 13.8
Concentric Circles of Interest in Assessment Results

teachers and instructors. Results at this level are still fairly local and focused on the individual, but also start to include relatively small but meaningful groupings (meaningful as defined by the user) given uses appropriate to that teacher/instructor role.

The next level of the concentric circles in Figure 13.8 is that of a progressively more general level of results, where results are communicated at the level of educational and training institutions. Here, the specific nature of individual results, and breakdowns of individual results, are typically far less consequential than a view of the results as data in aggregate to carry out goals such as review, planning, and evaluation. At this level, the performance of groups of test takers is typically analyzed and actions are identified based on the results.

Beyond that, moving further outward is the governmental and regulatory space for reporting, where individuals primarily matter for the (necessary and important) purpose of issuance of credentials. More of the results of interest at this level are for groups, with the assessment data fulfilling an informational/status purpose. Very little at this level is fine grained—the focus is on overall performance classifications for individuals and groups. The final, outer circle of interest is the public-facing side of assessment. This is the level of the kinds of databases and analysis tools such as the Data Explorers of TIMSS, PISA, PIRLS, and NAEP. Assessment results are completely scrubbed of personal identifiers and reporting is only at an aggregate level, with sample size suppression rules or bootstrap sampling methods used to shield the identification of individuals.

The overarching idea of these concentric circles is to encourage researchers and report developers to think about reporting efforts as a progression in communication. Reporting, for many tests, begins with the test taker and extends outward to other stakeholders. The nature of the results of interest necessarily change as stakeholders change, because the *use* of the results is different at each level.

Where?

When applied to results reporting, the question of *where* can be applied to format, as in, “Where are the results?” For many test takers, their results are detailed in the individual report, which is crafted to provide individual-level results in a highly structured way. Typically, such reports are static in the sense that whether disseminated on paper or onscreen via email or a secure portal, they are delivered as tightly arranged documents, with a specific sequence of results and information for every test taker, following the issuing agency’s template for the data story of interest. Rarely are individual reports for large-scale summative assessments marked by any measure of user choice in content or appearance; that is increasingly common for formative assessments.

This stands in contrast to group-level results: Though historically group reporting has filled volumes of expansive reports (e.g., the “Publications and Products” library of NAEP, <https://nces.ed.gov/pubsearch/getpubcats.asp?sid=031>), in recent years online tools for group reporting have proliferated (e.g., the NAEP Data Explorer, <https://www.nationsreportcard.gov/ndecore/>). In the former case, prospective users of the information obtain PDFs of static, large-scale results written by issuing agencies for reading and reviewing, while in the latter case, the users are in the position of exploring the data within the parameters of the publicly available tools, to answer their own questions about the data by, for example, selecting who is included, what results are of interest, and how those results are displayed (Zenisky & Hambleton, 2012b).

Interactive group-level reporting tools such as the NAEP Data Explorer and the International Data Explorer (<http://nces.ed.gov/surveys/international/ide/>) offer unprecedented customization, placing users in charge of pursuing their own data stories. This shift in how the reported narrative is constructed can be useful and empowering, especially to data-savvy users. That said, it can also be overwhelming and pose challenges to promoting appropriate interpretations of results. Those involved in developing online reporting tools should use tutorials and design elements to guide users and restrict access to unreasonable variable selections or analyses. Other strategies in this regard might include establishing a process for receiving and responding to inquiries, displaying data in multiple formats to support different processing preferences, and using a streamlined interface to the extent possible (Zenisky & Hambleton, 2007, 2012b).

One type of reporting tool that has been gaining traction is dashboards: highly visual interfaces that provide at-a-glance views of key information, often with some interactive features. Most dashboards currently available summarize learning analytics data for teachers (i.e., metrics of student progress and engagement, like time spent on online activities, grades, and number of outputs, such as discussion posts), but a growing

number are designed specifically for students (Schwendimann et al., 2017). The use of dashboards for reporting is variable: While some groups have been using them for many years (Brown, 2001), others have been more recently deployed in educational settings, as data mining, data visualization, and web-based tools have emerged in various disciplines to fulfill visual and functional aims in terms of data communication (Sarikaya et al., 2019).

There is growing research on ways to leverage learning analytics and the interactivity of dashboards to provide more customized results and recommendations (Verbert et al., 2013). Within the context of a formative assessment integrated with instructions such as Brightpath (<https://www.brightpath.com.au/formative-writing-assessments/>), users can interact with dashboards that connect information to specific next steps with real-time updating of student performance and even teacher evaluations. Another interesting application for dashboards is the use of open learner models, which are visual representations of what a student knows, as well as areas of difficulty that can be updated dynamically as more data become available (Bodily et al., 2018; Kay, 1997; Zapata-Rivera, 2021). For instance, a student receiving a static Grade 7 mathematics report may see that “understanding statistical variability” is an area for improvement and make a mental note of this result. In contrast, a student accessing a dashboard with an open learner model showing the same result could interact with the model by opting to answer additional questions to support their learning and, in turn, update their status on that content area (this interactivity is what makes the model open).

As a specific format within the realm of results reporting, with additional research dashboards can become a popular alternative or complement to static reports as consumer-facing, web-based applications with powerful data aggregation features that offer real-time indicators. Consider, for instance, the dashboards from exercise- and sleep-tracking apps accessed daily by millions of smartphone users, to obtain at-a-glance reporting of quantitative measures of health up to the minute of checking (e.g., steps taken, hours slept, heart rate). A key feature of dashboards, then, is this idea of real-time reporting, and in that respect data dashboards are perhaps best suited for use in results reporting contexts aligned with formative or diagnostic initiatives that update regularly and relatively frequently.

Since dashboards for assessment results offer a middle ground between static reports and highly customizable reporting tools and serve to meet a specific real-time reporting goal, it is important to determine which elements should be interactive and which should not, and this should align with the goals of the assessment program. Developers should also consider general guidelines from the dashboard literature, such as using customization to promote a sense of empowerment and agency (e.g., allowing students to set their own performance targets and to decide what normative information they want to see, if any), designing each element to inform a particular decision or set of decisions (e.g., ensuring each dashboard section has a purpose, such as deciding which content areas warrant additional review), and using multiple visualization approaches

(e.g., color, spatial position, and motion) to support rapid perception (Bennett & Foley, 2019; Few, 2006; Park & Jo, 2019). Last, those involved in creating dashboards may adapt recommendations and approaches from the results reporting literature, combining insights from broader dashboard research with specific guidelines for reporting assessment results (Corrin et al., 2019; Kannan & Zapata-Rivera, 2022; O'Donnell et al., 2021).

When?

In the terms of the data story, the *when* of results reporting is a fairly straightforward matter of now or later. Now, in this sense, is immediately at the conclusion of test administration. With the widespread use of computerized administration, testing agencies can provide test takers with their results before they leave their seat, displayed onscreen, and/or with a report of scores emailed to them, provided that the necessary scoring procedures and quality control checks are done in those brief moments. The “later” of score reporting can range from a few days to a few months because agencies may need time to score and verify performance. In large-scale summative educational testing in the United States, for example, it is not uncommon for results to be made available to districts after 2 to 3 months and perhaps take an additional 2 months to be distributed to the students themselves.

The dimension of *when* in reporting varies considerably depending on testing context. In credentialing, the results for a clear majority of tests are reported relatively quickly, where candidates receive their scores immediately or very shortly after the test session, and results are likewise seamlessly transmitted to certification and licensure bodies. In education, formative tests tend to report scores quickly, but as described, summative test reporting tends to take a great deal longer. The time-consuming nature of scoring (and, hence, delays in reporting) can be attributed to a few causes, such as the need to human score certain item types, to perform psychometric analyses, and to do other quality checks on the items and the scores, but such delays in reporting results are also a relative impediment to the use of scores (Brown et al., 2019). Per the *Standards* (Standard 8.8), the professional guidance around the *when* of testing indicates that results should be provided in a “timely” manner, but what constitutes timely may be a matter of debate and can be viewed in light of official test purposes. In some testing contexts, reports of results are expected and used quickly (such as entry into a profession), and in other contexts, longer intervals between testing and reporting may be more tolerated.

Why?

Arguably, the most interesting question of the data story metaphor as applied to results reporting is *why*. In the *Standards* (AERA et al., 2014), Standard 5.1 speaks to the fundamental requirement that test users should be provided with clear expectations of the characteristics, meaning, and intended interpretations of scores, but it falls to two other standards (8.8 and 9.16) to establish the underlying expectation that scores themselves are reported, particularly with respect to test takers.

Standard 8.8: When test scores are used to make decisions about a test taker or to make recommendations to a test taker or a third party, the test taker should have timely access to a copy of any report of test scores and test interpretation, unless that right has been waived explicitly in the test taker's informed consent document or implicitly through the application procedure in education, credentialing, or employment testing or is prohibited by law or court order. (p. 136)

Standard 9.16: Unless circumstances clearly require that test results be withheld, a test user is obligated to provide a timely report of the results to a test taker and others entitled to receive this information. (p. 146)

These two standards set a baseline for reporting to test takers, conditional on use (per Standard 8.8) and circumstances (Standard 9.16). If scores have implications for an individual, then individuals must be provided with their results report in a timely manner. Taking Standards 8.8 and 9.16 along with Standard 5.1 (described previously), it is clear that when scores matter, they must be provided along with guidance around interpretation and use.

However, the process of reporting results happens in line with test purposes (e.g., educational summative, educational formative, credentialing, admissions, psychological). This is an important point to maintain in the conceptualization and development of results reports for various intended audiences. Often, the *use* of scores falls to entities other than the test taker, and accordingly the nature of the report sent to those external entities hinges on what they plan to do with the data. In many—not all, but many—settings, reporting to the actual test takers simply involves a report that is informational in nature, and use is left to others. To this end, in those cases, the *why* of reporting depends on the intended user (the *who*). In effect, reporting to test takers in many cases fulfills the question of *why* with an informational aim, rather than an actionable use by the test taker. Then, for other, external audiences, the *why* of reporting is generally more aligned to the fundamental purpose of the test (to demonstrate competence in a profession, to rank order individuals to inform admissions decisions, to determine mastery of content for granting a diploma, etc.).

The main exception to this, of course, is in education. The reality of reporting in the 21st century is that most users of test data in educational settings have expectations for reporting that extend deeper into the data, beyond high-level performance characterizations and toward formative or instructional purposes, which are not purely informational in nature, nor are they often the validated purpose(s) of the test (see Brookhart & DePascale, this volume)—they are *actionable*. The *why* of reporting to these users is different yet again, in that their needs and interests in the data are centered on instructional planning and support at micro (individual) or macro (group) levels (Brown et al., 2023).

How?

Discussion of the methods and practices of score reporting would not likely be complete without some attention paid to the *how* of reporting, in this case meaning the

psychometric methods that are used to produce the scores and other results provided in reporting documents. Such methods can span from relatively simple descriptive values to scores that are obtained through complex statistical modeling approaches. In some ways, this is closely entwined with the *what* of reporting, in that it speaks to how scores and other results may be computed from test data. Of course, the *how* of obtaining scores depends on the source data and the reporting aim for those particular data. A few strategies for producing scores and other results are provided in the following pages, relative to reporting aims, reflecting a broad continuum of computational and conceptual strategies.

Raw scores are perhaps the simplest of approaches: They represent the number of points obtained out of the number of points possible, with no weighting or transformation done. Raw scores are often used in informal or classroom settings, but are not typically used to report overall test results on large-scale standardized tests for various reasons, including to ensure comparability of scores across forms where minor difficulty differences are detected or to minimize preconceived notions of the reporting scale (Hambleton & Zenisky, 2003). Some large-scale assessments have reported subdomain results using raw scores—or a simple derivative thereof, such as percentage correct—per Goodman and Hambleton (2004). Scale scores are a step up from raw scores in that some type of transformation is applied for reporting purposes, such as linear or nonlinear. Raw scores, and scale scores, can easily be averaged over test takers for local or more global indicators of performance, and in this way scores for individuals can be interpreted in norm-referenced ways against sample or population averages. Similarly, cut scores can be computed and applied to raw or transformed scores for grouping test takers into achievement levels (such as pass/fail or gradations of proficiency, such as those used in educational assessments and represented earlier in Figure 13.4).

IRT likewise offers much in the way of reporting. IRT can be used not only for the purpose of estimation, but also for reporting, because item difficulty and test-taker proficiency are on the same scale, which can be mobilized to add meaning to the reporting scale (Hambleton & Zenisky, 2017). Some especially powerful examples of this include the item mapping approach used by NAEP (see U.S. Department of Education, Institute of Education Sciences, National Center for Education Statistics, 2015), the score reports used on the Massachusetts Adult Proficiency Test (Zenisky et al., 2018), and the analogous Rasch-based Wright map (Measurement Research Associates, 2010). Item mapping is conceptually connected to the work by Beaton and Allen (1992) on scale anchoring, where specific points on the reporting scale, the anchor points, are illustrated by test content.

Because testing technology has been and is ever evolving, the data that can be used for the *how* of reporting are likewise expanding. Crowdsourced learning (Milligan & Griffin, 2016) serves as but one example of the use of logstream data for scale development and, ultimately, reporting. Indeed, efforts to report data based on not just scores

but also process data offer clear innovations for the *how* of testing (e.g., De Boeck & Scalise, 2019; Ercikan & Pellegrino, 2017; Xiao et al., 2022), as does advancing work in the field of learning analytics (e.g., Du et al., 2021; Oliva-Córdova et al., 2021; Siemens & Baker, 2012). As agencies consider scores that derive from other data sources, the meaning of scores and other results will continue to shift and reporting will accordingly need to change as well, to reflect results that are increasingly multidisciplinary and indicative of a different orientation in conceptualizing and representing performance.

Report Development Process

Quality score reporting does not happen by happy accident. It requires commitment from testing agencies to a process that is closely integrated into the larger schedule of test development activities, to define the necessary connections between the choices made in test development and the validity of the test score inferences to be communicated. (Zenisky & Hambleton, 2015, p. 601)

To this point, much of this chapter has focused on conceptual perspectives on reporting and to establish reporting as an essential activity in the tradition of the IUA of validity. With this grounding, the focus now turns to report development in earnest, and specifically models for crafting reports using thoughtful and collaborative processes. Models developed by Zapata-Rivera (2011) and Hambleton and Zenisky (2013) can be used to guide the report development process. Zapata-Rivera's (2011) model includes four main steps: "(a) gathering assessment information needs from stakeholders; (b) reconciling these needs with the available assessment information, (c) designing various score report prototypes, and (d) evaluating these score report prototypes internally and externally" (p. 37). We focus on the Hambleton and Zenisky (2013) model for the remainder of this section, but also highlight recommendations from Zapata-Rivera that apply to different stages of the development process.

Zenisky and Hambleton (2012a) introduced an initial version of the Hambleton and Zenisky model and it was described in more detail in later publications (Hambleton & Zenisky, 2013; Zenisky & Hambleton, 2015). The model was informed by knowledge of the reporting literature, best practices in test development, and direct experience with report design. Further, it stemmed from the idea that reporting efforts, like other processes including item analysis and standard setting, should follow a general cycle of development. The model was designed to be flexible and to apply to various testing contexts, so it emphasizes process considerations rather than rigid content and design requirements. As such, the model may be adapted to guide the development of reporting tools (e.g., dashboards for assessment results), as demonstrated by O'Donnell et al. (2021). Readers interested in developing such tools are encouraged to consider the Hambleton and Zenisky model, replacing "report" with "reporting tool," as well as literature from the learning analytics community on evaluating the usefulness, usability, and effectiveness of dashboards (see Corrin et al., 2019, for a review).

**FIGURE 13.9****The Hambleton and Zenisky Model for Score Report Development**

Note. Adapted from “Reporting Test Scores in More Meaningful Ways: A Research-Based Approach to Score Report Design,” 2013, by R. K. Hambleton & A. L. Zenisky, in K. F. Geisinger, B. A. Bracken, J. F. Carlson, J.-I. C., Hansen, N. R. Kuncel, S. P. Reise, and M. C. Rodriguez, *APA Handbook of Testing and Assessment in Psychology: Vol 3. Testing and Assessment in School Psychology and Education* (pp. 479–494). American Psychological Association. <https://doi.org/10.1037/14049-023>

At a high level, the Hambleton and Zenisky model (Figure 13.9) begins with four tasks: articulating how the test, results, and reports will jointly support intended inferences (1a), identifying all groups of intended report users (1b), completing a needs assessment for each of those groups (1c), and conducting a literature and document review (1d). The next steps involve using the information obtained previously to develop prototypes (2), completing as many iterations of field testing and revisions as needed for reports to be ready for operational use (3), and implementing a maintenance plan after the reports or reporting tools have been released to the public (4).

We describe each element of the model in more detail in the following paragraphs. But, before delving into the *how* of report development, it is important to consider *who* should be involved in the process. A variety of talents and perspectives are needed to tackle reporting challenges and foster innovation. Reporting is an interdisciplinary activity, and so teams of report developers should also be interdisciplinary. As described by Slater et al. (2019), individuals on report development teams may include graphic designers, user experience practitioners, cognitive science researchers, psychometricians, assessment developers, information technology staff, and accessibility experts. Teams may include developers who serve multiple roles, and consultants may be brought in if needed. Collaboration is key in each step of the development process, as described through the lens of the Hambleton and Zenisky model.

Phase 1: Laying the Groundwork

The first element of the Hambleton and Zenisky model, *articulation of reporting in design* (1a), requires deliberate consideration of the alignment among the purpose(s) of the test, test design features, and the aims of the report(s) under development. It cannot be overstated that reporting goals should be considered early in the test development process to ensure that decisions about content, format, and test length are in agreement with the kinds of information an assessment should provide. If there are distinct claims

about reports and score interpretations that are specified at the beginning of the test development process, then reports that are intended to support the IUA should likewise be framed out at that same time to ensure that test design choices actually gather and provide the data to support the eventual reporting activities and report contents, in effect a backward mapping of reports to the test development process. At this initial stage, it may be helpful to begin preparing a “prospective report”—a simple mock-up of what the final report might include that can be refined as more information becomes available and used to inform test development discussions (Zapata-Rivera et al., 2012).

The next element, *audience identification* (1b), involves naming the user groups that will need information from the report(s) to draw conclusions or take specific actions. In the K–12 context, the target users for a test taker–level report may be students and parents, while teachers and administrators may be the target users for a group-level report. In the credentialing context, those candidates scoring above the minimum passing standards and those below the minimum passing standard may perhaps be considered distinct user groups, because their reporting interests may be quite different depending on what side of the standard they are on. Jaeger’s (2003) work illustrated the multiple user groups that may rely on reports from an assessment program—up to nine groups in the case of U.S.-based NAEP. It must be understood as well that in the process of identifying user groups, such groups are composed of individuals, who bring varying interests, background knowledge, and needs to assessment data communication. In this step, audiences must be differentiated, but the variation within each user group must also be acknowledged.

Thus, after identifying the target audience, a *needs assessment* (1c) should be conducted to understand each user group’s information needs, as well as characteristics that might influence how members of the group approach assessment results. From an audience analysis perspective, Zapata-Rivera and Katz (2014) recommended focusing on the following areas:

- Needs: Users’ purpose for reviewing a report or reporting tool, exemplified by questions such as, “What inferences about or decisions concerning test takers does the user want to make?” (p. 447)
- Knowledge: What users already know and what information they need to fully comprehend the report, exemplified by questions such as, “What knowledge gaps might interfere with correct interpretation of the score report?” (p. 447)
- Attitudes: The feelings or biases that might influence users’ interpretations of the information reported, exemplified by questions such as, “What do users think about assessment generally?” and “What are their expectations about the test takers?” (p. 447)

The needs assessment should be viewed as a broad-based inquiry, extending well beyond a simple investigation of user groups’ familiarity with statistical terms (Zapata-Rivera & Katz, 2014; Zenisky & Hambleton, 2015). It must take place early in the test development process, to inform test development decisions and be informed by user reporting

needs and interests. Zenisky and Hambleton (2015) also recommended gathering general feedback on how users would like to access the report and what data elements they would like to see, which can then be reconciled with what the assessment program is able to support. Report developers may collect information for this step directly through focus groups or surveys or indirectly by reflecting on their own experience with the target audience. If an early prospective report was created, it can be shared with stakeholders, if appropriate, and refined based on key feedback from this stage.

The last element in Phase 1 of the Hambleton and Zenisky model is a *literature and document review* (1d). Report developers should be familiar with general principles from the literature (e.g., Hattie, 2010; Slater et al., 2019; Zenisky & Hambleton, 2012a), as well as findings specific to report components under consideration, such as visual displays (e.g., Hegarty, 2019; Ryan, 2006; Wainer, 1997b), language (Roduta Roberts et al., 2018), or representations of measurement error (e.g., Kannan et al., 2018; Zapata-Rivera et al., 2019; Zwick et al., 2014). It is also helpful to note which methods have been employed to gather feedback on reports, paying special attention to those involving similar assessments and/or audiences.

A number of organizations such as state departments of education to credentialing agencies regularly post sample reports and interpretive guides online (Knupp & Ansley, 2008). To learn from current design approaches, it is useful to examine those samples (or reporting tools, if applicable), keeping track of content and design choices of interest based on the assessment data available and audience characteristics. There is no combination of content and design elements that guarantees universal success, but reviewing a series of complete reports and interpretive guides helps the report development team in the process of beginning to imagine the possibilities (Goodman & Hambleton, 2004).

Indeed, interpretive guides play a pivotal role for report users seeking additional guidance. Reports should be self-contained and concise, including all essential information to support accurate inferences. However, paper or online interpretive guides should still be available for users who may not be as familiar with the context of the assessment or who may be interested in learning more. Goodman and Hambleton (2004) identified several interpretive guide components for consideration, including answers to common questions about the assessment, more information about its content and purpose, suggestions to improve performance, and guidance on where to find additional resources.

Phase 2: Report Development

In Phase 2, *report development*, the information gathered earlier in the process should be used to create a set of prototypes that are “aligned with the test’s goal(s), audience-specific and also rooted in best practices” (Zenisky & Hambleton, 2015, p. 593). Crafting multiple prototypes is helpful so that members of the target audience can react to a range of content and design options. Although it is not impossible, it seems unlikely that a group of report developers would get all elements right on the first and only prototype developed.

The prototypes may have text and design elements in common, and it is up to the report developers to decide how detailed the initial set should be. To the extent possible, the prototypes should reflect the “look and feel” of a complete report or reporting tool and be informed by data gathered in Phase 1. Prototypes missing key features may lead to inaccurate results during field testing, such as members of the target audience indicating that a design is not cluttered only because some or all text is missing, or having trouble understanding the flow of information because a major graph or other element has not yet been added. If multiple reports are needed, a list showing the audience and core data elements for each can assist with tracking development progress.

Phase 3: Field Testing

Always field-test graphs, figures, and tables on focus groups representing the intended audiences; many important things can be learned from field-testing report forms such as features of reports which may be confusing to readers. (Hambleton & Slater, 1997, p. 18)

Phase 3 involves an iterative cycle of *field testing* and *revisions* until the report is ready for implementation. An internal review by colleagues from different backgrounds or with sufficient knowledge of the target audience may be conducted prior to external review. Table 13.1 offers a comprehensive list of evaluation questions that may be used at this stage. The questions are grounded in best practices from the literature and are meant to promote critical reflection. Following internal review, recommendations that lead to minor changes can be readily implemented (e.g., wording suggestions to improve

Table 13.1. Updated Evaluation Form for Reviewing Reports

Report Element	Report Review Questions
I. Overall	A. What are the key intended interpretations of the report? B. How does the report reflect the interests and informational needs of key stakeholders? C. In what specific ways does the report present information that aligns to the purpose(s) of the assessment? D. What evidence has been gathered to support the validity of the report for intended user groups?
II. Content— report intro- duction and description	A. Does the report have a title clearly and descriptively identifying whether it is for an individual or a group? B. For group reports, how are the parameters for inclusion in the group defined? C. How are details provided about the content of the test(s) being reported, if it is not common knowledge for the audience? D. How is the purpose(s) of the test expressed, given the intended audience? E. If present, in what way does the introductory statement set a positive tone for the report?

Report Element	Report Review Questions
III. Content— scores and performance levels	A. How many different reporting scales are used on the report? Is the meaning and range of each score scale communicated, and how? B. How are the performance categories or psychological states being used (e.g., <i>Basic</i>, <i>Proficient</i>, <i>Advanced</i>) reflective of intended inferences, not stigmatizing, and described sufficiently for the intended audience? C. If it is not obvious, how is information provided to guide interpretation and use for each score and classification? D. What strategies are used to guide users away from known misinterpretations and misuses? E. How is the topic of score imprecision handled, to promote interpretation, for each result reported (i.e., overall and subdomains)? F. Have “probabilities” or “conditional probabilities” been used? If they are used, is the explanation clear? G. Is there sufficient information for the reader, without being overwhelming?
IV. Content— other perfor- mance indica- tors	A. Is there any linking of test results to possible follow-up activities? For example, with educational tests, are the results linked to possible instructional follow-up? B. If present, are relevant reference group comparisons reported with information on appropriate interpretations? C. If norms are provided, what steps are taken to describe the reference group in sufficient detail? D. If present, how are results of performance on individual test questions reported to facilitate use and understanding? E. If present, how are reports of scores from other recent and relevant tests explained?
V. Content—other	A. How does the report provide information about where to direct questions? B. Does the report provide links to additional resources about the test, testing program, and/or understanding test-taker performance?
VI. Language	A. What steps have been taken to ensure that the report is free of statistical and other technical jargon and symbols that do not facilitate or promote understanding and interpretation? B. What steps have been taken to ensure that the text is clearly written for users? C. If footnotes are used, are they clearly written for the reader? D. If the report (or ancillary materials) is translated/adapted into other languages, how is the translation/adaptation carried out? What steps were taken to validate the translated/adapted version?
VII. Design	A. What visual and/or narrative strategies are used to highlight the information that is most important based on the purpose(s) of the assessment? B. How is the report clearly and logically divided into distinct sections to facilitate readability?

(continued)

Table 13.1 (continued)

Report Element	Report Review Questions
	C. What visual or narrative strategies are used to communicate the key score information? D. Is the font size in the different sections suitable for the intended audience? E. What steps have been taken to ensure that the graphics (if any) are presented clearly to the intended audience? F. Is there a mix of text, tables, and graphics to support and facilitate understanding of the report data and information? G. What evidence has been collected to suggest that the report looks friendly and attractive to users? H. What are the steps taken to ensure that the report has a modern “feel” to it, with effective use of color and density (a good ratio between content and white space)? I. What steps have been taken to ensure that the report is free of irrelevant material and/or material that may not be necessary to address the purposes of the report? J. What evidence is gathered to suggest that the “flow” for reading the report is clear to the intended audience? K. How does the report align in layout and design to related materials published by the testing program?
VIII. Interpretive guides and ancillary materials	A. Is there an interpretive guide prepared, and if so, what steps have been taken to ensure that it is informative and clearly written? Has it been field tested? Are multiple language versions available to meet the needs of intended readers? B. If there is an interpretive guide, is there an explanation of both acceptable and unacceptable interpretations of the test results?

Note. Adapted from “Reporting Test Scores in More Meaningful Ways: A Research-Based Approach to Score Report Design,” 2013, by R. K. Hambleton & A. L. Zenisky, in K. F. Geisinger, B. A. Bracken, J. F. Carlson, J.-I. C., Hansen, N. R. Kuncel, S. P. Reise, and M. C. Rodriguez, *APA Handbook of Testing and Assessment in Psychology: Vol 3. Testing and Assessment in School Psychology and Education* (pp. 479–494). American Psychological Association.

clarity, small formatting changes), but more complex requests should be considered with caution, and it may be best to wait for external review to confirm the request is aligned with report users’ wants and needs.

During external review, it is imperative that report developers choose field-testing approaches that provide information not only on preferences, but also on comprehension. The report elements that users like and the elements they understand are not always the same (e.g., Wainer et al., 1999). Different approaches yield different information, and accordingly, it may be advantageous to use more than one method to obtain data about reports using multiple approaches.

Surveys may be an efficient way to gather data on both areas and reach a high number of participants. Typically, surveys used for field testing include images of the prototypes and a mix of rating scale and open-ended questions. Participants may be more willing to provide candid answers and may enjoy being able to explore

materials and answer questions at their own pace. However, depending on their level of motivation and interest, engagement with the questions may be lower than for methods with active facilitation. Last, report developers must decide whether to make the survey anonymous or request contact information to allow for follow-up questions.

Another option is to conduct focus groups (e.g., Forte Fast & Tucker, 2001; Ryan, 2006; Zenisky, Delton, & Hambleton, 2006; Zenisky, Hambleton, & Smith, 2006). They offer the possibility of hearing correct interpretations or misinterpretation of reports, allow asking follow-up questions as needed, and can be useful for getting answers to prepared questions as well as exploring unplanned but important topics that arise during discussion. To encourage full participation, Zenisky and Hambleton (2015) recommended holding separate focus groups with members of different user groups and being mindful of potential power imbalances among participants. Probing comprehension in a group setting can be challenging; participants may be unwilling to venture interpretations or admit that something is difficult to understand. An alternative to asking direct comprehension questions is asking questions such as:

- Do you think other [parents/teachers/students] would understand this information?
- Is there something in particular that might be confusing to them?
- What is your interpretation of this report?
- What would you do next now that you have interpreted this report?

Such questions can lead to many interactions among focus group members that can inform the adequacy of the report and areas for improvement.

An additional source of evaluative questions in this regard can be sourced from Ryan (2006). These can be tailored to be relevant to the intended user group as well as the person doing the ratings.

- Will a [user] find this information helpful?
- How could a [user] use this information?
- Could this information be modified to be more informative or helpful?
- How can this information be best presented?
- Might there be any problems in how this information is used?

These particular questions were posed as conceptual points to help study participants in the context of rating different proposed reporting formats, but can also be viewed as stand-alone questions that could be asked of participants.

Interviews are the most time-intensive option, but can provide rich information on an individual's perceptions, and participants may feel more comfortable sharing honest feedback on prototype elements that are difficult to interpret in this individual setting. Like focus groups, interviews can be based on a set of prepared questions or follow a more conversational style. Unlike focus groups, they can incorporate techniques

such as think-aloud protocols, where users are asked to voice their thought processes and reactions as they interact with a prototype. When there is particular interest in understanding how users navigate prototypes, eye tracking and direct observation may also be used.

Regardless of methods used to gather data on reports, report developers must be acutely involved in the process of identifying participants for feedback on reports and seek out research participants who may be able to provide wide-ranging perspectives on report prototypes. It is not sufficient to name intended user groups at a general level (e.g., “parents,” “teachers”) while ignoring the subgroups that are present within such groups. Broadly speaking, sex, race/ethnicity, socioeconomic status, proficiency in the primary language of the report, and technology familiarity (for web-based reporting efforts) may provide initial sampling frames for recruiting participants. For example, in a reporting jurisdiction with a high proportion of Spanish-speaking families, it would be appropriate to develop a sampling plan that ensures representation across the diversity of language status in that jurisdiction. This approach not only benefits a specific report document but also can glean insight about communication and access strategies around reporting. Similarly, if a report is developed in certification and licensure contexts that offer a diagnostic component for failing/low-performing candidates, with the aim of providing actionable information, then failing/feedback from low-performing candidates would be something that would likely be useful to include on a sampling plan. The process of gathering feedback at any point in the report development cycle can be time-consuming and complicated, but careful consideration of the research participants, including clear articulation of relevant subgroups for any individual user group and outreach to engage those subgroups, cannot be overlooked as an aspect of validating reports. Just as test developers seek out diversity in test specifications panels, item writers, and standard-setting panels, so too must diversity be prioritized in participatory research around reporting.

After analyzing the results from field testing and identifying areas of consensus, report developers must decide which content and design changes to make. Some improvements may be obvious upon reviewing the feedback, while others may not be immediately feasible or take additional consideration. For example, there may be consensus that a particular layout is confusing, but no suggestions on how to improve it. Depending on the magnitude of the revisions, additional field testing may be needed to investigate whether the changes had the intended effect. This phase is intended to be iterative, when appropriate.

Phase 4: Maintenance

The *maintenance* phase begins once reports become operational. As explained in the validity section, investigating whether reports are interpreted and used as intended is critical. This phase may include periodic evaluations using some of the same methods employed for field testing in addition to continuous monitoring of inquiries and comments from

report users received via customer support channels, online forums, and other outlets. If content or design flaws are identified, “easy fixes” may be implemented right away, or potential revision ideas may be accumulated over a certain period to implement a number of changes at once. As with other phases of the model, there are no strict rules about how often to conduct maintenance research and what methods may be involved, but critically there should be a plan in place, and the plan should be aligned with the process for gathering evidence of actual interpretation and uses of the information reported.

Summary

The Hambleton and Zenisky model presented here, supported by the principles and ideas from Zapata-Rivera (2011), is an approach to report development that aligns with research and practice. The driving force behind this model is to ensure that results reports, as a public-facing end product of the test development process, meet the known and articulated needs of the various intended users, through a collaborative and iterative series of steps. Evaluation is a critical aspect of this work, and the checklist provided in Table 13.1 offers report development teams opportunities to reflect on their work and the final report to demonstrate its validity relative to the test’s purpose and the communication process.

WHAT WE HAVE LEARNED

A theme throughout this chapter is that developing effective reports, whether static or interactive, requires careful consideration of the who, what, where, when, why, and how: specifically, who will use the results, what data are available, where the results will be reported, when they will be released, why results are needed, and how data will be turned into results. These factors are interdependent and, combined, create numerous possibilities. Teams developing reports or reporting tools may avail themselves of models such as the one in the previous section, but because effective reporting is so context specific, summaries of findings by report element may be difficult to find.

Gotch and Roduta Roberts (2018) conducted a review of 60 studies on individual reports published between 2005 and 2015, summarizing areas of focus, theoretical frameworks of communication, and data characteristics rather than findings regarding specific report elements. They noted that “data sets were often small or localized to a single context” (p. 46), highlighting the issue of generalizability. Although there have been no meta-analyses of findings from studies on results reporting to date, likely due to how context dependent such findings tend to be, some general guidance is available.

To this end, Figures 13.10 through 13.17 offer key recommendations from five sources: Goodman and Hambleton’s (2004) review of results reports and interpretive guides; Ryan’s (2006) *Handbook of Test Development* chapter on reporting practices, issues, and trends; Hattie’s (2009) principles for promoting the validity of reports; Zenisky and Hambleton’s (2012b) guidelines for developing online reporting resources; and Slater et al.’s (2019) chapter on designing reports for large-scale testing programs.

These recommendations are grouped on the basis of eight dimensions of reports and reporting: overall; content—report introduction and description; content—scores and performance levels; content—other performance indicators; content—other; language; design; and interpretive guidance and ancillary materials (these dimensions align to the report elements of the checklist presented in Table 13.1).

These works offer advice based on findings and practical experience from scholars who have dedicated substantial portions of their careers to improving the communication of assessment results. Although visualization ideas from Wainer are not directly represented, Wainer's extensive contributions and publications significantly informed the work of Goodman and Hambleton (2004) and Ryan (2006).

Goodman & Hambleton (2004)

"Consideration should be given to the creation of specially designed reports that cater to the particular needs of different users." (p. 219)

"Personalize the student score reports and interpretive guides." (p. 219)

"Reports should be piloted with members of the intended audience." (p. 219)

Ryan (2006)

"A score report should be related to content standards as clearly and explicitly as possible." (p. 705)

Hattie (2009)

"The validity of reports is a function of the reader's correct and appropriate inferences and/or actions about the test takers' performance based on the scores from the test." (p. 3)

"Evidence is needed to demonstrate how readers are interpreting reports." (p. 4)

"A report should be timely to the decisions being made (formative, diagnostic, summative, and ascriptive)." (p. 13)

"Anchor the [report or reporting] tool in the task domain." (p. 9)

Zenisky & Hambleton (2012a)

Static: "Pay attention to the reporting interests and needs of users, as presenting results in static format means users see only what is shown to them." (p. 179)

Interactive: "Have users articulate their data analysis needs." (p. 181)

"Look into what others have done. Many states and publishers are being very creative in developing online interactive tools." (p. 181)

Slater et al. (2019)

"Design the report so that viewers can see and understand the most important information in 10 seconds or less." (p. 98)

"Make sure that the report design can accommodate unusual but possible conditions, such as very long names or very low or high scores." (p. 99)

"Follow Web Content Accessibility Guidelines (WCAG; Caldwell, Cooper, Reid, & Vanderheiden, 2008)." (p. 99)

FIGURE 13.10
Key Reporting Recommendations: Overall

Goodman & Hambleton (2004)

"Include an easy-to-read narrative summary of the student's results at the beginning of the student score report." (p. 219)

"Devices such as boxes and graphics should be used to highlight main findings." (p. 219)

Ryan (2006)

"Score reports should highlight important results in some way, (e.g., boxes, boldface type)." (p. 706)

Hattie (2009)

"A report should provide justification of the test for the specific applied purpose and for the utility of the test in the applied setting." (p. 11)

Slater et al. (2019)

"Emphasize the most important information in the score report. . . . The most important parts of the report should command the most attention." (p. 98)

FIGURE 13.11

Key Reporting Recommendations: Content—Report Introduction and Description

Goodman & Hambleton (2004)

"Include all information essential to proper interpretation of assessment results in student score reports." (p. 219)

Ryan (2006)

"[Results] should be reported in relation to performance standards." (p. 705)

"[Results] should be reported at the finest level of detail for which reliable information can be provided." (p. 706)

"A score report should include information about precision for all scores presented." (p. 706)

Hattie (2009)

"Maximize interpretations and minimize the use of numbers." (p. 5)

Zenisky & Hambleton (2012a)

Static: "Try out different report formats (summary, highlights, full-length reports) and data displays (text, graph, and tables) with intended audiences to ensure that materials are understood and the conclusions being drawn are appropriate." (p. 179)

Interactive: "Start with things that are manageable, and look into developing comparatively simple web interfaces supported by databases that let users select results for a content area, unit of analysis (school, city/town, region/county, state), and perhaps limited demographic characteristics." (p. 181)

The Road Ahead: Opportunities in an Evolving Reporting Landscape

While much research and effort has been exerted to formalize reporting efforts within the broader domain of test development, the ongoing reimaginings of assessment spurred in part by technological advances within and outside assessment demonstrate that reporting is a topic that itself is not static, and work in this area is ongoing. In this section, several priority areas for future work are briefly highlighted.

**Goodman & Hambleton (2004)**

"Score reports should include easy-to-read text that supports and improves the interpretation of charts and tables." (p. 219)

"Small fonts, footnotes, and statistical jargon should be avoided." (p. 219)

"Key terms should be defined, preferably within a glossary." (p. 219)

**Ryan (2006)**

"Avoid jargon unfamiliar to the intended audience." (p. 706)

"Provide an explanation or glossary for any measurement terms used." (p. 706)

"Use text to explain graphs, charts and tables." (p. 706)

**Slater et al. (2019)**

"Ensure that any language in the report is appropriate to its intended audience, at the proper reading level." (p. 98)

"Avoid technical language that might be difficult for non-experts to understand." (p. 98)

FIGURE 13.15**Key Reporting Recommendations: Language****Goodman & Hambleton (2004)**

"Score reports should be clear, concise, and visually attractive." (p. 219)

"Care should be taken to not try to do too much with a data display (i.e., displays should be designed to satisfy a small number of preestablished purposes)." (p. 219)

"Data should be grouped in meaningful ways." (p. 219)

**Ryan (2006)**

"Score reports should be clear, as simple as possible, and uncluttered." (p. 706)

"Use simple and clear graphs, charts, and tables." (p. 706)

"Score reports should use print features such as font size, style, and spacing that make it as easy as possible for the reader to understand the report." (p. 706)

**Hattie (2009)**

"Each report needs to have a major theme." (p. 7)

"A report should be designed to address specific questions." (p. 11)

"Readers of reports need a guarantee of safe passage...and destination recovery." (p. 4)

"The answer is never more than 7 plus or minus two." (p. 6)

"A report should minimize scrolling, be uncluttered, and maximize the 'seen' over the 'read.'" (p. 10)

**Zenisky & Hambleton (2012a)**

Interactive: "Different users have different capabilities for understanding quantitative data, so look into presenting data in multiple formats when possible (tables, graphs, narrative, etc.);" (p. 181)

**Slater et al. (2019)**

"Create a strong visual hierarchy that guides the viewer's eye appropriately through the report" (p. 98)

"Eliminate visual clutter . . . Avoid repeating elements of the report, except where repeating them makes the report clearer." (p. 98)

"Avoid using lines that add to visual complexity. Instead, use shaded areas to delineate space." (p. 98)

"Use visual embellishments such as icons only when they make it easier for users to correctly interpret the report. . . Avoid any visual element that may have a negative connotation." (p. 98)

"Colors, used meaningfully, can make the report easier to interpret. However, make sure that the report can convey all its information even if the viewer cannot accurately differentiate colors or if the report is printed or photocopied in black and white." (p. 99)

FIGURE 13.16**Key Reporting Recommendations: Design**

Goodman & Hambleton (2004)

"Include detailed information about the assessment and score results in a separate interpretive guide." (p. 219)

"Include sample questions in the interpretive guides that illustrate the types of achievement represented by each performance level." (p. 220)

"Include a reproduction of student score reports in the interpretive guides to clearly explain the various elements of the reports." (p. 220)

Zenisky & Hambleton (2012a)

Informational Web Pages:

"Ask stakeholders what information about the testing program would be helpful for them to know." (p. 182)

"Review other testing programs' websites to find out the kind of programmatic documentation they make available." (p. 182)

"Post the technical manual and updates online as available." (p. 182)

FIGURE 13.17

Key Reporting Recommendations: Interpretive Guides and Ancillary Materials

Reporting in the Formative Assessment Context

Reporting results from formative assessments is a growing area of research and operational development. While the focus of most reports for summative interpretations is a total score indicating overall achievement in relation to a target construct, such a broad indicator of performance is typically much less interesting and useful in formative contexts. Formative interpretations use a range of formats and delivery methods, but their defining characteristics are being administered *during* instruction and providing feedback to inform adjustments to teaching and/or studying approaches. Informing immediate action to support student learning is central to formative assessment, creating unique challenges and opportunities for reporting.

While expediency is desirable in all testing contexts, it is essential to formative interpretations: results must be ready in time to make a difference. Rapid reporting increases the relevance of the information provided and the probability that educators will act on the results (Brown et al., 2019). Specificity is also important. Reports for formative interpretations should provide sufficient detail so that users can identify areas of strength and weakness and know where to focus to make improvements. These finer grained results have traditionally included item-level feedback and scores or achievement levels for specific content areas or attributes. More recently, the options have expanded to include process data.

Process data may include time spent on each assessment task, logs of which resources were used at different points, logs of answer changes, click streams, and keystroke logs. Turning such data into insights holds substantial promise, but perhaps most especially in formative contexts, because it can paint a richer picture of student learning. An example of this is found in Milligan & Griffin (2016), who elaborated a generalized six-step methodology for constructing measures using click-stream data. However, research on how to do this, how to report process data, and how to establish the validity of this practice is still in its infancy, and there is much yet to be learned (Provasnik,

2021; Zapata-Rivera et al., 2021). Analysis approaches drawn from the cognitive diagnosis modeling literature, such as the attribute hierarchy method, may also be helpful here (Roberts & Gierl, 2010).

With or without process data, formative assessment results tend to be more detailed than results for other types of assessments, creating the challenge of designing reports or reporting tools that communicate detailed, personalized feedback in ways that are clear and actionable in addition to being automated to support rapid reporting. This may be done by combining digital reporting with assessment designs that provide finer grained results (e.g., Brown et al., 2019) and employing specific strategies such as the use of formative hypotheses to offer suggestions on next steps (Zapata-Rivera et al., 2012) and online tutorials to support comprehension of the reporting tool (Brown et al., 2019). The benefits of feedback to teaching and learning are well documented, and so are the complexities of providing feedback effectively (Hattie & Timperley, 2007; Wisniewski et al., 2020). Technological advances are creating exciting opportunities for advancing the ways we report feedback from formative assessments.

Leveraging Technology for Reporting

Interest in using technology to better communicate assessment results has steadily grown since the start of the millennium. At the time of Goodman and Hambleton's (2004) review of K–12 reporting across 11 U.S. states, only one state posted information related to results reports online. A few years later, this practice had become so common that it prompted the development of guidelines for informational web pages about results reports as well as guidelines for online results-oriented documents and interactive tools (Zenisky & Hambleton, 2012b). Bulut et al. (2020) also proposed recommendations for providing feedback from assessments in an online environment, and Hattie's (2010) commonly cited principles for report development arose from the context of developing web-based, interactive reporting tools.

Many of these recommendations and principles are similar to those for paper-based reports. For instance, Zenisky and Hambleton (2012b) suggested “presenting data in multiple formats when possible” to support users with different information processing needs (p. 181), Hattie (2010) advised that “each report needs to have a major theme” (p. 7), and Bulut et al. (2020) recommended “an aesthetically pleasing design without information overload” (p. 64). Bulut et al.'s (2020) remaining recommendations, presented verbatim, echo several of the guidelines from Figures 13.10 through 13.17.

- The score report should be tailored to meet the needs and characteristics of the target audience, such as students, parents, and teachers (Hambleton & Zenisky, 2013; Zapata-Rivera & Katz, 2014).
- The score report should present the feedback in different forms, including narrative text, tables, and figures.
- The layout of the score report should be simple, with key results highlighted (Goodman & Hambleton, 2004; Slater et al., 2019).

- Feedback presented in the score report should include a set of actions that students can take to improve their future performance (Daniels & Bulut, 2019; Hattie, 2009; Jonsson, 2012).
- If interactive elements (e.g., visuals and tables) are to be used, how students will interact with these elements should be considered in the design process (Bulut et al., 2020; Slater et al., 2019).
- Usability studies with students should be carried out to test whether the content of feedback is easy to follow (Slater et al., 2019; Zenisky & Hambleton, 2012b).

What is different in technology-based reporting is that there is usually no physical constraint on how many elements can be included, and interactivity offers possibilities that were not available before, such as on-demand interpretive text, performance details, and interactive tutorials (e.g., Zapata-Rivera et al., 2016).

In thinking of how to characterize next-generation reports in other innovative ways, it may be that the near future may be app based and use the screen and app-based functions to engage users in ways that current results reports may not (Linares-Vásquez et al., 2017). In the very near future, what users think of as reports may look and feel very different from current “score reports.” Other forward-looking research in the areas of big data and visualization may be similarly instructive, in terms of integrating machine learning, developing novel visualizations, conceptualizing different patterns of interaction with data, and alternative user interfaces (Andrienko et al., 2020). This thinking in the area of big data echoes the model-based approach advanced by Zenisky and Hambleton, 2012a), since Andrienko et al. (2020) suggested understanding and “designing the user interactions first” (p. 4), followed by development of systems to support such interactions.

With so many content and design options available, report developers must be very familiar with the needs and preferences of their audience to develop interfaces that will seamlessly guide them—interacting with online resources and tools to explore score data and other results successfully involves greater user engagement than reading a static report. It also may require background knowledge about the assessment itself and the construct measured to formulate specific questions and use the tool or tools as intended. It is also helpful to consider likely misinterpretations and misuses, which become more numerous when interactivity is added, and make adjustments to support the purpose of the assessment. These are critical considerations that developers of online reporting tools must carefully understand and articulate at the outset of that development work, to ensure that these issues are addressed throughout report tool development, including attention paid to providing context and background knowledge for use of any tool. Then, several rounds of gathering user feedback and making refinements are usually needed when developing interactive tools, and relying on a model such as the one proposed by Hambleton and Zenisky (2013) may aid in this process.

Some challenges are unique to online reporting, such as matters of access and ease of navigation. The way users access online reports or reporting tools should be secure

and convenient. Further, the document or tool itself should be easy to navigate, providing users a “guarantee of safe passage” (Hattie, 2010, p. 4), with the most important information made prominent by the design and visual cues, helping users decide where to look next. If the practices of online reporting since the year 2000 are any indication, it is highly likely that online reporting will continue to grow in popularity, bringing about new ways to communicate information from assessments and interesting challenges.

Data Visualization

Approaches to visualizing assessment results have continued to evolve. Classic resources on displaying quantitative data remain relevant (e.g., Kosslyn, 2006; Tufte, 1983, 1990; Wainer, 1997a, 2005) and can now be supplemented by more recent findings from fields such as cognitive science, information visualization, and user experience. Hegarty (2019) provided a thorough discussion of contemporary data visualization best practices and principles that apply specifically to results reporting.

Additionally, the refinement and greater availability of data visualization tools has allowed psychometricians to become more involved in prototyping and producing graphics for reports and reporting tools. Consider the functionality of the following selection of popular open-source data visualization packages for the programming language R (similar tools are also available for Python):

- *ggplot2* (Wickham, 2016): A package for creating static graphics with elegant default features and flexible customization options, based on Wilkinson’s (2005) *Grammar of Graphics* structured approach for constructing visualizations (<https://ggplot2.tidyverse.org/>)
- *plotly* (Sievert, 2020): A package for creating modern, interactive graphics powered by a JavaScript charting library; it may also be used to make *ggplot2* graphics interactive using the *ggplotly* function (<https://plotly-r.com/>)
- *shiny* (RStudio, 2020): A package and web application framework for creating interactive dashboards with R, often used in conjunction with *plotly* (<https://shiny.rstudio.com/articles/#deployment>)

Because results reports are composed of both content and communication, hand in hand with these tools for visualization is an evolution in what reports look like and how the data are accessed by stakeholders. One increasingly common strategy for reporting is the use of digital databases and user-selected reporting queries, and indeed this has shifted the control of the data story from psychometricians and report developers to users (Zenisky & Hambleton, 2012b).

Along the lines of strategies for visualization, a next frontier for reporting, especially with respect to next-generation assessments, is to continue to build on interdisciplinary contributions from cognitive science, marketing and communications, and dissemination practices in other scientific domains to leverage existing and emerging strategies for data understanding and use. In particular, the work of Hegarty (2011,

2019; Padilla et al., 2018), among others (e.g., Hullman et al., 2011; Ratwani et al., 2008), has helped bridge understandings of visual–spatial display cognitions to guide action in a number of areas, such as radiology reports (Alarifi et al., 2021), clinical monitoring (Khasnabish et al., 2020; Reese et al., 2020), meteorology and climate (Argyle et al., 2017; Gerst et al., 2019; Harold et al., 2016), and mapping (Hegarty et al., 2016; Johannsen et al., 2018). There is much to be gained by leveraging modern visualization tools and insights from other fields to improve the visual elements of reports and reporting tools.

Reporting for Next-Generation Assessments

Assessment is changing. From constructs measured to delivery mode, from item formats to sequencing of measurement opportunities in adaptive and gamified assessments, many tests today are substantively different in one or more significant ways than those of just a decade or two ago. As this evolution in tests and measurement continues, it is at least in part driven by users and stakeholders who seek not only different information from assessments but also to use test data more efficiently and effectively (Brown et al., 2023). In this way, reporting—beyond a global score or performance level—is centrally ingrained in the next generation of assessments.

Next-generation assessments are not marked first by technology, but rather a more fundamental shift in paradigm to prioritize process and information, rather than status or outcome. This will necessitate continued work not only on reporting but also next-generation psychometrics, to support the inferences and information that are increasingly sought. The ongoing efforts to report subscores reliably are but a precursor to the challenges that lie ahead in terms of making useful sense of process data (e.g., Bergner & von Davier, 2019; Provasnik, 2021) and, importantly, to devise ways to communicate these data in ways that are supported by evidence. Emerging work in areas such as big data, natural language processing, and digital learning environments will be critical to informing these desired shifts in report contents (Cope & Kalantzis, 2015; Mislevy et al., 2012).

CONCLUSION

Communicating test score information matters. (Hambleton & Zenisky, 2013, p. 492)

Reporting assessment results is not easy. It is the culmination of a long process of assessment design and development, fundamentally marked by a systematic and serious effort to provide information about individual and/or group performance relative to educational and psychological constructs of interest. As discussed here, reports can be conceptualized through the lens of a data story, where the elements of the report are purposefully chosen, arranged, and field tested with prospective users to communicate specific information about test performance. Much research has focused on reporting in recent years, and the addition of guidance to formalize the process (Hambleton &

Zenisky, 2013) gives structure and purpose to activities that are critical for the development of useful report documents and tools.

In this chapter, the intent has been to reinforce the importance of reporting as part and parcel of the IUA for an assessment. If users are to interpret and use any assessment, they must have access to data in a way that supports those efforts. The work of Kane (2006, 2015) and Hattie (2009, 2010) is instrumental in shaping the perspective on validity and reporting we adopted, and the idea of “interpretability” as suggested by O’Leary et al. (2017) adds an interesting and potentially useful dimension to the conversation around validity and the role of reporting in supporting test interpretation and use.

In some ways, it may almost be easier to focus the conversation about report development on graphics, colors, layout, and design because those are easily manipulated key features of the end product of the report development process. However, as is evident in the earlier conversation around effectiveness, the true test of the success of a report is in its use. The criticality of engaging in reporting needs and wants at the outset of test development cannot be overstated, because the priorities and decisions made early on define the parameters of the data (from a validity perspective) that will be reported later. Interpretations that may be informally desired but are not discussed, defined, and/or prioritized from the beginning are likely to be *unvalidated* and, therefore, relegated to inappropriate uses of results.

If there is a final point to be made, it is the importance of when the conversation about interpretation and use—and reporting—takes place, so that test developers and stakeholder groups alike have a clear understanding of the *what* of reporting, to ensure that the assessment fulfills those known reporting needs (and wants). This takes time, it takes a team, and it takes planning. The evidence for effectiveness (understood as use) comes later, through Phase 4 of the Hambleton and Zenisky model (2012a, 2013) with evaluation and maintenance, but there is no substitute for a strong foundational process for reporting, building on needs assessment, stakeholder input, and consideration of reporting strategies, always, always, in light of test purpose and use.

NOTE

1. Throughout this chapter, we honor the legacy of our colleague and this chapter's third author, Ronald K. Hambleton, by incorporating specific quotations drawn from his extensive body of work on this topic. Professor Hambleton's countless contributions have significantly shaped our field and continue to frame our discourse. His passing on April 28, 2022, was a profound loss, but his voice and influence endure through his writings, which we are privileged to share here.

Realizing Fairness Through Accessibility for All Test Takers and for Specific Groups

Michael C. Rodriguez

University of Minnesota Twin Cities

Martha L. Thurlow

University of Minnesota Twin Cities (Retired)

The *Standards for Educational and Psychological Testing* (American Educational Research Association [AERA] et al., 2014), hereafter referred to as the *Standards*, are forward thinking in projecting fairness as a foundational concept for all educational and psychological measurement. The *Standards* described several general views of fairness, including equitable treatment during the testing process, absence of measurement bias, validity of individual test score interpretation and use, and access to the intended measured constructs and achievement domains. Increasingly, the concept of *accessibility* has been identified as a key aspect of realizing fairness in educational and psychological testing. Overall, a fair test maximizes construct and domain-relevant information, regardless of irrelevant individual characteristics and test contexts, to ensure valid test score interpretation and use for all test takers.

Zwick (this volume) notes the interconnectedness of the three foundational chapters in the *Standards*—validity, reliability, and fairness—as well as their interrelationships with concepts such as bias, construct-irrelevant variance, opportunity to learn, standardization, universal design for assessment (UDA), and others. In the foundational discussion of fairness in the *Standards* is the recognition that fairness is a broad concept that includes an overarching standard about the entire testing process being designed to minimize construct-irrelevant variance to promote valid score interpretations. The fairness standards are organized in four clusters that address (a) test design, development, administration, and scoring; (b) validity of score interpretations; (c) accommodations to remove construct-irrelevant barriers; and (d) safeguards against inappropriate score interpretations. Zwick moves beyond these concepts to consider fairness in the context of opportunity to learn and selection (admissions to higher education and employment). She also argues that fairness must be addressed through a larger validity argument which provides “a chain of reasoning using documented evidence to support the fairness of the intended uses and interpretations of test scores” (Zieky, 2016, as cited in Zwick, this volume, p. ##).

For the first time, the *Standards* eliminated chapters devoted to individuals with specific characteristics, such as those with disabilities and those from different cultural and linguistic backgrounds. Instead, a focus on all test takers was woven throughout the chapters with an emphasis on meeting the needs of all test takers throughout test design, development, implementation, reporting, interpretation, and use. Realizing accessibility is critical in this approach, which is much more than just providing accommodations to some students. Accessibility is a concept that has emerged slowly and been applied to educational and psychological tests as it has become clear that test takers include culturally and linguistically diverse groups of individuals.

The purpose of this chapter is to apply the theory and concepts of a fairness argument to all test-taking populations, both in general and for specific groups of test takers. We explore these through the lens of accessibility and what it means in general for all test takers, as well as through the perspective of specific groups, including individuals with disabilities, English learners, those from different racialized and ethnicized groups, and those living in poverty. We address fairness for all types of assessments, including tests of achievement most often used in preschool through Grade 12 (P–12) school settings

(e.g., used for formative, interim, or summative purposes), higher education classroom settings, campus-wide assessments of student learning outcomes, admissions tests (e.g., ACT, SAT, GRE, Law School Admission Test [LSAT]), and licensure and certification exams. At the end of most sections, we provide implications for practice, or practice and research, and summarize some of the key guidance promoted and informed by the scholars reviewed in those sections.

Accessibility is the condition where test takers have “unobstructed opportunity to demonstrate their standing on the construct(s) being measured” (AERA et al., 2014, p. 49). A related approach, which has become a common component of test design principles, is UDA, borrowed from principles of architecture regarding “test design that seeks to maximize accessibility for all intended examinees” (AERA et al., 2014, p. 50), to be responsive to test-taker characteristics and the testing context(s). In addition, we expand the notions of UDA by including the principles of universal design for learning (UDL) created by CAST (<https://www.cast.org/>), a broader conceptualization of access that acknowledges that access to content and assessment tasks is necessary, but not sufficient; test takers need access to learning opportunities. Together, a fair test “reflects the same construct(s) for all test takers, and scores from it have the same meaning for all individuals in the intended population” (AERA et al., 2014, p. 50), regardless of racialized status, ethnicity, gender, age, socioeconomic status, special education status, or cultural or linguistic background. We use the term racialized status, rather than race, acknowledging that race is a social construct and that minoritized individuals are ascribed to racial groups, marginalized, and subjected to racism and oppression (in many ways, this includes ethnicity). As employed by Russell (2024), the term racialized denotes “the active process of creating categories into which humans are membered” (p. viii).

Furthermore, fairness is of concern in each stage of test design, development, administration, scoring, interpretation, and use. The fairness chapter in the *Standards* addresses four general views, including (a) fair and equitable treatment of test takers, (b) fairness as access to the measured constructs, (c) fairness as lack of measurement bias, and (d) fairness as validity of score interpretation and use; the latter two views are addressed comprehensively by Zwick (this volume). Finally, we explore the promise of culturally and linguistically responsive assessment to provide accessibility and achieve greater test fairness.

Fairness is often discussed in terms of test-taker characteristics needing additional or unique considerations in test development (see Huff et al., this volume), administration and scoring (see Shermis et al., this volume), and reporting (see Zenisky et al., this volume). However, it is important to acknowledge that fairness challenges are less about the test-taker characteristics and more about the quality, inclusiveness, and responsiveness of test design and implementation, where challenges result when test characteristics interact with test-taker characteristics in unintended (or unanticipated) ways (Kettler et al., 2018), thus the focus on accessibility and universal design principles. We agree that radical goals can be achieved “when educational tests focus on promoting the success of *all* students” (Sireci, 2021, p. 7).

FAIRNESS IN EDUCATIONAL TESTS AND ASSESSMENTS

For our purpose, we focus on fairness in the measurement of education achievement and do not directly address more purely psychological assessments, employment tests such as cognitive ability or personality tests, assessments of job performance, or other tests typically in the purview of clinical or industrial-organizational psychology. Both educational and psychological tests and assessments have fairness concerns (e.g., see Geisinger, 2015), and although many of the issues and contexts have parallels in psychological testing, our focus is more directly applied to testing in education settings or for education purposes.

Fairness and accessibility are concerns for all types of educational tests and assessments and all proposed purposes (including those for which validity evidence may or may not exist). For tests with more high-stakes outcomes, more rigorous evidence is needed to support fairness and accessibility, as with validity evidence. This includes tests of achievement for interim and summative purposes with implications for individuals (see Brookhart & DePascale, and Ho & Polikoff, both this volume); tests used for admissions to higher education, such as the ACT, SAT, GRE, LSAT, Medical College Admission Test [MCAT], GMAT, and others (see Camara et al., this volume); tests used for licensure and certification (see Margolis et al., this volume); and tests used for assessment of so-called social and emotional, character, behavioral, or intra- and interpersonal skills (see Kyllonen & Zu, this volume).

Our purpose is to apply the theory and concepts of fairness (see Zwick, this volume) to test-taking populations, both in general (i.e., accessibility for all test takers) and for specific groups (e.g., English learners, individuals with disabilities). “Regardless of the purpose of testing, the goal of fairness is to maximize, to the extent possible, the opportunity for test takers to demonstrate their standing on the construct(s) the test is intended to measure” (AERA et al., 2014, p. 51). Of course, such opportunity to demonstrate standing is provided by the test developer and administrator; the test should enable such access given the needs of the test taker.

A comment is needed at this point regarding terms used throughout the chapter, including test and assessment and construct and domain. The authors of the *Standards* described a test as a tool or procedure to systematically sample test-taker behavior in a specified domain in a standardized process. Assessment includes a broader set of systematic methods for obtaining information about a person’s characteristics or performance; assessment includes processes to collect relevant evidence, interpret the resulting information, and inform a decision (Russell, 2022). Both include systematic processes and both require domain specifications to support intended interpretations and uses.

In this chapter, we use the word *test* when we mean a tool containing items and tasks administered and scored in systematic ways to measure (a quantitative activity) what a person knows and can do relative to the targeted domain; we use *assessment* when we mean the broader range of processes, both qualitative and quantitative, informal and

formal, to similarly collect evidence of what a person knows and can do. In addition, a *construct* is a specific “concept or characteristic that a test is designed to measure” (AERA et al., 2014, p. 217), whereas a content *domain* is “the set of behaviors, knowledge, skills, abilities, attitudes, or other characteristics to be measured by a test, represented in detailed test specifications and often organized into categories by which items are classified” (AERA et al., 2014, p. 218). Although construct and domain appear to be used interchangeably in most educational measurement texts, we prefer the term domain in most education contexts because the tests we write about primarily include measures of achievement, with systematic reference (inference) to what people know and can do as reflected in test specifications (often including many constructs). We use the terms employed by other authors when representing their specific arguments and claims.

Fairness and the Choice to Test

The fact that a test is used presupposes the use of an inclusive decision process that determined that testing is an appropriate, meaningful, and useful method to collect evidence to support decision-making. At this early stage in the testing process, fairness considerations abound. Many decisions occur on a regular basis employing information about knowledge and skills across the life span, from early childhood through careers (e.g., progression through P–12 grade levels, placement in special education or gifted/talented programs, admissions to higher education institutions, or licensure and certification). Evidence can be collected through a wide range of informal to formal qualitative and quantitative approaches. Especially in accountability-based settings, decisions are improved when they are informed; yet what qualifies as evidence is value laden and culture bound. Drawing heavily on the work of Messick (1975, 1980, 1981), Kane (1992) argued that “the legitimacy of test use rests on the assumptions about the possible outcomes (intended and unintended) of the decision to be made and on the values associated with these different outcomes” (p. 530). Messick (1965) argued for attention to regulating ethical standards to justify test use.

Values enter our considerations in a number of ways, including the framing of the decisions that need to be made in education settings, as well as the inclusivity of who is at the table to determine the relevance of impending decisions. When testing is introduced as a means through which evidence can be collected, additional questions must be addressed. Those questions include what sources of evidence to gather to inform decisions; what we value as evidence can vary substantially and impact the determination of what to measure and how to measure it. Such questions are addressed in the final section, where we discuss accessibility through cultural and linguistic responsiveness.

Because fairness addresses the treatment of individuals and groups, a decision to test must consider the appropriateness of test use for all individuals and groups in the test-taker population, including those who may be tested in the near future. This includes opportunity to learn, prior test experience, access to test preparation, access to the test content itself in terms of cultural and linguistic accessibility and language of testing, and ability to respond to items or tasks as required by the test administration procedures.

“A proposal to use a test for a particular purpose, then, should be appraised in light of the probable future consequences of the testing, not only in terms of what it entails but also in terms of what it makes more likely” (Messick, 1975, p. 962). Zwick (this volume) discusses the possibility that, in some cases, the decision to not use a test is most appropriate. For example, if the use of a diagnostic reading test for the purpose of identifying students who need reading remediation identifies 80% to 90% of the students of color in a large population of mostly nonimmigrant children but only 10% of White students, a decision to not employ such a test is warranted, regardless of technical or psychometric quality.

Implications for Practice

Practitioners should secure diverse participation and include key stakeholders in the decision-making process regarding whether to use a test to inform certain decisions. Fairness requires consideration of whether testing is appropriate for all potential test takers and whether a test is of high enough technical or psychometric quality across the test-taker population to warrant use. Test developers and test users should collaboratively contend with the request of Messick (1975) to appraise the probable uses and future consequences of the testing program.

FAIRNESS AS ACCESSIBILITY FOR ALL TEST TAKERS

Accessibility Defined and Explored

“Optimal accessibility is implicitly promised to all” test takers (Kettler et al., 2018, p. 1), as is fairness in testing. Accessibility principles apply to instruction as the opportunity for individuals to learn the disciplinary knowledge and practices through an intended curriculum and to assessment as the opportunity for test takers to demonstrate the disciplinary knowledge and practices required by the test content (Kettler et al., 2009). Full access to instruction and assessment minimizes bias and increases fairness (Kettler et al., 2018), connecting the instruction and assessment accessibility principles directly to the notion of accessibility in the *Standards*.

Equity in access has been an important objective of federal education legislation (e.g., the Civil Rights Act of 1964 and Elementary and Secondary Education Act of 1965 [ESEA]) and case law (e.g., *Brown v. Board of Education*, 1954), particularly in the context of special education (e.g., Education for All Handicapped Children Act of 1975, reauthorized as the Individuals With Disabilities Education Act [IDEA] in 1990). A large body of legislative and federal laws and administrative rules protects inclusion and equitable access to instruction and assessments.

Prior to the 2014 *Standards*, researchers and practitioners were exploring and clarifying the meaning of accessibility. Willingham and Cole (1997) indicated that fair tests measure the same construct for all test takers with the same meaning for all individuals in the population. More specifically, test accessibility is “the degree to which a test and its constituent item set permit the test taker to demonstrate his or her knowledge

of the target construct” (Beddow, 2012, p. 98). These definitions are consistent with the notions of fairness in the *Standards*, and here we embrace the definition offered by Beddow.

Test score error variance due to accessibility barriers could originate from physical, perceptive, receptive, emotive, and cognitive sources, sources that may be linked to test or item characteristics, administrator characteristics, or administration contexts and practices (Beddow, 2012; Elliott et al., 2018). In its most general sense, “accessibility—defined as the extent to which a product, environment, or system eliminates barriers and permits equal use of components and for a diverse population of individuals—is necessary for effective instruction and fair testing” (Elliott et al., 2018, p. 1). In the broader context of fairness, we include potential accessibility-limiting sources due to social, cultural, and linguistic contexts and other construct-irrelevant characteristics of test takers, not directly addressed in the sources previously discussed. In particular, accessibility principles that recognize the unique challenges of ensuring that assessments are accessible for Indigenous populations are promising. For example, Hawaiian educators developed principles for Hawaiian culture-based education focused on the purpose of the test, the design and content of the test, the context in which the test is conducted, and how the results are used (Nā Lau Lama, 2007). This work resulted in tests that embodied shared meanings, aligned with the Indigenous elements in the curriculum and language of instruction (in some cases, bilingual instruction), and sustained culturally grounded practices such as *hō’ike*, which includes meaningful authentic tasks (Nā Lau Lama, 2007).

Accessibility Factors That Affect Fairness

There are three components to accessibility relevant to test fairness, including access skills, target skills, and adaptations (Ketterlin-Geller, 2008; Kettler et al., 2018). Test takers need access skills to allow them to perform well on tests, skills that we often take for granted and assume are present prior to testing. In most cases, such skills are developed through test-taking experiences, including informal classroom tests, and sometimes through test preparation courses or training programs. In some cases, test preparation can help level the playing field and secure an equitable level of test-taking skills across test takers. A common recommendation when employing new item types or preparing test takers with little test-taking experience is to provide opportunities for students to practice so that they can know what is expected and how to interact and respond to test items. However, there are limits to test preparation, where some activities may cross ethical boundaries and cause inferences to be invalidated and, as such, not support fairness as accessibility. These include, as the most egregious, releasing and practicing on operational items or focusing effort on studying released test content and items over a deeper exploration of the learning objectives emerging from content standards on which the test is based. However, as suggested previously, some practice may be useful for those unfamiliar with the item formats or tasks.

Test takers need to explore, understand, and employ disciplinary knowledge and skills required to perform well on a specific test given the targeted knowledge and skills intended to be measured. Much of this chapter addresses accessibility to target knowledge and skills. There is a substantial literature on the accessibility of instruction to support opportunity to learn (Kettler et al., 2018). And in some cases, accommodations or modifications are needed to facilitate access to both instruction and testing. One area of persistent challenge is the degree to which the disciplinary knowledge and practices are culturally or linguistically relevant to the test taker—making explicit the limited degree to which a construct or domain is defined and represented in instruction, in practice, and on the test.

What do we mean by “the degree to which a test and its constituent item set permit the test taker to demonstrate his or her knowledge of the target construct” (Beddow, 2012, p. 98)? Our operational definition of accessibility has a hidden component of significant ambiguity—the target construct. We may simply accept the test developer’s target domain (construct) as declared in the test specifications. Or, we might ask: Does the domain definition prohibit the possibility of allowing some test takers to demonstrate their disciplinary knowledge and skills from culturally and linguistically relevant disciplinary knowledge and practices? In the United States, much of the curriculum employed in P–12 and higher education is deeply entrenched in middle-class Euro-centered and colonialist history and perspectives of what people should know and be able to do. Consider the practice of wild rice cultivation (a centuries-long tradition in American Indian communities in Minnesota), which embodies disciplinary knowledge and practices from science, mathematics, history, and agriculture and provides rich opportunities to explore reading, writing, and storytelling; test items that place subject matter disciplinary knowledge in contexts known to students make them relevant and accessible (see, for example, Randall, 2021). Culturally and linguistically relevant disciplinary knowledge and practices are important sources to secure deeper accessibility and fairness in testing via fair domain definitions. Construct and domain definitions play a critical role in test fairness and validation (Randall et al., 2023).

Others also have argued that fairness is enhanced through principles of access via adaptations, including test modifications or accommodations (e.g., Rose et al., 2005; Thompson et al., 2004; Thurlow et al., 2016; Thurlow, Liu, et al., 2013; Zieky, 2016), whereas, in some cases, fairness and validity are reduced in the presence of barriers to access or sources of construct-irrelevant variance. We emphasize the applicability of accessibility principles across the life span, in the many settings and purposes of testing. In those contexts, there are multiple levels at which tests are administered, interpreted, and used, including interpretation and use at the individual (e.g., GRE) and group (e.g., National Assessment of Educational Progress [NAEP]) levels. An important component of accessibility, when no other modifications are possible, is the appropriate provision and use of accommodations.

There are many aspects of test design, administration, and reporting and use that potentially interact with test-taker characteristics that may call into question the fairness

of test accessibility. Although test developers work to attend to every possible personal characteristic or experience in the testing process, some groups have historically faced discrimination and significant barriers to education and career opportunities. In a similar way, there are as many testing conditions and contexts under which fairness can be realized as there are potentials for barriers and interference for fair test interpretation and use. Here, we briefly describe several of the more prominent and potentially promising conditions under which fairness can be enhanced and supported. We also highlight the importance of accessibility features and accommodations for supporting fair testing and note the role of testing consequences.

Implications for Practice

Test developers and users should ensure that all test takers have adequate test-taking access skills and have access to appropriate test preparation that is available freely or at low cost. Test developers must make explicit the source of target domains and explore alternative sources of disciplinary knowledge and practices, vis-à-vis the diversity within the target test-taker population. As necessary, when additional adaptations are not possible, accommodations may be identified that fulfill the goals of access and fairness.

FAIRNESS AS ACCESSIBILITY FOR SPECIFIC GROUPS OF TEST TAKERS

Much of the history of thinking about accessibility as an avenue to fairness has grown out of concerns about fairness of testing results for specific groups of individuals. Considerations of fairness have been enhanced through principles of access (e.g., Nā Lau Lama, 2007; Rose et al., 2005; Thompson et al., 2004; Thurlow et al., 2016; Thurlow, Liu, et al., 2013; Zieky, 2016) that identify ways to reduce the presence of barriers to access or sources of construct-irrelevant variance. Accessibility principles can be applied across the life span, in the many settings and purposes of testing. In those contexts, there are multiple levels at which tests are administered, interpreted, and used, at both the individual and the group levels. An important component of accessibility has traditionally focused on the provision of accommodations and their appropriate use.

Initially, the push for thinking about how to make tests available to individuals grew out of the need to identify ways to allow individuals who were blind, who were deaf, or who had certain types of learning disabilities to take tests that would produce results that could be interpreted in the same way as the results of other individuals. We provide here an overview of the progression of work starting in the 1980s. It was not until the 1990s that discussions about accessibility began for English learners. Again, these efforts were focused almost always on accommodations. In the early 2000s, a number of states were engaged in enhanced assessment grants to transform accommodation practices and support item development and test delivery; these efforts were brought to scale in a large funding opportunity for consortia of states to develop college- and career-readiness assessments that were to be accessible to the greatest numbers of

students (Race to the Top Fund, 2009), formalizing a paradigm shift in thinking about accessibility (Larson et al., 2020). Rather than a paradigm in which accommodations were the only avenue to accessibility, accessibility became the guiding goal for all tested individuals, with tiers of support from universal design for all, to features designated for any student by an adult or decision-making team, to accommodations for students with disabilities and English learners.

It is because of the historical progression in thinking about accessibility that we first address fairness through accessibility for individuals with disabilities and then for English learners. Following these two groups, we explore how accessibility has been part of the vision for other groups, including racialized and ethnicized groups, and individuals from low socioeconomic backgrounds. There is support for such attention in the *Standards*:

For some test takers, factors related to individual characteristics such as age, race, ethnicity, socioeconomic status, cultural background, disability, and/or English language proficiency may restrict accessibility and thus interfere with the measurement of the construct(s) of interest. (AERA et al., 2014, p. 52)

However, we note that it is not racial stratification or other characteristics themselves that are the relevant factor, but the discrimination and racism that create disparities in outcomes; this is addressed more directly in the final section on accessibility through cultural and linguistic responsiveness.

Individuals With Disabilities

Early work focused on nonstandard administrations of higher education admissions testing (Laing & Farmer, 1984; Willingham et al., 1988) as the way to enable certain individuals with disabilities to participate in assessments. The researchers who examined nonstandard administrations of the ACT (Laing & Farmer, 1984) and the SAT and GRE (Willingham et al., 1988) focused on who might be eligible for accommodations and the effects of specific accommodations (e.g., statistical differences in predictive validity, reliability, factor structure, differential item functioning). During this early research, so-called nonstandard administrations (i.e., accommodations) included the use of braille, large type, and extended time.

Defining accessibility as the provision of accommodations continued for decades and early on expanded beyond college admissions exams to assessments administered to K–12 students with disabilities. Accommodations initially were defined as changes to the materials or procedures of testing that allowed students with disabilities to take tests but did not change the content or targeted knowledge and skills being measured (Pitoniak & Royer, 2001; Thurlow et al., 2003). These notions were later refined to mean changes that minimized construct-irrelevant variance and promoted the measurement of what students with disabilities know and can do, thus providing access while ensuring the validity of score interpretations and uses when accommodations are used (Bolt & Roach, 2009; Laitusis & Cook, 2007). In the *Standards*, test accommodations are

adjustments that do not alter the assessed construct that are applied to test presentation, environment, content, format (including response format), or administration conditions for particular test takers, and that are embedded within assessments or applied after the assessment is designed. Tests or assessments with such accommodations, and their scores, are said to be *accommodated*. Accommodated scores should be sufficiently comparable to unaccommodated scores that they can be aggregated together. (AERA et al., 2014, p. 215)

Use of accommodations as a means to access for K–12 students was supported through policy changes, which resulted in part from analyses of state testing policies (Thurlow et al., 1993, 1995). The 1997 reauthorization of IDEA required that all students with disabilities participate in state- and district-wide assessments with accommodations as appropriate. This requirement heightened awareness of the role of accommodations during assessments and, in turn, their use during instruction and their implications for score interpretation and use (Heaney & Pullin, 1998). It also led, after considerable study, to the provision of accommodations in NAEP (Lawton, 1995; Olson & Goldstein, 1996).

Concern about access to the general education curriculum and assessments through the availability of accommodations in instruction and during testing has generated a rich body of research (e.g., Buzick & Stone, 2014; Cawthon & Leppo, 2013; Gregg & Nelson, 2012; Laitusis & Cook, 2007; Thurlow & Kopriva, 2015). Extensive work has improved the analyses of state assessment accommodations policies (e.g., Lazarus et al., 2009) and documentation of the percentage of students with individualized education program (IEP)-assigned accommodations (see Thurlow & Wu, 2019).

In 2004, the reauthorization of IDEA required states to report on the number of students with disabilities receiving accommodations during statewide assessments. These data revealed the large variation in the percentage of students with disabilities who are assigned accommodations across states (Thurlow & Wu, 2019), which, depending on the grade and subject area, could range from as little as 0.7% to as high as 89.9% of students with disabilities. They also provided information about differences in accommodations assigned for reading and mathematics tests and by grade level. Unfortunately, only state-level data for general education assessments are available; those data do not provide information on whether this type of variability exists for students who have the same disability category label.

Researchers, through hundreds of studies, have focused on a wide array of accommodations (e.g., read aloud, text to speech, sign language, word prediction) for these test takers and examined not only the effects of accommodations, but also the results of surveys about their use. A substantial body of research has been accumulated on the effectiveness of accommodations for individuals with disabilities. Phillips (1994), in presenting a case for defending the validity of accommodations, asked, “Would non-disabled examinees benefit if allowed the same accommodation?” (p. 104), where an affirmative answer would suggest that the accommodation may not be defensible. The differential-boost hypothesis (Fuchs et al., 2000) proposed that an accommodation

that increases accessibility for individuals with unique needs should result in higher scores for individuals with disabilities but not for individuals without disabilities. Later, this hypothesis was replaced with the interaction hypothesis (Sireci et al., 2005), which proposed that the increase in performance would be greater for individuals with disabilities than for other individuals, but that the scores of all test takers might increase some.

Several meta-analyses and reviews have been conducted to aggregate the effects of accommodations for individuals with disabilities (Buzick & Stone, 2014; Gregg & Nelson, 2012; Rogers et al., 2014, 2016, 2019, 2020). Although it was generally reported that accommodations do in fact make a difference in the performance of individuals with disabilities, those effects varied in complex ways across test subject matter, the nature of the accommodation, and the ways in which accommodations were administered.

The singular focus on accommodations for access and fairness changed in the 1990s when advocates realized that accommodations were not a sufficient mechanism for providing access for some students with disabilities. In 1997, IDEA required that states develop (by the year 2000) alternate assessments for those students who were unable to participate in the general assessment with or without accommodations. The evolution in the development of these alternate assessments covered years in which there was confusion about the performance standards of other alternate assessment options that had been allowed by policy and regulations, such as alternate assessments based on grade-level achievement standards (Quenemoen, 2009; Wiener, 2005) and alternate assessments based on modified achievement standards (AA-MAS; Lazarus et al., 2015). The AA-MAS generated concerns about lower (inequitable) levels of expectation (Thurlow, Lazarus, & Bechard, 2013) and psychometric quality (Rodriguez, 2009, 2011); eventually, the regulation allowing it was rescinded (U.S. Department of Education, 2015), just months before the enactment of the Every Student Succeeds Act (ESSA, reauthorization of ESEA), which disallowed any alternate assessment other than the alternate assessment aligned to alternate academic achievement standards (AA-AAAS) for ESSA accountability purposes.

ESSA clarified that the AA-AAAS is appropriate only for students with the most significant cognitive disabilities. Because *students with the most significant cognitive disabilities* is not an IDEA disability category, states are required to develop their own guidelines and definitions (Thurlow et al., 2019). Researchers have found, though, that students who participate in AA-AAAS tend to have intellectual disabilities, autism, and multiple disabilities (though not all students in those categories have the most significant cognitive disabilities), and yet still vary widely in their characteristics (Erickson & Geist, 2016; Erickson & Quick, 2017; Kearns et al., 2011; Towles-Reeves et al., 2009).

Further, ESSA clarified that students with the most significant cognitive disabilities are to be taught and assessed on the same content standards as their peers without disabilities, although possibly at reduced depth, breadth, and complexity. The test development community has been challenged by the need to develop AA-AAAS

appropriate for the range of students in this group, with the goal of producing results that support fair and valid test interpretations and uses. Despite these challenges, AA-AAAS are held to the same requirements as other tests for design and development that supports fair and valid test interpretations and uses (U.S. Department of Education, 2018). Much has been learned in the process of developing AA-AAAS that meet these requirements (e.g., Thurlow & Quenemoen, 2016), yet the expansion of what accessibility means for these students continues to be a challenge. The progression of thinking about accessibility for school-age students with disabilities leads to the argument that, for certain individuals, access could mean different standards for performance, in part because of the possibility of differences in disciplinary knowledge and skills covered in instructional practices and tailored approaches to learning to meet individualized learning goals, as well as extended learning periods through age 21 and beyond. This shift in thinking has not (yet) drifted into other assessments and other individuals being assessed.

As noted earlier, nonstandard administrations began in the 1980s with attention to accessibility for individuals with disabilities outside the K–12 school system. By 1990, the Americans With Disabilities Act required that any business or agency receiving federal funds had to make accommodations available. It stipulated

(A) making existing facilities used by employees readily accessible to and usable by individuals with disabilities; and (B) . . . acquisition or modification of equipment or devices, appropriate adjustment or modifications of examinations, training materials or policies, the provision of qualified readers or interpreters, and other similar accommodations for individual with disabilities. (42 U.S.C. 12/11, Section 101[9])

Clarification of the individuals who qualified for accommodations was provided in the 2008 reauthorization of the Americans With Disabilities Act; this clarification was viewed as broadening the population of individuals with disabilities who were eligible for accommodations in higher education and the workplace. Because of concerns about the provision of these accommodations in practice, the U.S. Government Accountability Office (USGAO, 2011) issued a report calling for improved federal enforcement of the right to testing accommodations. It brought renewed attention to the role of accommodations regardless of age, as well as to the decisions made about whether to provide accommodations to individuals:

Given the critical role that standardized tests play in making decisions on higher education admissions, licensure, and job placement, federal laws require that individuals with disabilities are able to access these tests in a manner that allows them to accurately demonstrate their skill level. While testing companies reported providing thousands of test takers with accommodations in the most recent testing year, test takers and disability advocates continue to raise questions about whether testing companies are complying with the law in making their determinations. (USGAO, 2011, p. 29)

Attention to college admissions testing continues to increase, in part because of state adoptions of college admissions tests since the NCLB act required high school state-wide assessment. This attention is to a broader array of individuals with disabilities and a broader set of accommodations. Although testing companies report providing thousands of test takers with accommodations, test takers and disability advocates continue to question whether testing companies are complying with the law in making their determinations (USGAO, 2011).

Including the K–12 and higher education systems, individuals with disabilities comprise about 13.6% of the population (2021 American Community Survey; U.S. Census Bureau, 2023). These individuals are, at various times in their lives, taking tests. For example, the number of individuals with disabilities taking the Praxis II tests for educators is increasing (U.S. Department of Education, 2010). Estimates of overall participation of individuals with disabilities in credentialing exams are not available (van den Heuvel et al., 2016).

Attention also has been given to considerations for individuals with disabilities taking other types of tests, particularly those used for career decisions (Nester, 1993), including law exams (Eichorn, 1997; Thurlow et al., 1997) and medical exams (Little, 1999), to name a few. These early works almost exclusively focused on a concern about giving test takers an unfair advantage by providing them with accommodations during testing (Phillips, 1994).

We acknowledge that early employment of accommodations was an important vehicle to provide access to tests for many individuals. However, in the spirit of fairness through access, these earlier attempts were not sufficient for many to accurately and meaningfully represent their disciplinary knowledge and skills in ways that were relevant and responsive to the purposes of the tests.

The addition of alternate assessments was one way to provide access to assessments for those students with more significant or challenging disabilities. Still, over time, this access avenue was limited by federal law to a very small percentage of the student population, thus limiting their potential as a general accessibility approach. In addition, universal design principles have received partial attention rather than full application and use in a way that would eliminate much of the need for accommodations. Part of the hesitation may be due to the need to document the access needs of students with disabilities, which are generally documented on IEPs as accommodations. Further, it is only recently that other avenues to access, such as computer-adaptive tests, have attempted to conform to a person's ability level by focusing item selection to optimally locate the person on the ability continuum (reducing the need to administer items that are too hard or too easy and thus less informative). A major limitation with computer-adaptive tests is that they select from items that are limited in scope, modality, and format, as constrained in the item and test specifications. As of yet, there are not computer-adaptive tests that either select or build tasks (through automated item generation or the use of artificial intelligence) that acknowledge how the test taker might best engage in an assessment of their content knowledge and skills.

Universal Design

Universal design is largely known in the assessment industry through descriptions in the *Standards* and publications of the National Center on Educational Outcomes (Thompson et al., 2004, 2005), referred to as UDA throughout this chapter. In the *Standards*, UDA is described as a means to maximize fairness by defining constructs precisely, avoiding item or test characteristics that may introduce construct-irrelevant variance specific to some groups, and being intentional about selection of font size, administration time, and linguistic load, among others. In addition, UDA calls on test developers to “avoid item contexts that would likely be unfamiliar to individuals because of their cultural background” (AERA et al., 2014, p. 58).

CAST was founded in 1984 and has championed UDL. Although they have undergone revision over time, CAST promotes UDL guidelines to secure access and participation of all learners in challenging and appropriate learning opportunities. The guidelines are based on the why, what, and how of learning, through the provision of multiple means of engagement (stimulating and motivating learning), representation (presenting content in multiple ways), and action and expression (differentiating ways for students to express their knowledge and skills). In 2020, CAST initiated a community-driven process to revise the UDL guidelines (<https://udlguidelines.cast.org/>), with attention to equity, inclusion, and fairness. These guidelines are much broader than those for UDA and explicitly enable culturally and linguistically responsive approaches to assessment through the acknowledgment of multiple ways (means) of knowing and doing (we address this directly in the final section).

Implications for Practice and Research

Test developers and users should employ the principles of UDA and UDL for test and assessment development and administration and, as a corollary, encourage the use of UDL to enhance accessibility of instruction and learning experiences. Test developers and researchers should support research programs addressing the effectiveness of the application of UDA and UDL, particularly regarding the extent to which more intensive applications of these principles might reduce requests for accommodations. In addition, state and federal education leaders should intensify efforts to develop high-quality AA-AAAS as a positive direction to achieve accessibility and acknowledge important differences in how some individuals learn, access disciplinary knowledge and skills, and convey what they know and can do.

English Learners

English learners emerged as a group that required special consideration for inclusion in K–12 education testing programs almost immediately after concerns were initially raised about the exclusion of students with disabilities (see August & Hakuta, 1994; LaCelle-Peterson & Rivera, 1994). In general, in the United States English learners are students whose native language is not English and who are eligible for English language development services. They have difficulties in reading, writing, speaking, or listening

in English that are severe enough to deny them the ability to achieve in classrooms where the language of instruction and assessment is English (National Center on Educational Outcomes, 2020). These characteristics result in difficulty accessing not only the content of instruction but also the assessments designed to measure their content knowledge and skills, as well as their English language proficiency.

In the K–12 education system, identified English learners are eligible to receive English language development services, with the expectation that eventually they will leave English learner status because they have gained proficiency in English reading, writing, speaking, and listening (Linguanti et al., 2013), thus being prepared to fully participate in English-instruction classrooms. Researchers have estimated a 3- to 7-year period to develop academic English proficiency to support schooling, with a slightly longer time for older immigrant English learners, with a shorter range of 3 to 5 years for oral proficiency and a longer time given socioeconomic background and age of immigration (Collier, 1989; Garcia, 2000; Hakuta et al., 2000).

English learners have been the subject of research on assessment accessibility. In part, this attention followed the attention given to students with disabilities, and much of the research has been carried out in the K–12 school system. Similar to individuals with disabilities, access to the curriculum and to assessments is a concern for English learners. Increasingly, researchers focused on the effects of various accommodations for English learners (e.g., Abedi & Hejri, 2004; Abedi et al., 2000, 2004; Kopriva et al., 2016; Kosak-Babuder et al., 2019). A substantial body of research has been accumulated on the effectiveness of accommodations, following a similar methodological path from a differential-boost hypothesis to an interaction hypothesis for these students. A number of meta-analyses and reviews also have been conducted to aggregate the effects of accommodations for English learners (Kieffer et al., 2009; Li, 2014; Liu et al., 2018; Vanchu-Orosco, 2012). Findings generally are less promising for English learners than for students with disabilities, but still vary in complex ways across test subject matter, the nature of the accommodation, and methods of accommodation administration. In a systematic review, Rios et al. (2020) reported that for the most part, accommodations used with English learners lacked evidence of effectiveness; most were accommodations employed for individuals with disabilities.

Researchers confirm that accessibility is a broad issue that applies beyond school years. With the National Education Longitudinal Study (National Center for Education Statistics [NCES], 1988), researchers revealed that 12 years after their eighth-grade year, only about 13% of English learners had earned a bachelor's degree, compared to 25% of non-English learners (Kanno & Cromley, 2013). Attention to the college-entrance assessments that these and other students take to gain access to postsecondary education is increasing (e.g., Moore et al., 2018), yet remains underdeveloped.

There is a growing body of work that supports the use of bilingual or multilingual assessments, in cases where English would be the language of instruction and assessment. Bilingual assessment can take multiple forms (Caesar, 2020). On a minimalist

side, with digital delivery of tests, the test developer can embed a translation dictionary in the test by enabling a hover-over dictionary tool (or some other process to get immediate translation of each word in a test). A more encompassing approach is to provide a bilingual experience, where items are presented in a native language and English simultaneously (e.g., side by side). Bilingual assessment embodies the characteristics of accessibility by opening up access to the test and test questions by eliminating the barriers due to language (e.g., see efforts with the National Assessment of Educational Progress; NCES, 2023).

Another approach is to create assessments in multiple languages, as done with the international assessment survey programs (e.g., Trends in International Mathematics and Science Study [TIMSS] of the International Association for the Evaluation of Educational Achievement), especially in contexts with non-English instruction, including in learning settings that are engaging in language revitalization and immersion. Multilingual assessment efforts require additional layers of psychometric analyses to ensure score comparability because the explicit intention is for international comparisons of disciplinary knowledge and skills. Testing programs develop and deploy common content frameworks that are used to develop test specifications through which items are developed and translated into dozens of languages.

When the intent is to provide optimal access, translation makes sense. But in the United States, where the primary language of instruction is English and although there is no official national language, most state testing programs function under an assumption that an important outcome of education is proficiency in English (implied by federal school accountability regulations). However, there are states that test in multiple languages at various grade levels in both reading and mathematics to accessibly measure disciplinary knowledge and skills without the interference of English language proficiency. At least one other state, Hawaii, has encompassed Indigenous language knowledge and practices into state achievement content standards and thus has included tasks relative to Indigenous language in the state achievement tests. There are a growing number of examples of the inclusion of Indigenous language knowledge and practices in national assessment programs across the globe (e.g., Guatemala, New Zealand, Canada, and Australia).

The National Council on Measurement in Education (NCME, 2020) statement on testing with English learners promotes an approach to test development and administration that acknowledges specific factors relevant to these learners. The statement emphasized consideration of the following: (a) language is culturally grounded because culture is often expressed through language; (b) when possible, the language of the test should be consistent with the language of instruction; (c) test administration modes should be familiar for English learners; (d) English receptive and productive language skills should be strong enough to provide full access to the test; and (e) the presence of special needs or disabilities further complicates test accessibility. With greater understanding of the nature of English language development, test developers will achieve greater fairness in testing for all students.

Faulkner-Bond (2020) argued for the consideration of the language of test takers relative to disciplinary language that may be embedded in the test. She recommended oversampling English learners in test development and validation processes to gain deeper understanding of the role of language uses in local settings, in instruction, and within disciplines, as well as discipline-specific language use in the articulation of content standards (how we describe what test takers are expected to know and be able to do). The fundamental ways test takers come to learn and understand disciplinary content and practices are influenced by local contexts, sociocultural contexts, instruction (as practiced locally), and other ways. The operational assumption that test scores are not influenced by language proficiency not only ignores these contexts, but also ignores that we often know less about the language proficiency of non-English learners than we do of English learners. After reviewing the structure and results of several assessments of English language proficiency, regarding comparability, Faulkner-Bond suggested that the focus should be on comparability of uses and interpretations rather than psychometrics, as well as on how proficiency is defined and measured.

Finally, there is growing recognition that native language skills are important to not only sustain, but also continually develop, particularly in early childhood (Duran et al., 2019; Wackerle-Hollman et al., 2019, 2022). In addition, most states award a seal of biliteracy

in recognition of students who have studied and attained proficiency in two or more languages by high school graduation . . . to help students recognize the value of their academic success and see the tangible benefits of being bilingual. (<https://sealofbiliteracy.org/>)

Sufficient evidence exists to support multilingual development, begging the question as to why so many tests continue to be administered in English only.

Implications for Practice and Research

Test developers and users should consider the role of language of instruction, language proficiencies in test and native languages, native and test language similarities, availability of validity evidence to support score interpretation and use, evidence regarding fairness, possible presence of specific disabilities, quality of English learner identification, and quality of language instruction and supports. They also should appreciate and recognize the sociocultural contexts in which students live and learn, from test and assessment design to score reporting, interpretation, and use. The research basis for the use of accommodations with English learners is inconsistent and limited, with stronger promise based on research with forms of bilingual assessment—an area that deserves additional attention, consistent with the goals of accessibility and UDL.

Racialized/Ethnicized Groups

Because of the persistence of disparities between racialized and ethnicized groups in education opportunities and outcomes, federal legislation required states to report

on the education achievement levels of major racialized or ethnicized groups. We acknowledge that these persistent disparities are largely driven by oppression and racism, limiting education access and opportunities. Because of this, federal legislation has been used as a tool to ensure education access and opportunities. As part of President L. B. Johnson's War on Poverty, the ESEA authorized the federal government to direct federal dollars to the most disadvantaged children through state governments, resulting in wide expansion of state departments of education. Through the 1994 reauthorization of ESEA as the Improving America's Schools Act, states were required to implement challenging content and performance standards and state assessments of them; to include all students in them; to report on performance broken down by racialized and ethnicized status, gender, English proficiency, migrant status, disability, and economic status; and to hold schools accountable. Because many states either did not recognize the requirements or chose to ignore them, the 2001 reauthorization of ESEA, the No Child Left Behind Act (NCLB), significantly increased the Title I accountability requirements with sanctions for failure to do so. States were required to establish grade-level content standards and assessments of achievement of those standards; to report performance (achievement proficiency rates) of students by racialized and ethnicized status, and socioeconomic status, as well as English learners and students in special education; and to hold schools accountable for adequate progress toward the standards (see Ho & Polikoff, this volume).

When investigating fairness and equity in education opportunities and outcomes, racialized categories have been employed for decades (Bohrnstedt et al., 2015; Coleman et al., 1966; Cottrell et al., 2015), with some evidence that standardized testing may play a role in reinforcing segregation (Knoester & Au, 2015). In this work, the concept of race implies a history of housing segregation (resulting in education and occupation disparities) that is connected to occupation segregation (resulting in income and health disparities) that is connected to education segregation (resulting in occupation disparities)—cycles of segregation that limit access to education and career and life opportunities (Cottrell et al., 2015). We note that these cycles are the product of oppression and racism that further the reproduction of disparate opportunities and outcomes. Race and ethnicity are relevant to the extent that they reflect different levels of performance, as an outcome of racism, and such differences call into question qualities of the test itself or result in exacerbating existing disparities and inequality through unintended negative consequences. For example, in 1969, the Association of Black Psychologists called for a moratorium on testing Black children because of disproportionate placement in special education and developmental settings (a result of discrimination and racism), further excluding them from general education opportunities (Garrett Holliday, 2009).

Perhaps the most significant regulations regarding the role of racialized status in education outcomes came in the NCLB reauthorization of ESEA in 2001. President George W. Bush called on the country to end the soft bigotry of low expectations,

acknowledging that achievement gaps have persistently fallen along racial and socioeconomic lines. However, Bush mistakenly argued that education achievement gaps produced discrimination, arguing for a causal direction that was inconsistent with the vast body of evidence indicating the opposite (Rubel & McCloskey, 2019). Through the rules and regulations from NCLB, states were required to report student group performance on academic standards-based tests based on racialized and ethnified status, socioeconomic status, English learner status, and special education status. This was the first federal requirement for states to report on and respond to student group performance that was rigorously enforced, with a requirement that to be counted as achieving adequate yearly progress, 95% of students had to participate in the state's assessments. Prior to this, some students often were exempted from participation because of various exceptionalities, particularly for students receiving special education services (McDonnell & McLaughlin, 1997) or English language services (August & Hakuta, 1997).

Substantial research has addressed the associations between concentrated poverty and segregation in schools with disparities in education supports, lower expectations, increased disciplinary actions, and education achievement and school completion. Even though the nation's diversity continues to increase, schools in the United States are becoming increasingly more segregated, with some regions returning to pre-civil rights levels of segregation (Frankenberg et al., 2019; Reardon et al., 2019); again, we note that racial segregation is a direct result of oppression, discrimination, and racism. Using data from NAEP, it is clear that school achievement test performance is strongly associated with school composition or segregation (Bohrnstedt et al., 2015), where in the United States,

- on average, White students attended schools that were 9% Black, whereas Black students attended schools that were 48% Black;
- schools with greater than 60% Black students tended to be located in urban areas and in the South and the Midwest;
- achievement was lower for Black and White students in schools that had the highest Black density but achievement gaps were not different regarding levels of Black density of schools; and
- the magnitude of achievement gaps, given Black student density of schools, was smaller when accounting for socioeconomic status (SES) and other characteristics, but was still nonignorable.

Many of the challenges that exist regarding racial stratification and educational testing are a function of inappropriate test interpretation and use, which are too often intertwined with discrimination and racism. We acknowledge that, in most settings, test use can provide a deeper understanding of individual and group knowledge, skills, and abilities and inform nearly all education decision-making. However, to realize the potential advances brought about by the use of educational tests, fairness must be secured. Part of the challenges that exist regarding racial stratification and educational testing are the

continued limitations of accessibility, particularly those associated with limited cultural and linguistic relevance of tests to culturally and linguistically diverse communities (this topic is discussed more fully in the section “Accessibility Through Cultural and Linguistic Responsiveness”).

Implications for Practice and Research

Test developers and users should secure the highest levels of scrutiny of test score quality and fairness. However, our current approach to test development and analysis is limited in the accessibility sense because of the exclusion of considerations for cultural and linguistic backgrounds of intended test takers. Education disparities have a deep and long history rooted in racism, which results in segregation and cycles of poverty. Federal requirements to report achievement levels by race and ethnicity uncover these disparities to some extent, and tests such as NAEP have been important indicators of the nation’s progress in addressing achievement disparities and the opportunity gaps producing them. To eliminate large-scale testing because it reflects disparities in opportunity would eliminate an important public policy indicator. However, to use such tests without acknowledging the contexts of racism and racial segregation could result in decisions that maintain segregation and continue to limit access to opportunities.

Socioeconomic Disadvantage

As with racial stratification, disparities in education opportunities and outcomes for students with different levels of SES have been a persistent challenge. SES also has a long-lasting trend connected to segregation and multigenerational poverty (Sharkey & Elwert, 2012). The authorization of ESEA was primarily focused on eliminating poverty through increased education opportunities, and reauthorizations through the Improving America’s Schools Act, NCLB, and ESSA maintained the focus on students and schools that experienced persistent disadvantage.

James Popham has long argued for the instructional relevance of testing and assessment. In his work on instructional sensitivity of tests, he argued that instructional insensitivity could result from items that produced correlations between item response and SES, where wealthier students would be more likely to respond correctly (Popham & Ryan, 2012). Popham (2007) argued that the SES composition of schools explained more variance in student performance on accountability tests than the effectiveness with which students have been taught or teachers’ instructional efforts. This position is consistent with decades of research where researchers reported that most of the variance in student achievement scores exists within schools rather than between schools, and most of the between-school variance is explained by school demographics resulting from segregation and not indicators of school quality (Coleman et al., 1966; Rodriguez & Nickodem, 2018).

We also acknowledge that SES and racial stratification are highly confounded because there exist significant disparities in wealth as a function of racial stratification, a trend

that continues to grow, as has the wealth gap between the richest and poorest families in the United States (Schaeffer, 2020). SES is clearly a construct-irrelevant factor, yet to the extent that it explains variation in access to opportunities and resources, it explains variation in achievement. Once again, elements of segregation and oppression are intertwined with cycles of poverty and limited access to opportunities that may provide greater education and social mobility.

Test Takers Facing Multiple Access Needs

Aspects of test development and administration that limit accessibility to some individuals with certain characteristics associated with education inequity and disparities tend to affect performance for multiple reasons, in part because of the multilayered and intersectional nature of disparities resulting from discrimination and oppression. For example, in 2015–2016, the percentage of students served through IDEA (special education services) was highest among American Indian/Alaskan Native students (17%) and Black students (16%) relative to White students (14%; NCES, 2019). Similarly, in 2016, 24% of Black and Latino children under the age of 18 were in families at or below the poverty level (based on the supplemental poverty measure), relative to 8% of White children (NCES, 2019). In addition, in fall 2017, 45% of the nation's Black and Latino students attended high-poverty schools (more than 75% eligible for free or reduced-priced lunch), whereas 8% of White students did so; 31% of White students attended mid- to high-poverty schools, whereas 75% of Black and Latino students did so (NCES, 2021). Note the differences between poverty rates and attendance in high-poverty schools as another indicator of segregation. There are persistent disparities in SES, employment, income, stable housing, access to healthcare, and other economic indicators across racialized and ethnicized groups, all of which have implications for education opportunities and outcomes.

Although much of the discussion about fairness for specific groups of test takers focuses on one group at a time, in reality, most of the individuals in these groups also belong to other groups for which there are concerns about fairness. For example, individuals with disabilities are frequently among the group of individuals in poverty; the U.S. Census Bureau reported that the poverty rate of individuals with disabilities aged 18–64 in 2018 was 26.9%, compared to 9.5% of individuals without disabilities (Semega et al., 2020); similarly, the U.S. Department of Labor (2021) noted that “across all age groups, persons with disabilities were much less likely to be employed than those with no disabilities” (p. 1). Among school-age children, researchers also have noted the connection between disability status and some disability categories with poverty (e.g., Schifter et al., 2019). Similarly, being an English learner is often associated with poverty and may be associated with immigration status.

Interest continues to grow about how best to assess the school-age population of English learners who have disabilities because of the unique characteristics they present in achieving a fair assessment process, characteristics that most testing programs are not designed to adequately address. The population of school-age English learners with

disabilities is increasing at a higher rate than the population of students with disabilities overall (Wu et al., 2021). Historically, the access needs of these students have been addressed in one of two ways. First, these students often have been treated as having special education needs in ways that eclipsed their need for English language development services and accessibility supports (National Council on Disability, 2018). This meant that when they were assessed, consideration was given to the disability access needs but not to their limited English needs. Second, as the access needs of English learners have been recognized, educators have been asked to think of a student's needs as though the student were two individuals—addressing the disability needs first, then addressing the English language needs; if there were conflicts in accessibility supports, then, again, their disability needs would be treated as more important than their English language development needs.

For too long, attention to the access needs of English learners with disabilities only focused on those English learners who did not have significant cognitive disabilities (National Center on Educational Outcomes, 2014). Questions about how to provide assessments that meet their access needs have been raised, with little action until federal law required that these students participate in both alternate achievement assessments and English language proficiency assessments (Christensen et al., 2018; Thurlow et al., 2017; Winter et al., 2018).

Educational measurement practices regarding accessibility for students with multiple categories of access needs continue to improve. Most states provide assessment accessibility manuals that address both students with disabilities and English learners, consistent with the recommended approaches of the Council of Chief State School Officers (Lazarus et al., 2021). However, these efforts are less likely to be occurring beyond testing in K–12 education settings, such as higher education admissions assessments (Lazarus & Thurlow, 2016) and certification and licensure assessments (Lazarus et al., 2017).

Implications for Practice

Test developers and users should analyze the role of disabilities, English learner status, racial stratification, living in poverty, and other public policy relevant characteristics, simultaneously or in combination to obtain a clear picture of item and test performance in complex social contexts. For example, they could employ or create methods to disentangle certain learning disabilities and English learner status because the natural process of being a multilingual learner may present behaviors that appear to indicate language delays. Additional recommendations are provided in the following sections regarding the role of differential item functioning and measurement invariance analyses. In the prevailing empirical research paradigm, we test interaction terms before testing and interpreting main effects. If the association between X and Y depends on Z , then the main effect of X is misinterpreted without considering the level of Z . In some cases, the multiple effects of X and Z on Y are additive or even multiplicative, and possibly nonlinear.

REALIZING FAIRNESS THROUGH TEST DEVELOPMENT

Test Development

Fairness finds its introduction in the earliest test development stages, from conceptualization to administration. Principled assessment design (PAD; see Huff et al., this volume) provides a flexible and explicit comprehensive approach to test development that acknowledges the important roles of UDA and fairness principles. As described by Huff et al., PAD requires the definition of the construct or domain to be based on disciplinary learning science evidence of how individuals learn and develop disciplinary knowledge and skills. Second, PAD requires “the explicit articulation of all assumptions, design decisions, and rationales for those decisions” (p. 446) through the employment of a coherent set of design tools. Third, PAD also makes explicit the reality that assessment is a process of reasoning from imperfect evidence, but when the evidence is grounded in principled design, tests can meet their most challenging purposes. Huff and colleagues acknowledge the relevance and connections between accessibility and culturally and linguistically responsive approaches to test development, noting that “without the precision and transparency demanded by the PAD process, incorporating accessibility and culturally and linguistically responsive features could jeopardize the validity of the inferences about what students know and can do” (p. 494). The authors also argue that evaluation of cultural and linguistic responsiveness is not done one item at a time, but across an item pool or an entire test form. In addition, accessibility and cultural and linguistic responsiveness are associated with motivation and engagement, which further enhance accessibility for all students.

Embedded in PAD are principles of UDA (Ketterlin-Geller et al., 2015; Thompson et al., 2002, 2004), which require test developers to fully consider and embrace all possible test takers during each stage of test development, beginning with the clarity of the construct definition or domain. Particularly when considering the purposes driving the development of a test and the construct definition stages, the extent to which purpose and construct definition apply consistently to all test takers will support fairness. Principles of accessible measurement (Beddow, 2012) also require greater attention to construct definition, to prevent many instances of differential item functioning and promote measurement invariance. In addition, while addressing the assessment of achievement with a focus on classroom assessment, Shepard et al. (2018a) reminded us of the importance of context:

All learning is fundamentally social, involving the individual's use of shared language, tools, norms and practices in interaction with his or her social context. . . . Sociocultural theory offers a powerful, integrative account of how motivational aspects of learning—such as self-regulation, self-efficacy, sense of belonging, and identity—are completely entwined with cognitive development. (p. 23)

This position has implications for domain specification and test development. Construct or domain definitions are often underdeveloped (naturally limited because of the lack of inclusion of diverse developers or narrow specification of disciplinary knowledge and practices), from classroom and state achievement tests to professional certification

assessments. In their argument centering on the role of sociocultural learning theory as a way to bring coherence to curriculum, instruction, and assessment, Shepard et al. (2018a, 2018b) argued that assessments designed to facilitate inferences about learning must be constructed with research-based models or theories of learning (the first component of PAD).

Regarding test development, fairness can be improved through explicit attention to fairness guidelines (Zieky, 2016) and quality assurance procedures (Allalouf, 2007, 2011, 2017) in the professional practices that produce test blueprints and specifications, item specifications, item-writing and -editing guidelines, item-writer training, item review processes, test assembly and review, scoring rules and computational procedures, and item and test analyses procedures of field-test and operational administration results (Oliveri & von Davier, 2016). Item-writing guidelines exist that specifically promote greater accessibility and fairness (Haladyna & Rodriguez, 2013; Rodriguez, 2011; Rodriguez et al., 2014; Zieky, 2016; see also ETS, 2022). Given the many approaches and stages of test development, the process should be a collaborative effort, rather than a linear staged process, through which fairness practices are shared among individuals with diverse experiences and expertise (Rodriguez, 2016).

As an example of accessibility-focused test development (or redesign), Wolfe and Gitomer (2001) demonstrated how domains can be made more accessible through improved assessment design and scoring. They focused their work on the National Board for Professional Teaching Standards' certification assessment of accomplished teachers, which includes a portfolio component where candidates provide evidence of accomplished practice, as defined in the standards. To do this, they set out to simply reduce the guessing candidates often engage in, trying to figure out (guess) what will be scored and what makes a difference. By explicitly describing how responses are scored and providing guidance to optimize decisions regarding the construction and content of the portfolio, they brought depth and clarity to the domains being assessed. In addition, they introduced additional structure to the assessment prompts and improved scoring by allowing for more benchmarks and training samples, rater training on bias, and rubric improvements.

Implications for Practice

Test developers and users should employ the principles of UDA and UDL through the PAD approach, perhaps in ways that go beyond surface features of tests and address the core aspects of domain specifications and inclusion of culturally and linguistically relevant disciplinary knowledge and practice (see final section). PAD holds great promise as a test development process that centers accessibility; accessibility features in PAD should be amplified.

Innovations in Item and Task Development

With widespread use of computerized testing and remote or cloud-based delivery, test developers have explored many alternatives for item formats. We use the term technology enhanced (TE) to describe such items, but other terms essentially describe

the same notions, including innovative and interactive items. In part, the purposes of TE item development are to create opportunities for test takers to interact with items and tasks to deepen the domain representation, tap difficult-to-measure higher order cognitive processes, represent pedagogically relevant features, include multimedia components expanding the sources of stimulus materials and reduce text dependence, employ more authentic contextualized elements in the test, allow for a wide variety of response modes, and increase test-taker motivation and engagement. These not only are goals of item development, but also become components or assumptions underlying the interpretation of item responses and test performance and introduce questions of accessibility and fairness.

There are too many forms of TE items to create an exhaustive list (see Bennett et al., this volume). However, some TE item features have become more commonplace in large-scale testing, including the use of drag and drop (structured or freeform), hot spots (clickable regions on images and displays or among listed options), figural drawing, ordering and sorting, and the use of a wide range of interactive tools such as balance beam, measuring devices, thermometer, telescope, compass, and even science lab equipment (virtual simulations). Russell and Moncaleano (2019) reported on the prevalence of various item types. They found that approximately 40% of 236 TE items that were released by large-scale K–12 education test programs aligned with a high level of domain fidelity, whereas nearly 40% provided low domain fidelity. This indicated potential challenges of TE items to meet the construct and domain definition clarity required by UDL and PAD.

One tool to support these efforts is the Technology-Enhanced Item Utility Framework (Russell, 2016; Russell & Moncaleano, 2019), designed to examine the fidelity with which TE items represent the intended construct. The framework enables TE item evaluation through structured human judgment regarding usability and accessibility, as well as construct fidelity.

Validity research has lagged behind the advances in item and test delivery innovations, in part because item developers often create tasks and sometimes deploy them without sufficient validation beyond psychometric item analysis. Early investigations of TE items addressed questions of psychometric properties and efficiency (Jodoin, 2003; Zenisky & Sireci, 2002). Some efforts have been successful in identifying TE items that may or may not contribute to domain representation and support test score interpretation. This work includes, as examples, think-aloud investigations of mathematics and English language arts items (Dolan et al., 2011), examination of associations with other measures and predictive evidence for a carpal tunnel release surgery simulation (Shanedling et al., 2010), and the detection of construct-irrelevant variance in a test involving the creation of mathematical expressions (Gallagher et al., 2002).

There are critical fairness and accessibility issues that must be addressed in the design and use of TE items (Stone et al., 2015; Strain-Seymour et al., 2009), such as accessibility for individuals with vision and fine-motor disabilities. Consider, for example, drag-and-drop items—this item type requires visual, fine-motor, and hand–eye coordination skills. Most TE item formats have similar requirements, requiring the test taker

to interact with elements presented on screen, thus presenting significant accessibility challenges. A team of researchers in the Accessibility for Technology-Enhanced Assessments Project (Shaftel et al., 2015) spent 3 years investigating questions of accessibility. Employing the principles of evidence-centered design (Mislevy & Haertel, 2006; Huff et al., this volume) and UDA (Thompson et al., 2002, 2004), including UDL for technology-enhanced assessments (Dolan et al., 2013), they engaged a panel of vision and motor skill experts to consider several categories of processing: perceptual (vision, hearing, sensory modalities), linguistic (oral, written, sign, braille), cognitive, motoric, executive (engagement, attention, motivation), and affective (test-taker psychological states and moods). The researchers studied TE items in original and accessible formats, engaged students in cognitive labs, and field tested items in 11 states.

The team found that “item accessibility can be improved for all students on all item types by providing access to assistive technologies” (Shaftel et al., 2015, p. 128). They recommended that (a) instructions should explicitly declare what test takers are expected to do; (b) graphic and font features should be visually simple and large and avoid dependence on colors; and (c) tasks requiring fine-motor skills, such as scrolling, should be minimized. “These studies permit preliminary conclusions about the effectiveness and fairness of alternative item presentations” (Shaftel et al., 2015, p. 165) for students with disabilities.

Researchers addressing the accessibility challenges of TE items illustrate that cognitive complexity is not fixed and depth of knowledge interacts with specific abilities of test takers. Braille and print versions of TE items may not retain the intended cognitive demands. Similarly, as noted earlier, familiarity with item formats and response modes is an essential element for fairness and accessibility, and this may differentially impact English learners and others with limited or interrupted formal education.

Implications for Practice and Research

Test developers should secure collaboration among item writers, accessibility experts, subject matter experts, diversity specialists, psychometricians, and others, since this is essential in the design of TE items. They should engage in rigorous evaluation of item and test quality, with explicit examination of accessibility and fairness, with a focus on the extent to which the expansion of TE items and other innovations obtain responses relative to targeted knowledge and skills. Decisions about item format choice naturally have fairness implications, including standard (non-TE) item formats—test developers choosing among item formats must consider principles of fairness and access (Albano & Rodriguez, 2018; Rodriguez, 2002).

A Sociocultural Framing of Differential Item Functioning

As a standard step toward fairness, in the field-test or pilot stages of item and test development and periodically with operational data, differential item functioning (DIF) is conducted to identify items for bias and sensitivity review. The fundamentals of DIF and the uses of DIF in fairness are described by Zwick (this volume). We also

acknowledge that many existing DIF practices are based on test-taker groups with heterogeneous groupings, typically based on racialized and ethnicized status, English learner status, and special education status. Within each of these groups, there may be substantial heterogeneity that masks more important DIF results based on national original, language group or linguistic dialect group, and specific types of disabilities (Ercikan & Oliveri, 2013), as well as the needs described in the section “Test Takers Facing Multiple Access Needs.” Such efforts are typically limited because of the smaller, more specific groups of test takers resulting in samples sizes too small to support DIF methods. However, empirical approaches to identifying sources of DIF help protect us against ad hoc interpretations (Alavi & Karami, 2010; Karami & Salmani Nodoushan, 2011).

For a deeper treatment of DIF in the context of intersectionality, see Russell et al. (2022). Intersectionality provides a theoretical framework (Crenshaw, 1989), grounded within Black feminist theory, that addresses the intersections of racialized groups, gender, and other social identities, focused on the social positions within a hierarchy of social power—jointly shaping human experience (Bauer et al., 2021). In addition, Russell (2024) provided a review of DIF procedures in the context of multiple conceptualizations of justice.

Here, we explore the sociocultural context of DIF. To do so, we review three DIF studies that addressed the content and contexts of items, relative to test-taker characteristics. Social models of learning acknowledge that individual learning and cognition occurs through social interaction. Although focused on classroom assessment, Penuel and Shepard (2016) provided a summary of social and sociocultural models they deemed appropriate in the context of assessment. Sociocultural perspectives of learning extend social models into cultural spaces and acknowledge what cultural and linguistic traditions, knowledge, and practices test takers bring to the testing space (Penuel & Shepard, 2016).

An Example in Primary Education

Banks (2006) employed two culturally grounded taxonomies regarding Latino and Black cultures in the United States to identify common elements through which cultural bias could be examined in tests, while acknowledging the within-culture heterogeneity. She identified items from several large-scale tests that exemplified cultural elements. Using the Terra Nova test performance data from Latino, Black, and White fifth-grade students, Banks bundled items based on the presence of culture-specific elements in correct or incorrect options and evaluated for differential bundle functioning (correct-option culture-based item) and differential distractor functioning (incorrect-option culture-based item). Banks reported that a small number of items illustrating each cultural element limited statistical detection power. However, Banks did conclude that DIF was more likely to occur for distractors than for correct options. She also demonstrated how “cultural aspects illustrated in correct and incorrect options” (p. 131) may influence item functioning. She encouraged researchers and test developers to create more comprehensive means for classifying the cultural features of items.

An Example in Secondary Education

Stricker and Emmerich (1999) investigated the Advanced Placement (AP) Psychology examination and potential gender DIF. In their review of prior DIF research, they summarized potential sources of DIF, including familiarity with the item content, including exposure, experience, and cultural loading, as well as test-taker interest in the content and potential emotional reactions to item content. To further study such potential sources, the authors asked 717 students in 19 high school classes to rate items from the AP Psychology exam on familiarity, interest, and unpleasant affect with four-point rating scales (*not at all* to *very*). The standardized mean difference between females and males (d) was computed for each rating variable of each item and compared to Mantel–Haenszel values across items. Across the 13 content areas, gender differences in ratings for familiarity and unpleasantness were not significantly different. There were gender differences in interest ratings, where motivation, developmental psychology, and abnormal psychology were of more interest to females and biological psychology and social psychology were of more interest to males. However, these mean d effects for familiarity, interest, and unpleasantness were associated with Mantel–Haenszel means across content categories. The more that familiar and interesting items were in a content category to females relative to males, the easier the items were for females (DIF advantaging females); the more that unpleasant items were in a content category, the more difficult the items were for females (DIF disadvantaging females). The authors argued that the gender-based differences found in the AP Psychology items likely developed through differential socialization of females and males at home, at school, and in the community.

An Example in Postsecondary Education

O'Neill et al. (1993) examined the GMAT regarding the potential Black/White and female/male DIF relative to the content and characteristics of the items. Although the proportion of items with moderate to large DIF was low, they found interesting results. Regarding verbal items, they found that reading comprehension items with stimulus materials referring to Black-membered and Latino-membered people (*membered* denoting the socially derived identification of people) and those with social science content (acknowledging overlap in these characteristics) were easier for Black test takers than for the matched group of White test takers, with the opposite being true for general material (material with no reference to specific ethnicized contexts) and items with humanities and science content. Regarding quantitative items, Black test takers performed better on items focused on calculations or formulas, whereas White test takers performed better on word items requiring test takers to set up the problem and translate the words to numerical expressions to solve. In addition, Black test takers performed worse on items with business-related contexts than the matched White test takers. Black test takers also performed worse on items with 50 words or more in the stem/stimulus, whereas Black test takers performed better on items with fewer than 50 words in the stem than the matched White test takers. The authors

suggested the possible effects of differences in reading ability and the relevance of item characteristics and the enacted curriculum experienced by test takers. They noted that internal and external advisory committees should review such results to identify implications for test content.

O'Neill and McPeck (1993) acknowledged the relevance of social issues regarding DIF interpretation. They commented on differential opportunities afforded to students of color by less-resourced schools and differential treatment by teachers, as well as lower expectations for students of color, "even when all students are enrolled in the same class. Until we recognize that these education inequities exist, we will not be able to understand DIF results in the proper context" (O'Neill & McPeck, 1993, p. 276).

Implications for Practice and Research

Test developers and users should provide greater attention to the sociocultural context in which tests purport to measure academic achievement to enhance fairness with respect to accessibility, where such achievement is also embedded in sociocultural contexts (see Ercikan & Solano-Flores, this volume). An important function of DIF analyses is gained through the aggregation of lessons learned, lessons that should be turned into item and test development guidance. Test developers should design DIF analyses in ways that address the heterogeneity within groups and the relevant features of items and tests and supplement the typical item-by-item DIF flagging procedures undertaken by most testing programs. They should employ DIF analyses to achieve justice-oriented goals (Russell, 2024).

ACCESSIBILITY THROUGH CULTURAL AND LINGUISTIC RESPONSIVENESS

Given the deepening understanding of the role of sociocultural contexts in teaching and learning, and in testing and assessment (Shepard et al., 2018a), we support the use of culturally and linguistically responsive (CLR) assessment to increase accessibility.

The Role of Cultural and Linguistic Backgrounds

Accessibility can best be understood by contrasting the knowledge, skills, and abilities that reflect the construct(s) the test is intended to measure with the knowledge, skills, and abilities that are not the target of the test but are required to respond to the test tasks or test items. For some test takers, factors related to individual characteristics such as age, race, ethnicity, socioeconomic status, cultural background, disability, and/or English language proficiency may restrict accessibility and thus interfere with the measurement of the construct(s) of interest. (AERA et al., 2014, p. 52)

The first point is what Ketterlin-Geller (2008) would call differentiating target skills from access skills—although such skills may be interdependent, particularly when the

construct of interest is imbedded in real-world scenarios. The second point suggests that our humanity (individual and group characteristics and lived experiences) may restrict accessibility to the extent the construct of interest may reflect the humanity of some and not others.

The authors of the *Standards* offered general examples of how tests may limit access to the construct for some by including idiomatic phrases and regional vocabulary unrelated to the target construct or stimulus contexts unfamiliar to test takers given their cultural background (AERA et al., 2014, pp. 52–53). These test characteristics were not further explained and specific examples were not offered. Most test developers now do consider person characteristics such as, for example, blindness, dyslexia, and limited English proficiency, and do consider the potential barriers facing these test takers. These characteristics are in part the basis for UDA principles to improve accessibility, but they are limited and do not explicitly require test developers to consider the socio-cultural contexts of test takers.

A threat to fairness is in test content, vis-à-vis test-taker culture and linguistic histories. As an example, the authors of the *Standards* argued that critical reading

should not include words and expressions especially associated with particular occupations, disciplines, cultural backgrounds, socioeconomic status, racial/ethnic groups, or geographical locations, so as to maximize the measurement of the construct (the ability to read critically) and to minimize confounding of this measurement with prior knowledge and experience that are likely to advantage, or disadvantage, test takers from particular subgroups. (AERA et al., 2014, p. 54)

The authors continued:

Differential engagement and motivational value may also be factors in exacerbating construct-irrelevant components of content. Material that is likely to be differentially interesting should be balanced to appeal broadly to the full range of the targeted testing population (except where the interest level is part of the construct being measured). In testing, such balance extends to representation of individuals from a variety of subgroups within the test content itself. For example, applied problems can feature children and families from different racial/ethnic, socioeconomic and language groups. (p. 55)

We contend, as do the scholars and measurement specialists exploring CLR, that such a balance is contradictory with the earlier advice of what to avoid and destroys the value of measures of critical reading, when the readings themselves are based on narrowly defined content domains void of the cultural and linguistic realities of students. How is it possible to “feature children and families from different racial/ethnic, socioeconomic and language groups” (AERA et al., 2014, p. 55) while avoiding “words and expressions especially associated with particular occupations, disciplines, cultural backgrounds, socioeconomic status, racial/ethnic groups” (p. 54), and other contexts that make representation of different groups authentic? Giving

extensive guidance about the avoidance of sensitive materials to item writers results in little to no representation of diversity, and when representation is present, it is only in surface features of items, resulting in items and context material with diverse names and places only. The neutral content approach to item and test development is insufficient.

In fact, Randall (2021, 2023) argued that neutralizing items by eliminating any reference or expressions associated with cultural backgrounds or other contexts specific to some test takers places the item within the dominant cultural context, essentially White, middle-class contexts; neutrality is unattainable. Randall (2021) asked test developers to develop a commitment to justice, consider their own positionality, and consider the sociocultural and other identities of the test audience, including the voices of the intended test audience in the test development process.

Finally, the authors of the *Standards* presented opportunity to learn as a relevant context factor, which is “the extent to which individuals have had exposure to instruction or knowledge that affords them the opportunity to learn the content and skills targeted by the test” (AERA et al., 2014, p. 56). Furthermore, disparities in school resources in some settings, including those with large populations of linguistically, racially, and ethnically diverse communities, and possibly rural and isolated communities, affect the quality and content of teaching and learning. Opportunity to learn is a restricted concept because it presumes the target content domain is appropriate and (exhaustively) comprehensive. Does the (specified) content domain include cultural and linguistic disciplinary content knowledge and practices? If we fully adopted the principles of UDL, we would acknowledge many ways of knowing and doing through providing multiple means of engagement, representation, and action and expression in instruction and assessment.

To extend the discussion in the *Standards*, Standard 3.2 requires test developers to minimize the possible effects of “construct-irrelevant characteristics, such as linguistic, communicative, cognitive, cultural, physical, or other characteristics” (AERA et al., 2014, p. 64). Much of the attention to such effects focuses on evidence such as DIF. However, when the entire test presents a uniform barrier, DIF will not uncover the effect on one or more items because the item performance is conditioned on the remaining total test score (which could be uniformly depressed as a result of a narrowly specified content domain). Similarly, a number of standards address the language of the test, relative to the native language or language proficiency of the test takers. Although a test may be administered in a relevant and appropriate language given the test purpose, as required in Standard 3.13, if the content is not relevant and appropriate, significant barriers to access remain. Another common method to address these barriers is external sensitivity reviews of test specifications and items—which typically focus on what items contain that may be problematic, not what items are missing in terms of CLR. Even though nearly every large-scale testing program has sensitivity review processes in place (many employ multiple stages of review), questionable items do find their way to operational tests (Dee & Domingue, 2021).

Content relevance is also addressed in the *Standards* regarding workplace testing and credentialing. An example is given where

“salt is to pepper” may be the correct answer to the analogy item “white is to black” in a culture where people ordinarily use black pepper, but the item would have a different meaning in a culture where white pepper is the norm. (AERA et al., 2014, p. 181)

In the context of developing educational tests, the authors of the *Standards* asserted that

focus is placed on measuring the knowledge, skills, and abilities of all examinees in the intended population without introducing any advantages or disadvantages because of individual characteristics (e.g., age, culture, disability, gender, language, race/ethnicity) that are irrelevant to the construct the test is intended to measure. (p. 187)

Standard 12.3 requires test developers and users of educational assessments to promote access to the construct for all intended test takers throughout all steps of test design. However, at this point, there is no discussion about the nature of the content reflected by test specifications, other than an acknowledgment that to allow access to test content, context, and response formats, test accommodations and modifications may be needed—again, a response to what is there, not an acknowledgment of what might be missing.

Although the authors of the *Standards* do not employ the language “culturally and linguistically responsive assessment,” the notions and elements of such an approach are present throughout. Authors of the “Fairness in Testing” chapter in the *Standards* interpreted fairness as “responsiveness to individual characteristics and testing contexts so that test scores will yield valid interpretations for intended uses” (AERA et al., 2014, p. 50), noting that such a definition exceeds what may be required legally. Similarly, they noted that strategies (accommodations) can be employed with tests and testing procedures “to be responsive to the needs of test takers with disabilities and those with diverse linguistic and cultural backgrounds” (p. 60) as well as other groups. Item and test developers are left with a challenge: to be responsive to the diversity of test takers regarding cultural and linguistic histories, but to avoid culturally and linguistically specific words and expressions and contexts that may not be familiar to some.

CLR Construct and Domain Definitions

Decisions about what to measure and how to measure pervade educational measurement and have done so since its beginning. Such decisions are often made not simultaneously, but sequentially, and not necessarily in a particular order. In education settings, many data collection strategies often default to a test as the tool of choice (how to measure), without substantial regard for the construct or domain of interest (what to measure). Certainly, some constructs and domains are better assessed through other means than a test. Such definitions are often made by policy boards (e.g., state school

board or professional associations), without the inclusion of broad representation from the test-taker population or their advocates or measurement specialists.

As described in the test design and development chapter in the *Standards*, the association between the test content and established content standards is critical—that “content specifications must clearly describe the content and/or cognitive categories to be covered so that evidence of the alignment of the test questions to these categories can be gathered” (AERA et al., 2014, p. 75). For most purposes, test specifications include descriptions of how the construct or content domain is represented on the test, which are often refined through the test development process (see Huff et al., this volume). Test specifications are defined broadly, including documentation of purpose and comprehensive details about content decisions. The test content should be fully described in the content domain, content specifications, or content frameworks. These often come from content standards defined by professional associations, education authorities (informed by subject matter experts), and job task or requirements analyses (see Margolis et al., this volume). Content decisions detailed in test specifications should include the sources and characteristics of reading passages, stimulus materials (e.g., illustrations, figures, graphs), practice-based cases, scenarios, vignettes, and contexts related to diversity and local, regional, or national relevance (Rodriguez, 2016).

In education settings, questions have been raised about the appropriateness or fairness of domain specifications and the identification of disciplinary ways of knowing and doing. Some of the clearest messages regarding fairness of construct or domain definitions come from the work of Indigenous educators. Tests should reflect relevant content and modes of understanding and learning to adequately assess what we expect individuals to know and be able to do. Although education researchers have long argued that culture and society play a role in cognitive development (e.g., Vygotsky, 1978), this acknowledgment has been late to influence assessment (for an example in the context of culture and language revitalization and assessment, see Kūkea Shultz & Englert, 2021, 2023). Some reviewers of this chapter argued that CLR principles may be more appropriate for classroom assessment than most large-scale testing programs; however, those engaged in the CLR work seek to influence testing across venues, purposes, and uses (Randall, 2021).

Some assessment researchers have promoted principles of culturally grounded validity evidence (what they called cultural validity) in the area of science assessments. Solano-Flores and Nelson-Barber (2001) argued that what they recommend would require a radical change in current test development and administration procedures, but the added effort may be necessary to achieve greater equity and fairness. They called into question the skills needed to develop fair assessments, such that test development teams should include cultural anthropologists and others who can bring a sociocultural perspective to the team. Specific disciplinary examples include mathematics in cultural contexts (Parker Webster & Yanez, 2007), mathematics in an authentic bicultural context (Lipka et al., 2007), and science

assessments acknowledging Aboriginal scientific knowledge and practices (Friesen & Ezeife, 2009).

A broad approach to this challenge is exemplified by the work of Canadian educators to incorporate Aboriginal content and epistemology throughout the education experiences of students (Claypool & Preston, 2011). An important fairness outcome of this work is the assertion that academic assessment must occur in a holistic context, recognizing physical, emotional, and spiritual forms of assessment. In a similar attempt to provide for fair testing of Aboriginal and Torres Strait Islander students in Australia, researchers are studying empirical data from large-scale testing, acknowledging the increasing cultural, ethnic, social, and linguistic diversity of the test-taker population. These researchers recommend greater balance of assessment types and alternative assessment approaches that are inclusive and participatory, particularly in the context of classroom assessment (Klenowski, 2016).

Another approach resulted in the transformation of large-scale assessments, including the Hawaiian state assessment program, supported by statewide collaboratives addressing Indigenous assessment. “Hawaiian culture-based education is based on a holistic view of the world and deep appreciation of interconnectedness” (Nā Lau Lama, 2007, chap. 2, p. 39), acknowledging that relevant knowledge and ways of knowing consider connectedness of worldviews and the assertion that “assessment within a Hawaiian context inherently includes the dimension of spirituality” (p. 38). Two principles of Hawaiian culture-based assessment include

E kuahui like i ka hana (Let everybody pitch in and work together): Assessment is strengths-based, respectful and constructive, looking for the particular attributes, contributions and potentials of the individuals or groups assessed, with particular emphasis on how they contribute to the larger community. Implicit in this approach is a respect for the “funds of knowledge” of students and their communities, an emphasis on growth, and continuous improvement that results from diligent effort. (p. 40)

Ma ka hana ka 'ike (In working, one learns): Assessment is personal in that it is appropriate to a particular individual, place and time. There is an emphasis on engagement as well as application of knowledge and skills in authentic ways. (p. 41)

Principles such as these directly impact the conceptualization of constructs and domains. These efforts extend what Moll and colleagues (1992) called funds of knowledge, the “historically accumulated and culturally developed bodies of knowledge and skills essential for household or individual functioning and well-being” (p. 133).

Test and Item Specifications in Support of CLR

Large-scale testing programs have item and task specifications describing sensitivity and bias concerns. Such specifications describe item content that should be avoided because of issues related to representation of diversity in content, illustrations, and contexts, with a focus on elements of stereotyping that should be avoided. Item

specifications also declare elements of language to avoid, including controversial or emotionally charged topics. In most cases, this includes avoidance of culturally embedded traditions, holidays, current events, politics, religion, and many other topics that might otherwise bring the test to life and make it relevant. Such sensitivity and bias-free practices not only leave the test context neutral (resolving to White, middle-class contexts), but also thus render it void of relevance to many test takers.

Haladyna and Rodriguez (2013) provided guidance for comprehensive item specifications, which also employ aspects of UDA and are supportive of the goals and components of PAD, beginning with precise descriptions of the construct, domain, knowledge and skills to be assessed, and specification of intended claims and relevant evidence. Item specifications also describe allowable item formats and their structures. Most important, item specifications describe the allowable sources and characteristics of reading passages, characteristics of stimulus materials (illustrations, figures, graphs), and characteristics of practice-based cases, scenarios, and vignettes. Item specifications lose ground regarding CLR in the descriptions (often long lists) of what to avoid, particularly regarding issues related to diversity; local, regional, or global affairs; and most topics that make school subjects, work, and life interesting.

The process of item development requires collaboration among a number of individuals and groups, including general test developers, item writers who typically are content or subject matter experts, measurement specialists (who may be psychometricians) and relevant specialists in areas such as culture, language development, gender issues and cognitive, emotional/behavioral or physical disabilities. (Rodriguez, 2016, p. 263)

Another potentially powerful contributor to item development is the test taker, where critical insight could be obtained through including student voices in K–12 education assessment development (Roach & Beddow, 2011), as well as student and community voices more generally. This collaborative process is rarely fully realized because item development and review typically occur sequentially, sometimes iteratively, but rarely collaboratively, with multiple specialists reviewing items, just not together. The *Standards* contains many instances of standards articulated with conditions such as “if appropriate” or “if possible.” For example, Standard 4.6 states,

When appropriate to documenting the validity of test score interpretations for intended uses, relevant experts external to the testing program should review the test specifications to evaluate their appropriateness for intended uses of the test scores and fairness for intended test takers. (AERA et al., 2014, p. 87)

We argue that such external review would be appropriate in all cases, particularly in the early stages of test specification development.

Assessment for Justice

There exists another movement in the educational testing and assessment arena that pushes CLR even further. It provides for a grander purpose than responsiveness. Some

have long argued that testing and assessment can serve an educational purpose, that individuals learn preparing for the test, taking the test, and reviewing the test (Mehrens & Lehman, 1991). There exist strong examples of tests of, for, and as learning (Bennett, 2015). To push these ideas in a progressive direction, educators are promoting the use of assessment to achieve justice goals—following the direction of efforts to promote social justice-oriented instruction (McLaren, 2000; Papa et al., 2016; Williamson et al., 2007). The introduction of social justice theory and goals in instruction and assessment has as its goal advancing opportunity, particularly for students who have been historically disenfranchised.

In the assessment realm, researchers have illuminated the important connections between assessment, justice, and opportunity (Gardner et al., 2009; McArthur, 2016). In the case of writing assessment, researchers, in collaboration with educators, ask the question, “How can we ensure that writing assessment leads to the advancement of opportunity?” (Poe et al., 2018, p. 379). They argue, and demonstrate, that by disrupting the historic disciplinary isolation of writing, writing assessment can promote student agency and advance opportunities for all students, consistent with the justice orientation of the field of writing and English education. This includes a reorientation of instructional approaches to writing, eliminating barriers to the potential source material and construction of writing exercises, and giving authentic purposes to writing and writing assessments, essentially unconstraining construct representation in writing assessment “to produce evidence related to fairness of comparable consequences for all” (Poe et al., 2018, p. 15).

In a state high school test of writing skills during the early 2000s, the following seemingly neutral and uncontroversial prompt was given to students: If you could change one thing about your life, what would it be and why? Unexpectedly, many students wrote stories about horrific neglect and abuse and illegal behaviors, both as victims and as perpetrators. Readers scoring the essays began to ask whether they were considered mandatory reporters and whether they were required to report cases to authorities—the identities of the students were known because the essay was part of the state accountability testing program. Were these truthful stories or were students writing fiction to display their skills? In addition, the state school counseling association took issue with the potential negative focus of the question because their collective mission was one of positive youth development with a focus on positive assets and opportunities for students. A seemingly neutral writing prompt required mass destruction of the written responses and the provision of counseling for test-response debriefing supports.

In the context of writing, justice prompts abound. Gonchar (2018) offered over 1,000 writing prompts, followed by 300 additional argument writing prompts. Among them were the following:

Should kids be social media influencers? Should all Americans receive anti-bias education? Should all companies require anti-bias training for employees? Is it offensive for sports teams and their fans to use native American names, imagery, and gestures? Do you support affirmative action in college admissions? What

rules should apply to transgender athletes when they compete? Why is race so hard to talk about?

Such prompts provide space to display writing skill, argumentation skills, and opportunity to express voice and to do so in a context that allows for multiple perspectives. Even among the GRE analytical writing prompts we find opportunities for students to explore issues of justice, possibly not because ETS is intentionally adopting issues of justice as part of a progressive mission, but because such issues are relevant to adults globally and acknowledge that there are multiple views, experiences, and perspectives. For example, one issue prompt the test employs asks test takers to discuss the statement: “The well-being of a society is enhanced when many of its people question authority” (https://www.ets.org/gre/revised_general/prepare/analytical_writing/issue/pool). An example of an argument prompt is based on a scenario of an anthropologist studying childrearing in an island society that identifies two very different approaches to childrearing when comparing observation-centered versus interview-centered methodologies—calling into question the validity of the interpretations of one set of results (https://www.ets.org/gre/revised_general/prepare/analytical_writing/argument/pool). In both examples, individuals who live in or experience multiple cultural settings will find the prompts relevant and be able to express their voice on issues of justice, perhaps motivating relevant engagement in the measurement procedure.

Although there is not a strong presence in the assessment literature, some are introducing practices targeting antiracist education practices, including instruction and assessment that promote the recognition and analysis of injustice and introduce disciplinary approaches to change (Inoue, 2015, 2019; Kishimoto, 2018). Through antiracist practices in teaching, learning, and assessment, assessment tasks are developed to disrupt racist beliefs in disciplinary knowledge and practices by directly confronting economic, structural, and historical roots of inequality (McGregor, 1993; although McGregor wrote about this in the context of teaching). In the assessment arena, antiracist approaches to assessment ensure that tasks are developed to sustain test-taker cultural and linguistic disciplinary knowledge and practices, rather than ignore or eradicate those ways of knowing and doing (Baker-Bell, 2020). Randall et al. (2023) introduced a justice-oriented antiracist framework for validation. They applied this framework to address construct articulation, data analysis, and score interpretation, uncovering racist logics within standard processes of assessment design. Randall (2023) provided a justice-oriented antiracist perspective on bias and sensitivity review, processes that occur at multiple stages of item development and review, including, for example, following DIF analyses.

Russell (2024) provided a comprehensive review of the role of oppression and racism, as well as White supremacy, to move the field toward antiracist approaches and increase fairness. Russell demonstrated how the White racial frame structures test development theories and practices in ways that perpetuate racialized social structures.

Although these scholars are leading the way, test development, administration, analysis, and use practices remain grounded in prior limited notions and applications of fairness.

Implications for Practice and Research

Test developers need to manage the somewhat conflicting guidance in the *Standards* by revising long-standing item-writing guidelines and sensitivity review procedures to focus not only on what to avoid in item and test content and contexts, but also what to include to embrace CLR. Researchers should develop agendas to evaluate the impact of such approaches. A CLR assessment research agenda should include the application of UDL guidelines that embrace the principles of multiple means in terms of the why, what, and how of learning and doing. Agencies, professional associations, and other entities charged with defining content domains and content standards regarding what people are expected to know and do must engage their constituencies in discussions of essential, necessary, and CLR content. To promote fair tests, from the purpose of testing, test domain specifications, item-writing guidelines, test construction methods, field-test procedures, and operational administration and scoring, the roles of cultural and linguistic disciplinary content knowledge and practices should be considered. We must begin to ask questions about the oppressive and racist frameworks under which we have worked in the past to promote antiracist and fair approaches for a better future to promote social equity, access, and opportunity; testing and assessment more broadly can be an important tool to achieve greater justice.

CONCLUDING REMARKS

Fairness in educational measurement is promoted through consistent commitment to inclusion, access, and rigorous attention to content coverage and relevance and the elimination of barriers to access and sources of construct-irrelevant variance. There are many conditions under which fair and valid score interpretation and use are supported and enhanced, beginning with the way decisions are made about the need and role for testing. A preliminary condition for fair test interpretation and use requires a comprehensive analysis of opportunity to learn, because unfair, discriminatory, or exclusionary practices prohibit fair and uniform score interpretation (AERA et al., 2014, see p. 54). This includes the biases employed in the definition and specification of constructs and content domains, as well as every phase of test development, administration, scoring, reporting, and use. For some test takers, fairness also depends on the use of accommodations because even the most accessible test may not be accessible to all. In addition, fairness regarding access to the construct or domain is about what is *not* included in the content domain as much as it is about what *is*.

“The National Council on Measurement in Education is a community of measurement scientists and practitioners who work together to advance theory and applications

of educational measurement to benefit society” (<https://www.ncme.org/about/mission>). In his NCME presidential address, Sireci (2021) proposed five values, based on scholars and theorists in the field, and consistent with the *Standards*, including the following:

1. Everyone is capable of learning.
2. There are no differences in the capacity to learn across groups defined by race, ethnicity, or sex.
3. All educational tests are fallible to some degree.
4. Educational tests can provide valuable information to (a) improve student learning, and (b) certify competence.
5. All uses of educational test scores must be sufficiently justified by validity evidence. (p. 12)

These are fundamental values that undergird fairness in testing. The NCME mission statement calls on us to “serve the common good” (Sireci, 2021), a focus that was elevated during Sireci’s leadership of the organization. To promote that goal, he called on the organization to

- (a) ensure we enforce adherence to our AERA et al. (2014) *Standards*, particularly as they relate to the provision of validity evidence to defend test use;
- (b) de-emphasize norm-referenced competitiveness in educational testing except in those rare instances where examinees actually are competing for a benefit;
- (c) reorient our practices so that we value students more than the score scale;
- (d) engage with teachers and other educators to collaboratively develop tests and interpret test scores;
- (e) reconceptualize our notions of standardization to make tests more flexible to students’ needs and funds of knowledge;
- (f) design test score reports for students that emphasize their strengths, rather than their weaknesses; and
- (g) take full advantage of technology to allow assessments to tailor themselves to the needs of each specific examinee, foster engagement in the testing process, and to be fully aligned with and integrated into instruction. (p. 14)

These steps offer another way to engage in the principles of accessibility.

Relying on the *Standards* (AERA et al., 2014) and the principles of fairness discussed throughout the chapter, a number of concerns and guidance include broader attention to balanced assessment and policy design (Brookhart et al., 2019; Chattergoon & Marion, 2016; Martineau et al., 2018). The primary focus of balanced assessment efforts requires a careful articulation of the purposes of assessment, followed by the identification or creation and selection of assessments to meet those purposes, where the more important and valued purposes encompass the majority of assessment efforts, reducing emphasis on less essential or informative assessment practices. In addition, no decision resulting in consequences for test takers, groups, or organizations should be made based on a single test score, especially without retake opportunities. A long-standing principle of good measurement practice is to employ multiple measures, which underlies much of the discussion throughout this chapter. Multiple measures capture a richer picture of the intended construct or content knowledge and skills and enhance our understanding of what people know and can do. Consistent

with fairness concerns, multiple measures may help to balance intraindividual measurement errors across assessments and allow for multiple ways for test takers to display their knowledge and skills.

Research-informed policies have strong grounding and promote fairness. As such, testing policies must be research informed to provide fairness for test takers from culturally and linguistically diverse backgrounds, as well as those with disabilities. Testing policies and their application will support fairness when they are research based, including policies regarding identification of individuals as English learners and those with disabilities.

A comprehensive test evaluation plan will include a comprehensive review of fairness in every step of the test development and operational stages. Additional focus needs to be given to the evaluation of item and test score functioning vis-à-vis cultural and linguistic characteristics, for example, evaluation of measurement invariance, differential item and distractor functioning, evidence from response processes, differential predictive validity evidence, and the search for unintended consequences among test-taker groups, acknowledging within-group heterogeneity.

A much larger constituency must continue to learn about the principles of testing and test interpretation and use in diverse contexts, particularly test takers with disabilities and English learners who may not be proficient in the test language, including test takers themselves, educators, families, community members, policy makers, teacher educators, workforce development and human resource specialists, and test developers. Test developers and users benefit greatly from reaching out to and engaging with members of diverse communities where tests will be administered and used.

Applications of fairness principles in score interpretation and use continue through the evaluation of potential intended and unintended consequences of testing. Of particular concern in the arena of test fairness is the potential reproduction of disparities and limited opportunities, which are also a function of policies outside the arena of education and employment, including housing, transportation, health, economic development, law enforcement and corrections, and others. The interpretation and use of educational and credentialing tests are not isolated, and public policies interact in unique and unintended ways. The role of consequences continues to be a debated issue (see Ercikan & Solano-Flores, Lane & Marion, and Zwick, all this volume, for additional discussions). Although we agree that the underlying disparities are the result of much larger and historical trends, policies, and social structures, our concern is about the extent to which tests may contribute to the maintenance of social stratification.

Principles of fairness are known and are being implemented and used in many settings. Educational measurement specialists and test developers and users have available to them a wide range of tools and resources to promote fairness in testing through accessibility for specific groups who have experienced challenges in test accessibility and, ultimately, for all test takers.

ACKNOWLEDGMENTS

We are grateful for the attention to detail and wise advice from reviewers throughout the process, including Michael Kane, Maria Araceli Ruiz-Primo, and Michael Russell, a special review by Julio Caesar, and the incredible support and patience of the editors, Linda Cook and Mary Pitoniak.

Part IV

Specific Applications of Assessment

Assessment to Inform Teaching and Learning

Susan M. Brookhart

Duquesne University (Emerita)

Charlie DePascale

Independent Consultant

In recent years, at least from the advent of the standards movement in the 1980s (Porter, 1993), expectations have risen that all assessments—not just those designed to be used formatively—will inform teaching and learning. This trend defines the overarching theme of this chapter: Educators, students and parents, and community members increasingly look to many different assessments for information about improving learning; that is, they look to assessments to serve a formative purpose. This chapter describes the variety of assessments that stakeholders press into service to inform teaching and learning, evaluates their use in this endeavor, and suggests what the future may bring as the arc of assessment continues to bend toward the formative.

CHAPTER PURPOSE AND SCOPE

Both *teaching* and *learning* have multiple definitions, depending on one's philosophical and psychological approach (Gitomer & Bell, 2016). This chapter focuses on assessment of what students know and can do in relation to learning goals that are taught and learned in school classrooms, with the intent of (a) informing teacher instructional planning and instructional moves and (b) informing students' thinking and understanding during classroom lessons, including the individual and social regulation of learning. Similarly, *assessment* has multiple definitions, with some emphasizing assessment instruments and others emphasizing assessment processes. This chapter reviews research about both assessment instruments and the processes in which they are used. As Bennett (2011, p. 7) noted, "process cannot somehow rescue unsuitable instrumentation, nor can instrumentation save an unsuitable process." Much of the research reviewed is from the United States, where teaching to learning goals is the common model of instruction; however, learning-oriented assessment is also a growing interest globally (Carless, 2007; Zeng et al., 2018). The chapter does not focus on the use of assessment information to inform curriculum revision, materials review, or policy adoption.

THESIS

Both educators and the public increasingly expect assessment to be formative and to be helpful to the learning of individuals. Since at least the 1990s, assessment users have been clamoring for more formative information, even from assessments not designed to provide such information, like grades or state accountability tests, as evidenced by educators trying to use annual accountability assessments for instructional change and by the generally unsuccessful attempts to add diagnostic scoring to large-scale tests. The logic is often some version of an argument that runs, in general, that if an assessment tells something about what has been learned, it also should have implications for what should be learned next. Growing interest in student learning theory, fairness, and social justice may be influencing this movement toward the formative as well (see Ercikan & Solano-Flores; Lane & Marion; Rodriguez & Thurlow; and Zwick, this volume). This chapter reviews a range of assessments with an emphasis on how they are being used to

inform teaching and learning, whether they were originally intended for formative use or not.

Three subthemes emerge in this press toward the formative. First, the nature of the information is broad. Depending on its source and purpose, assessment that informs teaching and learning can result in information that is qualitative (e.g., feedback comments) or quantitative (e.g., scores, grades), or sometimes both (e.g., a rubric level associated with a performance-level description). Information can be about individuals or groups: Assessment that serves a formative purpose can support students working through a curriculum, and it can also help support broader decisions about instruction. Second, both information quality—the validity or trustworthiness of the assessment information—and the quality of implementation in practice are key to the effectiveness of assessment in informing teaching and learning (Bennett, 2011). Third, teacher and student assessment literacy is key to the effective use of assessment to inform teaching and learning.

ORGANIZATION OF THE CHAPTER

The chapter is organized into five sections, the first of which is this introduction. The second section describes assessments of students' current learning status: those focused on the formative, including classroom formative assessment and interim assessment, and those focused on the summative, including grading and state summative assessment. Evidence shows that even assessments intended for summative purposes are used to inform teaching and learning. The third section describes methods of assessment that assess trajectories of learning through the learning process. It begins by describing how the assessments in this section differ from conventional assessments and then describes assessments focused on trajectories of learning: curriculum-based measurement, student learning objectives, and assessment based on learning progressions. In both the second and the third sections, assessments are described according to their purpose and uses, design, measurement considerations, implementation in practice, and their impact on learning. The chapter ends with a fourth section on future directions for assessment to inform teaching and learning and a fifth, concluding section.

ASSESSMENTS OF STUDENTS' CURRENT LEARNING STATUS

More and more, educators, parents, and community members seek to leverage any available assessment information to inform teaching and learning, whether from assessments originally focused on the formative or from those originally focused on the summative.

Assessments Focused on the Formative

Assessment that has as its primary purpose informing teaching and learning is called formative assessment, and it is typically distinguished from summative assessment, which has as its primary purpose certifying or reporting learning. Bloom et al. (1971)

moved formative evaluation, originally conceived at the curriculum level, into the classroom. They emphasized assessment to inform teachers' instruction. During the 1990s, several scholars demonstrated the importance of students in the evaluation process as well (Black & Wiliam, 1998; Natriello, 1987; T. J. Crooks, 1988).

No one definition of formative assessment has yet taken its place in the field as the only authoritative one. However, definitions do converge on formative assessment as an evidentiary process, the need for student involvement, and the intent to move learning forward—just collecting information about student learning is not sufficient. Current definitions of formative assessment can be grouped into four nested categories, according to whether, to be called formative assessment, a process need only provide information about student thinking; must provide information that is potentially useful; must provide information that is used with the intention of improving student performance; or must provide information that is used and that has a positive effect on student performance (Furtak et al., 2015). The 2008 Council of Chief State School Officers' definition of formative assessment in practice (CCSSO, 2018) is used in the glossary of the *Standards for Educational and Psychological Testing* (the *Standards*; American Educational Research Association [AERA] et al., 2014, p. 219):

Formative assessment: An assessment process used by teachers and students during instruction that provides feedback to adjust ongoing teaching and learning with the goal of improving students' achievement of intended instructional outcomes.

However, beyond the glossary entry, the *Standards* do not treat this kind of formative assessment. Other definitions have been noted (e.g., Andrade et al., 2019; CCSSO, 2018).

The term *assessment for learning* is very often used as a synonym for formative assessment. Often, whether one uses assessment for learning or *formative assessment* reflects one's research and practice traditions and cultural background. Some (e.g., Black et al., 2003; James & Pedder, 2006) use assessment for learning as a broad term and reserve use of the term formative assessment for instances when assessment information is actually used to improve learning. Conversely, Stiggins (2005) considered assessment for learning as one of several approaches to formative assessment, in which students are actively involved and "inside the assessment process, watching themselves grow, feeling in control of their success, and believing that continued success is within reach if they keep trying" (pp. 327–328).

For purposes of this chapter, Black and Wiliam's (2009, p. 9) definition of formative assessment will be used:

Practice in a classroom is formative to the extent that evidence about student achievement is elicited, interpreted, and used by teachers, learners, or their peers, to make decisions about the next steps in instruction that are likely to be better, or better founded, than the decisions they would have taken in the absence of the evidence that was elicited.

Wiliam (2010, pp. 24–25) identified five key points in this definition:

1. “Anyone can be the agent in formative assessment,” teachers, learners, or peers.
2. “The focus of the definition is on decisions,” not intentions.
3. The focus is on “next steps in instruction,” which he defined as “any planful activity intended to create learning” (p. 25), whether by teacher or learner.
4. “The definition is probabilistic” (“likely to be better”) and acknowledges that not every well-founded decision will result in improved learning.
5. “The assessment need not change the planned instruction.” Sometimes, formative assessment evidence affirms the teacher or student’s original instructional plan.

This section describes three kinds of assessments that focus on formative uses. Informing teaching and learning is the main intended purpose of classroom formative assessment (Black & Wiliam, 1998). Informing teaching, and thereby affecting learning, is one of three main purposes for interim assessment and is the primary use claimed by most school administrators (Clune & White, 2008; Dadey & Diggs, 2019). Common formative assessments also aim to inform teaching and are considered separately from interim assessments because they are often teacher developed (Heredia et al., 2016).

Classroom Formative Assessment

Several authors (e.g., Harlen, 2005; Penuel & Shepard, 2016; Ruiz-Primo & Brookhart, 2018; Shavelson et al., 2008) have suggested typologies for classroom formative assessment. Wiliam and Thompson (2008, p. 63) presented the formative assessment framework depicted in Table 15.1.

The framework shows how five key formative assessment strategies are related to the formative assessment process and its agents. The formative assessment process, sometimes called the formative assessment cycle, can be expressed as a question

Table 15.1 Framework Relating Formative Assessment Strategies to the Formative Assessment Process and Its Agents

	Where the Learner Is Going	Where the Learner Is Right Now	How to Get There
Teacher	Clarifying learning intentions and sharing criteria for success	Engineering effective classroom discussions and tasks that elicit evidence of learning	Providing feedback that moves learners forward
Peer	Understanding and sharing learning intentions and criteria for success	Activating students as instructional resources for one another	
Learner	Understanding learning intentions and criteria for success	Activating students as owners of their own learning	

Note. From “Integrating Assessment With Learning: What Will It Take to Make it Work?”, by D. Wiliam and M. Thompson, 2008, in *The Future of Assessment: Shaping Teaching and Learning* (1st ed.), pp. 53–82, C. A. Dwyer (Ed.), Routledge. Copyright 2015 by Taylor & Francis Group. Reprinted with permission.

loop from the point of view of students (Where am I going? Where am I now? How will I get there? [or sometimes How will I close the gap? or Where to next?]) (Assessment Reform Group, 2002; Hattie & Timperley, 2007; Sadler, 1989). This process is a scaffolded, practical presentation of the phases of the regulation of learning (e.g., forethought, performance, and self-reflection; Zimmerman, 2011). The phases overlap; for example, students can use information from any phase to do additional planning (forethought) or to further clarify the learning target in their minds (Where am I going?).

As the framework shows, student involvement is built into formative assessment. Regulation of learning can be taught and can begin as early as preschool. Self-regulation skills are important for all learners, including students with learning disabilities (Butler & Schnellert, 2015). This kind of formative assessment, where students understand what they are meant to learn and regulate their learning in pursuit of these learning intentions, helps students make sense of their own learning (Cizek et al., 2019; James, 2017). Co-regulation of learning (Allal, 2010, 2011; Andrade, 2013; Andrade & Brookhart, 2020; Hadwin et al., 2011) or interactive regulation (Perrenoud, 1998), where regulation of learning is affected by both self and other sources, is invoked when students use external information, for example, feedback from teachers or peers or information from print or electronic sources, which happens in most, if not all, classrooms.

The classroom context affects formative assessment practices. For example, in an evaluative classroom context, where it is not safe for students to be wrong, assessment can feel like quizzing to students because teachers use the information to categorize and judge them (Ames, 1992). In a classroom context more focused on learning than evaluating, where mistakes are seen as opportunities to learn, students are more likely to perceive information, even criticism, as helpful and positive (Brookhart, 2018; Jonsson & Panadero, 2018).

PURPOSE AND USES OF CLASSROOM FORMATIVE ASSESSMENT As Table 15.1 suggests, the central purpose of classroom formative assessment is to inform students' studying and learning and teachers' instruction and is characterized by a series of questions. Student use of information can range from very specific (for example, as students learn to use a capital letter and a period in a sentence, they may use a simple checklist) to more complex (for example, as students learn to organize essays, they may use a rubric to evaluate the presentation of their argument).

The two primary ways teachers use classroom formative assessment are to provide effective feedback about strengths and next steps and to decide on next instructional moves. Therefore, the main goal is not measurement of student achievement of a learning goal; rather, the primary information sought is a description of the status of student understanding (Heritage & Heritage, 2013). What is the student thinking? What is the next thought or experience the student should have? Some

descriptive evidence suggests that teachers who are expert in formative assessment use student work to understand how students are thinking rather than how correct their answers are (Davis, 1997; Hattie, 2009; Hattie & Timperley, 2007; Kroog et al., 2014; Minstrell et al., 2010; Otero, 2006). Information about student thinking is useful for supporting targeted next instructional moves or feedback (for example, “You seem to have more trouble when the fractions need simplifying; let’s work on that”).

DESIGN OF CLASSROOM FORMATIVE ASSESSMENT As Table 15.1 shows, Wiliam and Thompson (2008) described five strategies for formative assessment: (a) clarifying learning targets and criteria for success with students, (b) engineering effective discussions that elicit evidence of student learning, (c) providing feedback that helps improve learning, (d) activating students as resources for one another, and (e) activating students as the owners of their own learning. Table 15.2 gives some examples of tools and tactics for each strategy. Notice that some of these are informal and embedded in instruction and others look like more conventional, and more formal, assessment instruments. What makes these examples of formative assessment is that they are used formatively.

Probably the most noticeable, and the most foundational, change in teaching for many of those who practice formative assessment in the classroom is the explicit sharing of learning goals and the success criteria that will indicate how students are learning. All formative assessment practices depend in some way on that foundation (Brookhart, 2020; Wiliam & Thompson, 2008). For example, feedback from teacher, self, or peers may be based on the criteria. Students’ goal setting and self-regulation are based on their nascent understanding of what they are trying to learn. Questioning and other checking-for-understanding strategies monitor student progress toward the learning goal.

Feedback in Formative Assessment While all assessments provide some sort of feedback, feedback has a special place in formative assessment. Some definitions of formative assessment equate it with feedback. Other definitions of formative assessment consider feedback a major part of formative assessment but not the whole of it (Ruiz-Primo & Brookhart, 2018).

Originally, the study of feedback had its roots in behaviorism (Kluger & DeNisi, 1996), and feedback was seen as a type of reinforcement. Kulhavy (1977) critiqued this idea, pointing out that the stimulus–response environment in any learning program is constantly changing, and there is no good reason to believe that the same sequence of events that the feedback is supposed to reinforce will occur again. Further, he pointed out that feedback that is delayed for a day or more typically leads to increases in student retention, and if feedback were acting as a reinforcer, the effect would decay, not increase.

Table 15.2 Examples of Classroom Formative Assessment

Formative Assessment Strategy	Examples in Practice
Clarify learning targets and criteria for success	• Share and unpack learning target statements with students • Share and discuss examples of good work (exemplars) or examples of a range of quality of work with students • Create checklists, rubrics, or other tools that organize criteria and have students use them to monitor their learning • Co-construct criteria with students
Engineer effective discussions and tasks that elicit evidence of student learning	• Use open-ended and strategic teacher questions • Organize student response patterns so they respond to each other rather than to the teacher • Teach students how to ask effective questions • Check for understanding during learning: ◦ hand signals ◦ whiteboards ◦ quick writes ◦ concept maps ◦ question boxes or boards ◦ entrance or exit tickets ◦ student response systems with multiple-choice questions ◦ quizzes ◦ performance assessment ◦ structured discussions ◦ predict–observe–explain tasks (Shavelson et al., 2008)
Provide feedback that helps improve learning	• Using criteria, comment on strengths and next steps • Written feedback • Oral feedback and dialogue • Video feedback • Give students opportunity to use the feedback
Activate students as resources for one another	• Peer feedback
Activate students as owners of their own learning	• Self-assessment • Reflection at pause points during learning or at the end of an episode of work

Note. Adapted from “Integrating Assessment With Learning: What Will It Take to Make it Work?,” by D. Wiliam and M. Thompson, 2008, in *The Future of Assessment: Shaping Teaching and Learning* (1st ed.), pp. 53–82, C. A. Dwyer (Ed.), Routledge.

In recent years, feedback has come to mean “information provided by an agent (e.g., teacher, peer, book, parent, self, experience) regarding aspects of one’s performance or understanding” (Hattie & Timperley, 2007, p. 81). Interestingly, early studies of the feedback designed and executed using a behaviorist paradigm showed little to no effectiveness on learning (Harris & Rosenthal, 1985; Kluger & DeNisi, 1996), while more recent studies of feedback designed and executed using more constructivist approaches show much larger effects (Graham et al., 2015; Hattie & Timperley, 2007; Kluger & DeNisi, 1996). However, the effects of feedback are quite variable, and—as for formative assessment in general (Klute et al., 2017)—some are negative (Kluger & DeNisi, 1996). Studies with the highest effect sizes (Hattie & Timperley, 2007, p. 84) “involved students receiving information feedback about a task and how to do it more effectively. Lower effect sizes were related to praise, rewards, and punishment.” Finally, it may be as important—or even more important—to study the kinds of response processes feedback engenders as it is to study the effects of feedback on performance (Kluger & DeNisi, 1996; Van der Kleij & Lipnevich, 2021; Winstone et al., 2017).

In other words, some types of feedback are more powerful than others. Outcome feedback, sometimes called knowledge of results or verification (Shute, 2008), is the simplest and most common type of feedback (Butler & Winne, 1995). Outcome feedback tells students whether they were correct or incorrect. Formative assessment can produce this kind of feedback, and it is useful for some purposes, especially for tasks involving recall (Mason & Bruning, 2001). Outcome feedback about correctness coupled with knowledge of the correct response, as, for example, on the back of math fact flash cards or in some computer learning software, can be effective for memory tasks.

In contrast, cognitive feedback, sometimes called elaboration (Shute, 2008), contains information that students can use in their thinking (Butler & Winne, 1995; Hattie & Timperley, 2007; Tunstall & Gipps, 1996). Cognitive feedback helps students interpret the task, interpret their response or response processes, set goals and monitor progress, address particular errors, and give examples or guidance. These are the processes of the formative learning cycle, expressed in the language of self-regulation. This kind of feedback generally has more powerful effects on learning (Hattie & Timperley, 2007; Shute, 2008), although it is important to note that most of the studies in these reviews focused on current performance, not long-term learning (Soderstrom & Bjork, 2015). Teacher pedagogical questioning may be the most effective and immediate elaborated feedback, co-constructed with students in dialog (Heritage & Heritage, 2013). The distinction between outcome and elaborated feedback proves important in computer learning as well (Mason & Bruning, 2001; Van der Kleij et al., 2015). Of course, the possibility of elaborated feedback is related to the cognitive demands of the assessment task; complex tasks typically provide more opportunity for elaborated feedback.

Finally, personal feedback (e.g., “You’re so smart!”) is typically not effective for learning (Hattie & Timperley, 2007). This feedback does not provide information for improvement and may depress motivation.

Koenka et al. (2019) performed meta-analyses of studies investigating the impact of grades (outcome feedback) versus no feedback and grades versus comments on academic motivation and achievement in elementary and secondary school, respectively. Overall, receiving grades positively influenced achievement but negatively influenced learning, compared with no feedback. Overall, receiving comments as feedback resulted in higher achievement and internal motivation compared with receiving grades. Moderator analyses identified more complex relationships. Receiving grades demonstrated no impact on internal motivation for high achievers, as compared with no feedback, but was associated with lower internal motivation for lower achievers. Task-focused comments led to higher achievement and internal motivation, while global-affective comments (e.g., “Excellent! Keep it up!”) resulted in a smaller increase in internal motivation and no difference in performance. In general, these analyses supported the notion that outcome feedback can be helpful; however, for most learning tasks, especially performance tasks that require more than recall, elaborated feedback is more effective (Koenka et al., 2019).

From a measurement perspective, what connects outcome and elaborated feedback is the fact that all types of feedback are—or should be—based on the intended learning for which one seeks information (Brookhart, 2020). The intended learning outcome functions as the construct in assessment to inform teaching and learning (Haertel, 1985). From a learning theory perspective, what connects outcome and elaborated feedback is that both can be informational to students engaged in the self-regulation of learning and to teachers who wish to facilitate student learning in their instruction.

Student Use of Feedback If feedback is to affect learning, students need to make sense of it and use it productively. To do this, students need to appreciate feedback; make judgments about the quality of their own work; manage affect, especially negative emotional responses; and take action that improves their work. The first three of these skills interact, and all three affect students’ abilities to take action to improve their work or learning strategies (Carless & Boud, 2018). One important aspect of managing affect involves student beliefs about whether ability is fixed or malleable; the latter belief is known as a growth mindset. Yeager et al. (2019) found that a brief, online growth mindset intervention reduced the prevalence of fixed mindset beliefs among lower achieving ninth graders, increased grade point average in core classes, and was more effective in schools where peer norms were supportive of a growth mindset—an important finding that highlights the importance of the relationship between individual beliefs and the classroom climate.

Winstone et al. (2017, 2019) named this constellation of skills and dispositions learners' *proactive recipience* for feedback. They identified four recipience processes: self-appraisal, assessment literacy, goal setting and self-regulation, and engagement and motivation. Students' use of feedback depends on these processes as well as the characteristics of the feedback message and its content and the characteristics and behavior of the sender and receiver of the message (Winstone et al., 2017).

Jonsson (2013) found five challenges to university students' productive use of feedback. First, feedback needs to be useful. For example, one-liners and personal comments may not provide information students can use. Second, students prefer specific, detailed, individualized feedback, in part because they perceive it as helpful to them (e.g., Ferguson, 2011; Gamlem & Smith, 2013). Third, authoritative feedback may not be helpful, and much feedback in higher education has an authoritative tone. Fourth, many students do not know how to use feedback productively and may use it passively or indirectly (e.g., making a mental note for next time) or not at all, instead of revising and improving current work. Fifth, many students may not understand the feedback they are given, either because the writing is illegible (which Jonsson, 2013, found to be "a surprisingly common problem," p. 69) or because they do not understand the academic vocabulary, concepts, or criteria in the teacher's feedback. Jonsson and Panadero (2018, p. 546) extracted three conditions for productive student use of feedback from the growing literature on proactive recipience: (a) it helps if students perceive that the feedback is useful, (b) students need strategies for using the feedback, and (c) the feedback should be delivered without a grade. Similarly, writing about the K–12 context, Duschl and Gitomer (1997) argued that frequent, diagnostic assessment activities in classrooms can help students develop the thinking, reasoning, and problem-solving skills necessary for developing science learners.

In summary, feedback is integral to the learning process from both teachers' and students' points of view. Formative use of feedback is enhanced by teacher clarity and elaboration and students' understanding and productive use of feedback.

MEASUREMENT CONSIDERATIONS IN CLASSROOM FORMATIVE ASSESSMENT The validity or trustworthiness of information from formative assessment may be evaluated differently depending on the type of assessment. Informal formative assessment is usually based on some form of classroom questioning (e.g., questions used to prompt classroom discourse, for exit tickets or student reflection exercises, and so on). More formal formative assessment is based on a more formal instrument or tool, for example, an embedded performance assessment or quiz at a hinge point in a sequence of lessons.

A fairly robust literature on the quality of classroom questions predates the arrival of formative assessment in common practice (Cotton, 1988). In general, instruction that included classroom questioning during lessons produced higher achievement than instruction without classroom questioning. On average (Cotton, 1988),

approximately 60% of questions asked required lower cognitive processes to answer (e.g., recall or simple comprehension), 20% required higher cognitive processes, and 20% were procedural questions. Questions requiring lower cognitive processes were more effective at building factual knowledge and memory (Cotton, 1988). However, for older students, increases in questions requiring higher cognitive processes were related to increases in on-task behavior, length of student responses, number of relevant volunteered contributions, number of student-to-student interactions, student use of complete sentences, speculative thinking on the part of students, and relevant student questions.

More recently, researchers have attended to the quality of classroom discourse, a slightly broader notion than classroom questioning. Allowing students to talk about their thinking surfaces that thinking for interpretation by teachers, peers, and the students themselves (Michaels et al., 2008), so that it can be evidence for future teaching and learning moves. Enabling productive classroom discourse involves posing a question that is relevant to the intended learning goal and extending student discourse with prompts that help students respond to each other's thinking, for example, asking a student to restate someone else's reasoning, add their own reasoning, and explain their thinking.

Ruiz-Primo and Furtak (2006, 2007) found a relationship between the quality of middle school science teachers' informal questioning in formative assessment and the amount of student learning, although their study did not allow conclusions about causality. Students learned more in classrooms where teachers deliberately elicited student responses with the express purpose of using the information to move students closer to learning goals and interpreted and acted on the information accordingly. Classroom discourse also socializes students into the classroom learning community. For example, Forman et al. (2017) showed how the use of classroom discourse in a high school science classroom moved a classroom with more didactic question-and-answer discourse toward the kind of scientific argumentation more closely resembling that of scientific communities.

These kinds of projects do not shed light on the quality of teacher-developed formal formative assessment tools like classroom quizzes and classroom performance assessments that are authored or selected by teachers. Earlier literature, mostly from the 1980s and 1990s, evaluated the quality of teachers' classroom testing (Marso & Pigge, 1993), but the authors are not aware of current studies of the quality of the tests teachers use for formal formative assessment outside research projects. Similarly, despite the fact that calls for teachers to use more assessments of authentic performance are not new (Darling-Hammond et al., 1995; Wiggins, 1998), the authors are not aware of current studies of the quality of teachers' performance assessments, which may trade off broad representation of an achievement construct for depth in one area.

IMPLEMENTATION OF CLASSROOM FORMATIVE ASSESSMENT IN PRACTICE Most definitions of formative assessment emphasize the process of implementation, not the validity or trustworthiness of the information (Wylie, 2008). Teacher inferences

from student answers to questions can be key to making on-the-spot decisions to further student learning. Heritage and Heritage (2013, p. 176) described this interactional pedagogical practice as “the epicenter of instruction and assessment.” In a formative teaching environment, assessment by a teacher can be likened to hypothesis testing. A teacher can make a tentative inference about student understanding from a question and then revise that hypothesis as new information comes in, leaving much more room for revising inferences than for assessment that produces a static score report.

Teacher Use of Formative Assessment Practices While there are some isolated bright spots, on balance, research on teachers’ use of formative assessment information to provide formative feedback shows it is infrequent (Johnson et al., 2019; Schneider & Andrade, 2013; Yan et al., 2021). Some evidence suggests that interactional instructional decisions and follow-through that truly target a student’s current level of development and move the student toward deeper understanding for a particular concept are difficult to do and that high-quality practices of this type occur rarely and require rich professional development (Furtak et al., 2008; Heritage & Bailey, 2006; Randel et al., 2016; Wylie & Lyon, 2015).

When teachers shift from a view of teaching that emphasizes what they will present to a view of teaching that emphasizes what students will be trying to learn and what they will do to learn it, the classroom learning climate necessary to support the full benefits of formative assessment can be realized. This shift is a major change, from “instructivist” (Box et al., 2015, p. 972) or “social efficiency” (Shepard, 2000, p. 4) teaching focused on delivering content to learners to teaching that supports students as they construct their own meaning. Many teachers find this shift difficult. Research results about the effectiveness of preservice and in-service teacher education in formative assessment are mixed (Brookhart, 2017). In general, at both preservice and in-service levels, where attention was paid to changing teachers’ beliefs about learning and those beliefs did in fact change, there was evidence that teachers improved their formative assessment practices. These successful examples function as proofs of concept that effective formative assessment processes can be taught, but such developments are not common enough to be the rule. Other reviews of literature about teaching formative assessment practices and processes have come to similar conclusions about the necessity for, and difficulty of, teachers moving from a teacher-centered to a student-centered understanding of teaching and learning for formative assessment to be effective (DeLuca, 2012; Otero, 2006).

More than any other type of assessment, effective classroom formative assessment is advanced when teachers know both the principles of effective assessment (for example, how to construct questions and tasks that elicit evidence of learning) and how to observe or score the results. Similarly, effective classroom formative assessment is advanced when students know how to use assessment information to inform their learning. Effective classroom formative assessment also advances with the understanding and support

of administrators, especially building principals (Michigan Assessment Consortium, 2017; Schneider & Andrade, 2013).

Even when questions and tasks do elicit evidence of student thinking, it appears that it is difficult for teachers to use the information appropriately (Heritage et al., 2009; Ruiz-Primo & Furtak, 2006, 2007; Ruiz-Primo & Li, 2013; Schneider & Gowan, 2013). Despite the difficulty, professional development can increase teachers' abilities to design tasks and questions that elicit student thinking, interpret the resulting information, and use it to feed students' learning forward (Furtak et al., 2016).

Ruiz-Primo et al. (2015) explored the type of teacher actions resulting from judgments based on on-the-fly, informal formative assessment. They analyzed videos from 20 science and mathematics teachers and found the same patterns in each discipline. Meaningful interactions resulting from on-the-fly formative assessment were observed in 67% of the mathematics instructional tasks observed and 71% of the science tasks, sometimes also coupled with interactions to keep students on task. However, both mathematics and science teachers responded to formative assessment information with verbal feedback more than with instructional moves, and most of these responses occurred in the context of whole-class instruction as opposed to the context of individual work. These are only a few of the response patterns teachers could have at their disposal.

Student Use of Formative Assessment Practices Students' use of formative assessment varies. For example, students need to be taught to be effective peer assessors (Topping, 2013; van Zundert et al., 2010). Classroom and school norms affect students' formative beliefs (Yeager et al., 2019) and therefore their use of formative information. Boekaerts et al. (2006) emphasized that students pursue multiple goals in the classroom simultaneously, including wanting to be entertained, to belong, and to feel safe and valued, in addition to their academic learning goals, and that the instructional climate affects each of these. Similarly, Leighton et al. (2013; Leighton, 2019) proposed that the instructional climate, learners' mental models of emotion and cognition, and students' performance—their use of feedback—are related in predictable ways.

IMPACT OF CLASSROOM FORMATIVE ASSESSMENT ON LEARNING As students develop greater facility in regulating their learning, they become more powerful learners. As Black et al. (2006, p. 126) summarized, "Pupils' learning is more productive if it is reflective, intentional, and collaborative, practices which may not come naturally but which can be taught and can lead to pupils taking responsibility for their learning." Students who understand what they are trying to learn can be more intentional about their learning than those who do not, who simply comply with teacher directions. Looking at examples of work is one way that students come to develop an understanding of what high-quality work looks like and, by inference, the understandings and skills that underlie high-quality work. As Sadler (1989, p. 121) wrote, "In other words, students

have to be able to judge the quality of what they are producing and be able to regulate what they are doing during the doing of it.”

Increased achievement and increased student self-assessment capabilities result when students understand the criteria for good work (Andrade & Valtcheva, 2009). This has been found in many subject areas and grade levels, for example, primary projects (Higgins et al., 1994), elementary and middle school writing (Andrade et al., 2008, 2010; Coe et al., 2011), middle school mathematics (Ross et al., 2002); middle school special education (E. Lee & Lee, 2009); secondary school social studies (Panadero et al., 2012; Ross & Starling, 2008), and college biology (Hafner & Hafner, 2003).

Reviews of research on rubrics, which are one way to codify and communicate criteria for students, have suggested that one of their main functions is to clarify expectations and quality criteria (Jonsson & Svingby, 2007; Panadero & Jonsson, 2013; Reddy & Andrade, 2010). It is important that the criteria promote understanding and not a mechanical criteria compliance for a short-term performance boost (Balloo et al., 2018; Gitomer & Duschl, 1996; Sadler, 2014).

Estimating the size of the effect of formative assessment on student learning has proved more difficult than it sounds because formative assessment, as the framework in Table 15.1 shows, encompasses so many different strategies. In addition, fidelity of treatment can be an issue. Meta-analyses of the effects of formative assessment on achievement have shown generally positive effects (Kingston & Nash, 2011; Klute et al., 2017; H. Lee et al., 2020; Wiliam et al., 2004), with some of the effects being negative. Studies of the effects of formative assessment practices in specific disciplines have also found generally positive, but variable, effect sizes (Andrade et al., 2019; Burkhardt & Schoenfeld, 2019; Decristan et al., 2015; Graham et al., 2015; Herman et al., 2015). The variability may reflect the fact that formative assessment studies are not necessarily all investigating the same thing. When studies are screened to focus on a single important aspect of formative assessment, effect sizes can be higher. For example, H. Lee et al. (2020) found that formative assessment interventions that featured student-initiated self-assessment had an effect size of 0.61. Hattie and Timperley (2007) found an average effect across meta-analyses of feedback studies of 0.79.

EVALUATION OF CLASSROOM FORMATIVE ASSESSMENT INFORMING TEACHING AND LEARNING Classroom formative assessment is the type of assessment most clearly associated with informing teaching and learning. While elements of it such as feedback have a long history, classroom formative assessment has made a relatively recent arrival into assessment research. Theory is in development (e.g., Table 15.1) and research agendas have begun.

Classroom formative assessment, especially the more informal types, stretches conventional measurement thinking in terms of the nature and quality of the assessment process and tools. This stretching is necessary to bring the benefits of sound

assessment squarely into the learning community, typically a classroom, where learning takes place and where students and teachers can gather and use information to inform teaching and learning as it happens. Each classroom is a unique community of learners based on a give-and-take between a particular teacher or coteachers and their students. Classroom information requirements differ from the information requirements for standardized assessment—where context should not matter—in important ways. Formative assessment foregrounds the role of the student and often invokes contemporary learning theories that view the student as an active participant in assessment and learning. This changes the role of students from test takers to learners. Formative assessment is heavily dependent on the quality of the process, not just the quality of the tools, instruments, or questions, for its effectiveness. Formative assessment works best when both students and teachers know how to use it effectively. While research suggests formative assessment can have more impact on teaching and learning than other types of assessment, these challenges and others must be met, even if gradually, for classroom formative assessment to reach its full potential.

Interim and Benchmark Assessment

Many educators and districts use the terms interim and benchmark assessments as synonyms, and the terms have been used interchangeably in the research literature as well. Sometimes a distinction is made: Interim assessments can be parallel test forms for an external accountability test, covering an entire year's worth of content and administered two or three times during the school year to track student learning and achievement growth; and benchmark assessments can be nonparallel test forms covering a portion of the year's content (e.g., the first report period) and administered at a specified point in the school year and curriculum (Ferrara et al., 2019). This chapter uses the term interim assessments for both.

Many interim assessments are sold by test vendors. Interim assessments can also be sold as item banks or as item banking and testing software that can be populated with locally written items or items from other sources. Burch (2010, p. 147) defined interim assessment technology as “the software that is sold to schools and districts in order to gauge students' progress towards high-stakes summative tests and to comply with the test reporting requirement of the No Child Left Behind Act (NCLB) of 2001.” She argued that the upsurge in use of interim assessment technologies represents an intensification of educational privatization brought on by NCLB (Burch, 2006, 2010) and that this is at least partly because of pressure on schools to be “more efficient, more compliant, and more equitable” since NCLB (Burch, 2010, p. 147).

PURPOSE AND USES OF INTERIM ASSESSMENT Interim assessments are used to serve one or more of three general purposes: instructional, predictive, and evaluative (Perie et al., 2009). For example, an instructional purpose might be to identify particular

content or standards for remediation or reteaching. A predictive purpose might be to determine each student's likelihood of attaining a proficient score on the end-of-year state accountability test. An evaluative purpose might be to provide information about the effectiveness of an instructional program or some curriculum materials. In practice, most districts use interim assessments for several different purposes simultaneously, most commonly for instructional and evaluative purposes (Dadey & Diggs, 2019; Davidson & Frohbieter, 2011). Even when districts use interim assessment for predictive purposes, the intent of the prediction is to inform instruction before the state accountability test, not simply to make the prediction.

DESIGN OF INTERIM ASSESSMENT As the above definitions imply, most interim assessments were designed primarily to give predictive information. They often use a small sample of items across many standards and at the standard level are most reliable for decisions about groups. However, the logic used by district administrators when they purchase interims is that an investment in gathering interim information will support alignment of teaching and learning in the district, provide practice for state accountability tests, and provide information for teachers on the needs of both current and future students (Clune & White, 2008)—again illustrating that trend to want to add a student-level diagnostic purpose to all assessments. The fact that one assessment would not serve these purposes equally well is not typically considered (Perie et al., 2009); however, it is an important consideration in evaluating research on the effectiveness of interim assessments (Immekus & Atitya, 2016).

Interim assessments may be computer-administered or paper-and-pencil tests and usually result in one or more of the following kinds of scores: scale scores, percentiles, and proficiency-level ratings. The results are meant to be used by teachers and administrators to assist individual students (for grouping, remediation, and so on) or to assist with group planning (to identify strengths and weaknesses in current instruction and plan for future instruction). The intention is that educators will set goals, measure and evaluate progress, and use data to make changes. This process is focused mainly on educator learning and is relatively silent on student learning. The intended connection between interim assessments and student learning comes from the claim that measures are linked to learning standards. The most common responses to interim data are reteaching and review (Penuel & Shepard, 2016).

MEASUREMENT CONSIDERATIONS IN INTERIM ASSESSMENT Some commercially produced interim assessments have technical manuals that present standard kinds of information about reliability, validity, and scaling (e.g., Northwest Evaluation Association, 2019). Some, of course, do not. Many of the more established commercial products are reviewed in the Buros Mental Measurements Yearbook series (<https://buros.org/mental-measurements-yearbook>). Validation differs depending on the intended use of the interim: whether instructional, evaluative, or predictive (see also Lane & Marion, this volume).

Arguably the predictive use requires the simplest and most readily available validity evidence, to answer the question of how well performance on the interim predicts state accountability test scores. R. S. Brown and Coughlin (2007) investigated the availability and quality of predictive validity information for a selection of interim assessments used in the Mid-Atlantic region. They considered four assessments (the Northwest Evaluation Association's Measures of Academic Progress, MAP; Renaissance Learning's STAR; Study Island; and CTB's Terra Nova). While all four provided concurrent or predictive validity information of some sort, only one, Terra Nova, presented a truly predictive study.

Pereira and Tienken (2012) undertook a study in four middle schools to support the validity of using a computer-based interim assessment tool as recommended by the New Jersey Department of Education. The tool had pre- and posttests in mathematics and language arts. The product was marketed to predict achievement on the state accountability test. Findings indicated that the pretest and posttest had almost identical predictive power, prompting the authors to question the need for a posttest (Pereira & Tienken, 2012, p. 11). Further, Babo et al. (2014) reported that the odds ratios for passing the state test for pretest and posttest scores were close to 1, indicating little predictive power. This finding is consistent with broader finding of the large contribution of general mental ability to assessments of educational achievement (Deary et al., 2007).

IMPLEMENTATION OF INTERIM ASSESSMENT IN PRACTICE Dadey and Diggs (2019) identified and summarized 20 studies of interim assessment use. They found the most frequent reported uses were instructional, usually in the form of broad claims that interim results would be used to modify or improve instruction. All 20 of the studies they reviewed listed instructional purposes, for example, general instructional planning, grouping students, and providing remedial support. Sixteen studies also mentioned evaluative purposes, citing evaluation of teachers, programs, and curriculum and supporting resource allocation at the staff, school, and program levels. Eight studies cited predictive use of interim results and always the same one: predicting student performance on the state accountability test.

The process of gathering interim assessment information and using it to make decisions is usually framed as some sort of data-driven decision-making process (Penuel & Shepard, 2016), often more about management than about learning. Acknowledging this shortcoming yet wishing to harness the formative power that can be gained by gathering relevant data for specific learning needs, Wiliam (2018a, p. 47) called for "decision-driven data collection."

Marsh (2012) described a data use theory of action with five steps: (a) access and collect data; (b) turn data into information by organizing, filtering, and analyzing; (c) turn information into knowledge by combining it with teacher understanding and expertise; (d) apply the knowledge to arrive at a response and action, and (e) assess the effectiveness of the outcomes of that action. This is a very linear expression of what is inherently an interpretive process (Blanc et al., 2010; Farrell & Marsh, 2016). Accordingly, the

research studies in their Philadelphia project (Blanc et al., 2010; Christman et al., 2009) reframed the teacher data use process as sense making. They described three types of sense making in which teachers engaged with interim data. They described strategic sense making as the most common; it focused on short-term adequate yearly progress targets—things like identifying students who could, with just a little help, become proficient. Affective sense making, also common, focused on teachers' professional responsibilities and things they could do to motivate students and improve learning. Reflective sense making was least common; it focused on questioning and evaluating one's instructional practices.

The Urban Data project of the Council of the Great City Schools (Faria et al., 2012; Heppen et al., 2010, 2011) situated teacher data use within a broader theory of action with five key dimensions: (a) the district's assessment context, (b) supports for data use, (c) working with data, (d) instructional responses, and (e) improved student achievement. This theory of action considers contexts and supports as foundational to data use and achievement outcomes. Heppen and colleagues (2010) found that the assessment context in schools predicted the other key dimensions and that teacher attention to data was a significant, positive predictor of instructional responses. Bulkley et al. (2010) concluded that interims could serve instructional purposes, but only if strong district supports were in place.

The use of interim data is limited by time constraints, especially lack of time for remediation and the presence of pacing guides for instruction (Abrams et al., 2016), and also by the data culture or context in schools (Goertz et al., 2009; Heppen et al., 2010), as well as teachers' own facility with and attention to data (Faria et al., 2012; Heppen et al., 2010). One study using the web logs behind a district's information dashboard (Tyler & McNamara, 2011) found that, on average, teachers spent 2.3 minutes per week looking at the class roster page of their interim results and 30 seconds per week looking at individual student pages—or less than 3 minutes per week on the two results pages that contained information relevant to instructional adjustments. Another study of the use of interim assessments in an urban charter high school found that the tests, based as they were on grade-level standards, did not provide much useful information on students who were often more than 2 years behind in grade-level achievement. In addition, there were too many separate and varied standards on the tests to help teachers make decisions about what to do, since the students needed assistance in most or all of them. For these reasons, that testing program was abandoned after just over 3 years (Bancroft, 2010). Another study, using randomized controlled trials, found little evidence of changes in teacher practices as a result of having access to an interim assessment tool (Chojnacki et al., 2013).

Several studies describe the instructional decisions teachers report making on the basis of interim assessment results, and these studies also note great variability by teacher, including some teachers who do not use the information. Teachers who do use interim results tend to use it to identify topics to teach and students with needs in those topic areas (Abrams & McMillan, 2013; Abrams et al., 2015; Goertz et al., 2009; Oláh et al., 2010; Shepard, 2010), although these decisions are influenced by teachers'

perceptions of the difficulty of particular content and students' past performance (Goertz et al., 2009) and their perceptions of the assessment's design and item quality (Abrams et al., 2015; Farrell & Marsh, 2016). Most teachers have not been found to use interim results to change the way they teach content or to look for underlying reasons students may have developed misunderstandings (Christman et al., 2009; Goertz et al., 2009; Oláh et al., 2010). For example, a study of teachers' use of mathematics interim assessments found teachers mostly used results to group students or reteach procedural knowledge, rather than making sense of students' conceptual understanding (Oláh et al., 2010). Teachers report using interim data to identify students who could potentially move from *Basic* to *Proficient* or *Below Basic* to *Basic* by the time of the state test, to identify skills and concepts to reteach, to identify students with similar areas of weakness or strength, to change some classroom routines (Blanc et al., 2010), and, in mathematics, to locate and diagnose errors (Goertz et al., 2009).

Several studies discussed teachers' use of interim data as part of a larger assessment system that included classroom formative assessment, teacher-developed classroom summative assessments, teacher-developed common formative assessments, interim assessments, and state accountability assessments. Wilkerson et al. (2021) surveyed teachers in Nebraska and found that some teachers did not use data at any level (state summative, interim, or classroom formative), but those who did used data from interim assessments once or twice a month to inform instruction. Farrell and Marsh (2016) found teachers had the most mixed opinions of interim assessment data, which they often found less useful and less trustworthy than other kinds of assessment data. In the span of a district assessment system, data from state accountability tests sometimes influences grouping and instructional decisions at the beginning of the year (Abrams et al., 2016). Interim assessment data, as noted above, is most often used to decide *what* to teach to whom, often looking backward at what content needed reteaching (Abrams et al., 2016; Farrell & Marsh, 2016; Riggan & Oláh, 2011). Classroom formative assessment, in contrast, is used to help get students to explain their thinking (Abrams et al., 2016; Riggan & Oláh, 2011) and support decisions about *how* to teach or reteach going forward. Sometimes teachers looked to classroom formative assessment information to help explain or deepen their understanding of interim assessment results to make instructional decisions (Martone et al., 2018).

To use interim assessments well, teachers and administrators need to be able to read, interpret, and use a wide range of both norm- and criterion-referenced scores, as well as understand the concepts of standard error of measurement and standard error of the mean or other aggregated scores, the limited reliability of change scores, and the like. They also need the skills to communicate assessment results to parents and students in an understandable fashion. Many test vendors provide teacher resource material and professional development as part of their interim programs, but as reported previously, the evidence suggests that the inclusion of these resources does not necessarily lead to deeply conceptual differentiated instruction or to improved student achievement.

IMPACT OF INTERIM ASSESSMENT ON LEARNING A small number of studies have evaluated the effects of using interim assessments on student achievement. Faria et al. (2012) found that teacher data use and student achievement were statistically significantly but weakly correlated in middle school mathematics and elementary reading but not in elementary mathematics or middle school reading. Principal data use was statistically significantly correlated with student achievement only in middle school mathematics.

Three randomized studies were found, each investigating different interim assessments. One looked at the effects of using interim assessments (mCLASS in K–2 and Acuity in 3–8) in the state of Indiana in the 2009–2010 school year on the state ISTEP+ test (Konstantopoulos et al., 2013, Konstantopoulos, Li, Miller, & van der Ploeg, 2016; Konstantopoulos, Miler, van der Ploeg, & Li, 2016). Effects in mathematics were statistically significant in Grades 3–8 (not in K–2); effects were larger in the lower (10th and 25th) quantiles. Effects in reading were smaller and not always significant. The exact effect size depended on the grades included in the analysis and whether the analysis examined intent to treat or treatment on the treated (Konstantopoulos et al., 2013). A second study looked at the effects of a program implemented by the Johns Hopkins Center for Data-Driven Reform in Education, including the use of their 4Sight benchmark tests and associated professional development (Carlson et al., 2011), in 500 schools in seven different states, again using the state tests as the dependent variable. They also found significant weak effects in mathematics but not in reading. A third study (Cordray et al., 2012) looked at the effects of using the Northwest Evaluation Association’s MAP program in 32 elementary schools in Illinois in Grades 4 and 5 reading. MAP teachers were not more likely than control teachers to use differentiated instructional practices in their classrooms, and there was no significant effect on reading achievement in either Grade 4 or Grade 5. Another study in Massachusetts, using a matched comparison design, compared the 2001 to 2006 Massachusetts Comprehensive Assessment System (MCAS) scores for high-poverty middle schools that were in a pilot program using benchmark assessment with the scores of schools that were not. The intervention occurred in 2006, when the pilot schools used interim assessment technology software to develop quarterly benchmark tests. There were no differences between treatment and comparison schools, either in 2006 (Henderson et al., 2007) or 1 year later (Henderson et al., 2008).

EVALUATION OF INTERIM ASSESSMENT INFORMING TEACHING AND LEARNING The popularity of interim assessments grew from a perceived need for more frequent information for educational accountability assessment. However, the popularity of interim assessments and the pressure to use them for diagnostic decisions they are not designed to support presents interesting evidence of the movement toward insisting that assessment inform teaching and learning—the trend toward the formative use of assessment information.

On balance, then, two arguments are supported. First, teachers do not make much effective use of data from interim assessments. It does seem that educators’ use of

interim data can be described by one or more of the posited theories of action for data-driven decision-making. However, these processes alone, at least as used to date, offer only a very partial explanation of what happens as educators use data. Many teachers do not engage in these processes, or they do so with inadequate assessment literacy or with instructional adjustments that are topical or procedural rather than adjustments intended to support students' conceptual change.

Second, there is little evidence that using interim assessments improves student achievement. There are only a small number of studies of the effects of interim testing programs on student achievement. These studies yield only small and intermittent effects or no effects. Studies show teachers use item analysis as a main strategy for decisions about reviewing topics and procedures rather than seeking to understand student thinking, and items are only samples from an achievement domain and not the domain—the achievement standards or learning goal—itsself. Therefore, even if teachers did make better use of interim assessment data, it is not likely that their effectiveness would be dramatically improved.

Common Formative Assessments and Other District-Developed Assessments

Some districts design what they call *common formative assessments* to be administered across classes in a specific subject area and grade level at pause points in instruction, for example, after an instructional unit or series of related units. The intention is typically to inform teacher instructional planning.

PURPOSE AND USES OF COMMON FORMATIVE ASSESSMENTS Ainsworth and Viegut (2006, pp. 2–3) defined common formative assessments as “assessments collaboratively designed by a grade-level or department team that are administered to students by each participating teacher periodically throughout the year.” Teachers use information from common formative assessments for instructional planning for current students and for future planning for when they teach the same subject matter again.

DESIGN OF COMMON FORMATIVE ASSESSMENTS Common formative assessments are usually, although not always, tests and are sometimes performance assessments created or curated by teachers who teach common curricular material in a building or across a district. All of the literature, both professional and scholarly, consulted by the authors assumed quantitative scoring of some kind: right/wrong for selected-response tests and the use of a rubric, typically arranged as a proficiency scale on the standard, for constructed-response test items and performance tasks.

For Heredia et al. (2016), collaborative teacher design is part of the common formative assessment process. Ainsworth and Viegut (2006) added collaborative scoring. Ideally, the use of a common tool for formative assessment will decrease the variations in teacher formative assessment practices and potentially therefore maximize student learning (Heredia et al., 2016, p. 698). Some test vendors produce

assessments they call common formative assessments and market them to school districts, which circumvents the teacher design work and its benefits in terms of developing consensus on both formative assessment (Heredia et al., 2016) and supporting student learning (Furtak, Circi, & Heredia, 2018) and makes these products similar to interim assessments.

Common formative assessments are distinguished from other school-based tests, for example, departmental tests in secondary education, in that their use is intended to inform teacher instructional planning and not student grading. At their best, common formative assessments can inform both instructional planning and teacher professional development (Furtak & Heredia, 2014). Common formative assessments are a cornerstone of the professional learning communities movement (DuFour et al., 2010; Myers, 1996) that has gained momentum in school districts around the United States.

MEASUREMENT CONSIDERATIONS IN COMMON FORMATIVE ASSESSMENTS The professional literature recommends that teachers, typically in grade-level or subject area teams, study collaboratively standards, curriculum documents, and other instantiations of what students should know (e.g., textbooks, examples of student work, or previous student performance data) to establish what they will design their common formative assessments to measure (Ainsworth & Viegut, 2006; DuFour et al., 2010). To date, the authors of this chapter have found no studies of the quality of teacher team–developed common formative assessments. However, the heavy emphasis on teacher teams identifying standards or learning progressions and aligning common formative assessment items and tasks to them, in regard to both content and level of thinking, suggests that the content-related evidence for validity—and a match between the tested and taught curriculum—may be a strength of common formative assessments.

To make sure information from locally created common formative assessments is of high quality and can support instructional decisions, the professional literature simply advises district teams to look at recommendations from assessment experts; released items from other testing programs, including on websites such as that for the National Assessment of Educational Progress (NAEP; <https://www.nationsreportcard.gov/nqt/>); and examples of performance assessments and rubrics from local or other sources (DuFour et al., 2010). District teams are advised to refine assessments after use according to established standards for evaluating assessments (Ainsworth & Viegut, 2006). Given the documented variability of teachers' assessment practices in other areas (see, for example, the section on "Grading"), it is reasonable to expect that this advice will be followed more in some places than in others and that there will be variability in the quality of common formative assessments.

IMPLEMENTATION OF COMMON FORMATIVE ASSESSMENTS The process of implementing common formative assessments may be quite loose or it may be more structured, depending on how teams in any given school operate. It is typically part of a school

improvement process. For example, the Team Learning Process (DuFour et al., 2010, pp. 26–33) calls for a process in six steps: (a) identify essential outcomes all students must learn; (b) create common pacing guides and curriculum maps all teachers will follow; (c) develop multiple common formative assessments; (d) establish a target score for proficiency in each skill on each assessment; (e) administer common formative assessments and analyze results; and (f) celebrate strengths and identify and implement improvement strategies. This is a standards-based approach.

The Formative Assessment Design Cycle (Heredia et al., 2016; Furtak & Heredia, 2014) uses a learning-progressions approach, in five steps: (a) reflect, (b) explore student ideas, (c) design tools, (d) practice using tools, and (e) enact tools. Then the cycle repeats, beginning with reflection; typically, the tool (the common formative assessment) is also revised. Reflection is based on current teaching practices as well as student work. Exploring student work can include looking at aggregated data as well as examples of individual student work, with a focus on student thinking.

When done well, the work involved in aligning content standards with the assessments can serve as professional development for the teachers (Frey & Fisher, 2013). Gallimore et al. (2009) conducted a 5-year quasi-experimental study of teacher professional development using an inquiry protocol and found that teachers' attribution of improved student performance changed from implicating external causes to attributing learning to their own teaching. Part of the protocol involved looking at indicators of student learning, designed by the teachers together.

Assessment literacy requirements for teachers creating tests or performance assessments aligned with standards, to be administered across classes, are high. Teacher assessment literacy rises as part of the process (Furtak et al., 2014, 2016; Heredia et al., 2016), and assessment validity rises because the work is informed by collaboration with teachers and access to their pedagogical content knowledge (Ball et al., 2008). Even with support, however, teacher growth in understanding of learning progressions and the assessment strategies and tools that will elicit evidence about them takes time and involves struggle (Furtak, 2012; Furtak & Heredia, 2014).

IMPACT OF COMMON FORMATIVE ASSESSMENTS ON LEARNING Little published evidence of the impact of common formative assessments on learning was found. Gallimore et al. (2009) reported evidence that when teachers used inquiry and followed a learning problem long enough to understand it, assess it, and address it, student achievement improved. This professional development included the use of some assessments that could be described as similar to common formative assessments. Frey and Fisher (2013) found that the use of common formative assessments helped increase student achievement in writing.

EVALUATION OF COMMON FORMATIVE ASSESSMENTS FOR INFORMING TEACHING AND LEARNING Common formative assessments involve teachers in a collaborative process to check on student progress on learning standards in their curriculum. In principle this

is a sound idea, and there is some evidence that when done well, teachers and students benefit. However, there is also evidence that assessment design is difficult for teachers to do well, and because of recommendations in the teacher professional literature it is likely that many common formative assessments of unknown quality exist. One key to effective use of this type of assessment is increased literacy on the part of teachers regarding the construction and interpretation of assessments. Increased literacy may also help teachers select, rather than design, appropriate assessments.

Assessment Focused on the Summative

When assessment informs teaching and learning, it is being used for a formative purpose. Therefore, it may seem that assessments designed for summative purposes should have no place in this chapter. However, there is evidence that both effective teachers (Wiliam et al., 2004) and successful students (Brookhart, 2001) use information available from summative assessment to inform future planning. Moreover, as assessment trends toward the formative, it is more and more common that educators are expected to use all available data sources, including summative, to inform teaching and learning (Farrell & Marsh, 2016; U.S. Department of Education [U.S. DOE], 2009; Wilkerson et al., 2021).

In effect, because learning is ongoing, most K–12 summative assessments fulfill their immediate summative purpose, but in the larger picture serve more as periods at the end of sentences rather than as the end of a story. This chapter will consider the use of two common forms of summative assessment, grading and state accountability testing, for formative purposes.

Grading

Grading refers to the symbols assigned to individual pieces of student work or to composite measures of student performance on student report cards. A long history of research has led those who study measurement to question the reliability and validity of grades and, sometimes, therefore, to dismiss their importance. However, grades loom large in the educational experience of all students and are the activity on which teachers spend most of their assessment time, at least at present. They are perhaps the most universally used assessment to inform teaching and learning (Brookhart et al., 2016).

PURPOSE AND USES OF GRADING Grading has a wide array of purposes and uses. Grades are used to inform teachers, students, and parents/caregivers about teaching and learning at many different levels, for example, to support next steps in instruction or studying for a small amount of instructional content or to make broader decisions about next year's teaching or course taking. Grades are used to rank and sort students for various placement and selection decisions, for example, as part of decisions about placing students with special needs in classes or programs, qualifying students to participate in extracurricular activities, and college admissions. Grades can be used to evaluate teachers, schools, and educational programs. Informally, students and teachers

use grades to do all sorts of things they were never meant to do, for example, support classroom behavior management or students' sense of self-worth (Covington, 1992; Thomas & Oldfather, 1997).

A recent grading reform in the United States, called standards-based grading, reports student achievement relative to content standards established for a particular grade level. Reformers claim this gives students, parents, and educators more useful feedback (Peters et al., 2017). In other words, in standards-based grading, grades are assumed or intended to inform teaching and learning and that purpose is assumed to be primary. Standards-based grading, therefore, makes explicit that grades are to be used formatively as well as summatively, something that traditional grading practices typically do not do. Standards-based grading principles call for reporting academic achievement separately from behaviors, effort, and attendance; referencing both assessment and grading to standards; using report card grades to report current achievement status by prioritizing the most recent evidence of learning; allowing students to edit and resubmit work; using proficiency-based rubrics and decision rules for aggregating them that take their ordinal nature into account; and using quality formative assessments as well as summative assessments (Guskey & Bailey, 2001; Peters et al., 2017).

DESIGN OF GRADING Grades come in many forms. For traditional report cards in the United States, the most common is an ordinal scale of letters (often ABCDF). Many high schools report grades as percentages (0–100), and many schools at all levels that use the ABCDF scale for report cards grade individual pieces of student work on the percentage scale. Many other countries (e.g., Botswana, Canada, Sweden) use some version of a categorical scale, typically letters. An ordinal scale of proficiency levels (e.g., *Advanced*, *Proficient*, *Developing*, *Emerging*, or 4, 3, 2, 1) is often used with standards-based grading, a practice that evaluates student achievement against individual standards rather than subject areas overall. The process of assigning grades is at present mostly a teacher function, although students can be involved, and there is evidence students are fairly accurate in their appraisals of their own work (Sanchez et al., 2017).

MEASUREMENT CONSIDERATIONS IN GRADING Grades have the distinct disadvantage that the general public thinks they understand their meaning (“I’ll give that restaurant an A+”; “C is average”), when often such meanings no longer apply, if they ever did. Different stakeholders may view grade categories differently. For example, Waltman and Frisbie (1994) found that on average—and with much variation—parents and fourth graders thought the average mathematics grade was a C+ when in fact it was a B.

Validity In the early 1900s, in what would now be called validation research, studies sought to describe the relationship of grades to intelligence, assuming that intelligence was the construct grades were supposed to measure, just as the purpose of schooling was to sort students so that the bright students received more education and the duller

students left school for more menial jobs (e.g., Banker, 1927). As the philosophy of teaching shifted from sorting students to a more achievement-based approach, studies of the validity of grades shifted to comparing grades with tested achievement, as measured by a standardized test (e.g., Moore, 1939), expecting strong relationships between these two measures of achievement. However, this is not and has never been the case (Bowers, 2011; Brookhart, 2015; Brookhart et al., 2016). Over half a century ago, Miner (1967) demonstrated that graded achievement and tested achievement are not the same construct.

There is ample evidence that teachers use nonachievement factors in grades (Brookhart, 2013), against the recommendations of measurement professionals (Stiggins et al., 1989), which may explain part of the difference. Bowers (2009) termed the variance in grades not accounted for by standardized tests of achievement a “success at school factor” (p. 623). His study replicated the existence of the nonacademic factor in U.S. students’ grades that Lekholm and Cliffordson (2008) had found in Sweden and named it, arguing that this measure of success at school should be useful for educational decision-making beyond the information available from standardized test scores.

That high school grades are a slightly better predictor of first- and second-year college grades than ACT scores (Westrick et al., 2015) also supports the notion that high school grades include some sort of success-at-school factor. Galla et al. (2019) showed that the incremental predictive validity of high school grades (beyond test scores) for on-time graduation from college was explained by student self-regulation, while the incremental predictive validity of test scores (beyond grades) was explained by cognitive ability. This study is important because it adds a theoretical framework, self-regulation, to the practical idea of a success-at-school factor. (See also Camara et al., this volume, for a review of research related to admissions and predictive validity.)

There is some evidence that grades can yield higher quality information if certain effective grading practices are followed (Pollio & Hochbein, 2015; Welsh et al., 2013; Willingham et al., 2002). There is also ample evidence that high-quality grading practices are not always followed (Brookhart et al., 2016). Cumulative grades, but not individual grades, are valid for purposes of predicting and sorting (Anderson, 2018). Evidence is not strong for the validity of either cumulative or individual grades to provide information about student achievement of specific learning outcomes.

Reliability In the early 1900s, the accuracy of the 100-point scale was questioned (e.g., Starch, 1913), and categorical grading was adopted to increase reliability—or at least as a trade-off between perceived precision and reliability. Most grades currently, in the United States and around the world, use a categorical scale of some length. The categories may be based on cutoffs on a percentage or other point scale or on performance-level descriptions for each of the categories.

Recently, attention has turned to the reliability of grade point averages. Beatty and colleagues (2015) found an overall estimate of reliability of .86 for first-year college grade point average and .93 for overall grade point average. Westrick (2017) reported

the range of reliability values for fourth-year cumulative grade point averages at each of 26 four-year institutions was .89 to .92. Thus, while grades on single assessments may be unreliable, cumulative grades are reasonably reliable (Anderson, 2018). Again, though, the reliability in question is reliability for relative ordering. Although this is an important quality, it pertains more to some of grading's many purposes than to others. Reliability of proficiency classification, for example, was not studied.

For some grading purposes, most notably the sorting and ranking ones, the added precision that comes with aggregating, especially up to the level of a grade point average, adds reliability. For other grading purposes, most notably the feedback-related purposes of conveying information about student achievement of specific subject area content or standards, the added precision may muddy interpretation. In the case of a borderline grade, for example, there may not be a meaningful difference in achievement between a very high B and a very low A, but the categories proclaim such a difference and students and teachers may act on the basis of that difference.

When categorical (ordinal) grades are used, nonparametric statistical techniques are best suited to aggregating component grades on students' tests, projects, and other summative assessments into composite grades for reporting. In the early 21st century, that aggregation is most often accomplished with grading software, much of which was developed by programmers who have not studied the nature of grades and treat them parametrically (e.g., using means, standard deviations), with calculations often carried to several decimals and imputing a precision that was not there to begin with. For better or worse, grading software removes some of the decision-making about grading from teachers' hands.

IMPLEMENTATION OF GRADING IN PRACTICE Research on teacher grading practices, for example, what assessments teachers count in a report card grade, has been much studied since the early 1900s and reviewed periodically (Brookhart, 1994, 2013; Brookhart et al., 2016; A. D. Crooks, 1933; Kirschenbaum et al., 1971; Smith & Dobbin, 1960). All these reviews concluded that the most effective grading system would be to report student achievement on established standards, using explicit criteria, and all found that then-current grading practices typically did not do that. Standards-based grading reforms, beginning in the 1990s and gaining more traction in the 2000s, are intended to remedy this situation. The movement is gaining momentum, but definitive studies are not yet available.

Much research on teachers' grading has used a practical, rather than theory-based, approach and simple survey methods. General findings include the following (Brookhart, 1994, 2013): Teachers try hard to be fair to students, including informing them of what will contribute to their grade. Achievement measures, especially tests, are the major components in grades; teachers commonly also consider effort and ability. Elementary teachers use more informal evidence and observation than secondary teachers, who base grades more on paper-and-pencil tests and other written activities.

Finally, teacher grading practices vary widely, partly because different teachers view the meaning and purpose of grades differently (Frary et al., 1993; Vanlommel & Schildkamp, 2019).

Two recent research agendas (McMillan, 2001; McMillan et al., 2002; Randall & Engelhard, 2009, 2010) support the conclusion that while teacher grading practices are much maligned, in fact academic achievement is the factor teachers consider most heavily. Teachers reported considering academic enablers (McMillan, 2001), such as effort, in students' grades as a way to evaluate students' academic engagement, which some teachers value as part of school learning. Randall and Engelhard (2010) also found that academic achievement is the factor teachers primarily consider when assigning academic grades. They found interactions among ability, achievement, behavior, and effort: with high effort and behavior, low-achieving, low-ability students receive an average grade of C+, and in general, high effort and behavior boosts the grades of students of any ability somewhat. Thus, studies continue to find that teachers' grading practices mix achievement and nonachievement factors, but it seems clear now that achievement is the main component of grades, and teachers' use of other factors is generally reported to be motivated by what in their view is good for students.

If, in general, improving teacher assessment literacy is difficult (C. Campbell, 2013), in grading it is even more difficult because of the multiple conflicting viewpoints teachers hold about grades. For example, Olsen and Buchanan (2019) investigated changes in the understanding and grading practices of teachers involved in year-long professional development designed to reform grading practices in two secondary schools. Change did occur, but it was partial and did not necessarily have the intended effects. Teachers sometimes adapted recommended strategies and then refined them to fit their classroom context, in the process using a belief system that the grading reforms were meant to change.

Students, too, need some basic assessment literacy to understand and benefit from the feedback inherent in the grades they receive. Almost by definition, successful students navigate this well, eagerly wringing any information they can get from their grades to learn more and continue to do well in school (Brookhart, 2001). Students need to learn that grades apply to their learning and not to them as people, that grades are changeable, and that, at least to a large degree, that change is under their control. These lessons, of course, only hold true in situations where teachers' grading practices are supportive of learning.

IMPACT OF GRADING ON LEARNING Grades constitute a form of summative feedback that is used for reporting and certifying student learning. However, successful students also use grades as part of their self-regulation of learning, as they learn to become self-monitoring; as part of their self-efficacy development, as they learn how grades sum up their performance; and as part of their metacognition, as they use grades as one piece of evidence to judge the quality of their own understanding (Brookhart, 2001).

Students consider grades a type of feedback. For example, Harris et al. (2014, p. 121) asked a sample of New Zealand upper primary and lower secondary school students to create a free-response drawing of their experience of feedback—44% of the drawings included grades or scores.

Lipnevich and Smith (2009a,b) pointed out that the most common type of feedback students receive in class is grades. Nevertheless, the U.S. college students in their focus groups deemed grades unnecessary if the purpose of the activity was to learn. In addition, they exhibited negative emotions when receiving a low grade; some became angry at the instructor and others reported dissatisfaction with themselves or embarrassment. In a survey of teacher education students in Australia, “stated grade” was rated as the least useful type of feedback with the exception of group verbal feedback; “written summary” and “brief comment throughout” were rated most useful (Ferguson, 2011).

College students want feedback even on graded work (Pitt & Norton, 2017), using the term *feedback* to mean comments. This study of UK university students showed they interpreted grades and any additional feedback differently depending on their feelings of competence, their feelings about their lecturer, and their level of emotional maturity. One of the students in Pokorny and Pickford’s (2010) focus groups of college students in the United Kingdom commented that feedback (comments) accompanying final graded work was moot, since “it’s way too late to do anything about it” (p. 24).

The effects of grading practices on students’ motivation to learn has also been studied. T. J. Crooks (1988) and Covington (1992) both showed the effects of school evaluation practices on students. Covington (1992) called for practices that fostered what he called “motivational equity” (p. 21); not all students can learn the same things, but all students should experience evaluation practices that support student learning (p. 21):

Everyone can experience feelings of resolve and a commitment to think more, and to dare more; feelings of being caught up in the drama of problem solving, and of being poised to learn and ready to take the next step.

He showed that low grades do not accomplish this. Lohbeck (2019) found that for a sample of German fourth graders, self-reported grades in mathematics and German predicted academic self-concept in the respective domain (but not the other), which in turn predicted self-perception of effort in the domain. In other words, students whose grades give them evidence that they are effective learners in a domain may be motivated to continue to expend effort in learning in that domain.

EVALUATION OF GRADING INFORMING TEACHING AND LEARNING Grades are used for wide range of purposes, some of which they serve better than others. Grades are multidimensional measures of situated school learning and correlate only moderately with standardized achievement measures. Grades have a long history as assessment

information used to inform teaching and learning. There is evidence that grades can be supportive of student learning if certain grading practices are followed, although there is great variation in grading practices. Grading may be one of the most difficult areas in which to support and improve teacher assessment literacy because many people (teachers, parents, students, etc.) have strongly held opinions and feelings about grading, based on their own grading histories.

State Summative Assessment

High-stakes, large-scale assessment has affected teachers' instructional practices (Faxon-Mills et al., 2013; Pedulla et al., 2003); that is, state summative assessment has been and is being used to inform teaching and learning. However, the ability of such assessments to inform teaching and learning is limited, at best.

PURPOSE AND USES OF STATE SUMMATIVE ASSESSMENT State summative assessments are typically administered beginning in March or April and are not intended to provide information to inform the instruction of students within the current academic year. Rather, state summative assessments, also referred to as state accountability tests or simply state tests, are intended to serve state and federal accountability purposes, including district-, school-, teacher-, and student-level accountability. State summative assessments may provide information that is useful to teachers to evaluate their instructional practices or useful to schools and districts to evaluate their curricular and instructional programs.

DESIGN OF STATE SUMMATIVE ASSESSMENT Beginning in the 1990s, many state assessments were designed to serve as examples of the type of assessment that should be occurring in the classroom. The increased use of constructed-response items, direct writing prompts, and performance tasks within traditional end-of-year assessments and alternative formats such as portfolio assessments is evidence of this desire to give students a test worth teaching to (Resnick & Resnick, 1992; Rothman, 1995; Shepard, 1991). For example, one state wrote that the purpose of state assessments was “to improve classroom instruction by (a) providing useful feedback about the quality of instruction and (b) modeling effective assessment approaches that can be used in the classroom” (Massachusetts Department of Education, 1999, p. 4).

The implementation of NCLB in the early 2000s brought both increased stakes in terms of school accountability and increased testing with the requirement of annual testing of all students in Grades 3 through 8 plus one grade in high school (NCLB, 2001). The 2010s further increased the stakes and footprint of state summative assessments in the classroom with longer tests, more complex standards and tasks, the declaration of an “honesty gap” between national test scores, state test scores and teacher grades, and the use of test results for teacher evaluation (Achieve, 2013). These factors converged to create an expectation that state summative assessments can, should, and must provide “actionable information” to inform teaching and learning (CCSSO, 2013;

U.S. DOE, 2015), another instance of the pressure to extract such information even from assessments not designed for it.

The primary information from state summative assessments is an indication of student performance in relation to state achievement standards in terms of scale scores and achievement levels. State summative assessment operationalizes the state's content standards and performance expectations, showing teachers how the state is interpreting the content standards. In many state programs, this information is supplemented by sets of released items with annotated samples of exemplar student responses to constructed-response items or essays. All of this information is designed to help increase teachers' and administrators' understanding of the state's interpretation of the content standards and expectations for students at each grade level. Teachers and administrators are expected to use such information to calibrate their expectations for student performance with those of the state (Madaus et al., 2009; Parsi & Darling-Hammond, 2015).

MEASUREMENT CONSIDERATIONS IN STATE SUMMATIVE ASSESSMENT Federal peer review has ensured that the process of gathering data and producing scores on state summative assessments is typically sound. Operational best testing practices employed routinely by assessment contractors in conjunction with federal requirements and peer review for state assessments systems, including requirements regarding accessibility and the availability of accommodations, and the commonplace practice of convening technical advisory committees for state testing programs help ensure the quality of the process and the validity of the results, although the availability and quality of validation studies related to state assessment programs remains a concern. State assessment programs, however, are not immune from real and perceived errors or irregularities in test administration, scoring, or reporting, which are often consequential and highly publicized (Rhoades & Madaus, 2003). In addition, there are long-standing concerns about the generalizability of results from state summative assessments and test score inflation due to test preparation and a narrowing of instruction to the particular standards, or portions of standards, included on the state summative assessment (Koretz, 2017).

The process of designing state summative assessment programs for school accountability, including the selection (or rejection) of items based on their statistical properties, however, limits the usefulness of the information gathered through state summative assessments to inform teaching and learning because the assessments' design focuses on the summative purpose. State assessments are designed to produce information about overall student achievement of, or proficiency on, state standards, focused appropriately on the validity of inferences related to these broad student outcomes. In contrast, most instructional decisions require more fine-grained diagnostic information. In addition, measures to inform teaching and learning need to provide timely information about student performance and the instructional process, and they should be based on an explicit theory of student learning and a theory of action related to improving instruction (Ing et al., 2021).

Measures that inform improvement in instruction need to be explicitly linked to a theory of improving instruction (Bryk et al., 2015). In contrast to measures for the purposes of accountability, measures for improvement provide timely information about the improvement process to address questions such as, How can processes central to the theory of improvement be altered to be improved? (Solberg et al., 1997). That is, rather than indicating whether a student has learned something, measures for improvement speak to the processes that support student learning instead of focusing solely on the outcomes of student learning. Not surprisingly, multiple measures are needed for this ambitious purpose of improving instruction at scale (see, e.g., Takahashi et al., 2022). No single measure can provide all the necessary information for what is required to increase the quality of instruction (Bennett, 2015; Bennett & Gitomer, 2009; Newton, 2010). Instead, a comprehensive system of measures is needed to gather the necessary information to inform instructional improvement efforts, including outcome measures such as indicators of student learning (ranging from daily analysis of students to student performance on annual standardized achievement measures) as well as measures for improvement that inform the daily work of those in the system who are working toward the same improvement goals. In such situations, the same measures may be used for different purposes by different users (Gitomer & Duschl, 2007).

Increased pressure to provide more information and more actionable information from lengthy state summative assessments has led to the reporting of subscores for individuals and groups of students. Given that most state summative assessment programs are designed to fit unidimensional item response theory models and often contain a small number of items measuring specific content standards or strands, subscores provide little, if any, useful, reliable information to inform teaching and learning (see Zenisky et al., this volume).

IMPLEMENTATION OF STATE SUMMATIVE ASSESSMENT IN PRACTICE Expectations that state assessment and accountability data could or should affect teaching and learning in some way still exist. That rhetoric abounds on state and district education websites. The U.S. DOE has encouraged the use of district data systems, including state summative test results, for informing teaching and learning and suggested data literacy supports for teachers (U.S. DOE, 2009, 2011). At the beginning of the NCLB era, there was concern about state test data having negative effects on instruction. For example, Pedulla et al. (2003) classified states according to the severity of the state summative test's consequences for districts, schools, and teachers and for students. They surveyed classroom teachers and found that teacher responses varied with the severity of stakes and with level (elementary/middle/high school). Teachers reported feeling pressure to raise scores on the state-mandated tests. A large percentage of teachers reported pressure to deliver instruction that ran counter to their own beliefs about good teaching practice.

There is some evidence that some teachers use state assessment results to inform changes in curriculum content and emphasis, changes in pedagogy, and changes in teacher interactions with individual students (Faxon-Mills et al., 2013). Changes in curriculum included changes in sequence and emphasis of topics, a focus on basic skills, and a focus on higher order skills, depending on the state and study. Changes in pedagogy included a focus on test preparation and changes in instruction and assessment practices. Changes in interactions with students included individualizing instruction and focusing on students who were close to the proficiency cutoff and could potentially cross it and increase pass rates; these students have been referred to as “bubble kids” (Faxon-Mills et al., 2013), an unintended consequence of NCLB accountability requirements that has been alleviated by the use of indicators that consider student performance across the achievement continuum. Similarly, Au (2007) found that the primary effects of high-stakes testing on teaching were curriculum narrowing, fragmenting subject area knowledge into test-related pieces, and increased use of teacher-centered instruction; however, in some cases the high-stakes tests led to curriculum expansion, synthesizing subject area knowledge, and student-centered instruction. Some of these changes might have potentially positive effects on learning, for example, focusing on student thinking or integrating knowledge, and some might have negative effects, for example, focusing on some students more than others or increasing lectures and other teacher-centered instructional methods.

More recently, some studies have reported that while some teachers use state test results, at least in a general way, classroom assessment—both summative and formative—is more closely linked to decisions about changes in instruction. For example, Wilkerson et al. (2021) found that Nebraska teachers’ use of state summative, interim, and formative assessment data to inform instruction was consistent with the frequency of administration of each type of assessment, with data from state summative tests being used least often.

Farrell and Marsh (2016) studied five high-needs middle schools in three districts. They found that state assessment results were used mostly at the beginning of the school year for grouping students but were not associated with other changes in instruction.

IMPACT OF STATE SUMMATIVE ASSESSMENT ON LEARNING Any impact of state summative assessment on student learning would be mediated through its impact on curriculum and teaching, as described in the previous section. Given this distal connection to teaching and learning and its intended purpose as a summative tool for accountability, one might argue that it is inappropriate to even ask questions about the impact of state summative assessment on learning. A primary purpose of federally mandated state assessment programs, however, is to support Title I, which is intended “to provide all children significant opportunity to receive a fair, equitable, and high-quality education, and to close educational achievement gaps” (Every Student Succeeds Act, PL 114-95, 2015, Sec. 1001. Statement of Purpose).

Therefore, one way to examine the impact of state summative assessment on student learning that might be appropriate is in the way that it was intended to be used: that is, in terms of the extent to which test scores indicate that progress has been made in providing equity in educational opportunity and closing achievement gaps. Results from NAEP and international assessments indicate that the achievement gap by socioeconomic status has remained large and stable since the 1970s (Hanushek et al., 2019). Results from the NAEP Reading and Mathematics tests at Grades 4 and 8 since 1992 showed modest impact on the pace of reductions in the gap in performance between Black students and White students through 2005 (Braun et al., 2010). NAEP results showed little change in achievement and in the size of the White–Black and White–Hispanic achievement gaps from 2010 to 2020 (U.S. DOE et al., 2020).

EVALUATION OF STATE SUMMATIVE ASSESSMENT INFORMING TEACHING AND LEARNING State summative assessment programs are designed to provide summative information for accountability and administrative purposes. The growing clamor for more formative information from all assessments perhaps causes more discomfort in the area of state summative assessment than for other types of assessment because its intended purpose and design are decidedly summative. It remains to be seen whether state summative assessments can be redesigned to better provide desired formative information.

Some states are considering the use of through-year assessment models, which emerged as an alternative to a single end-of-year test during the 2009–2010 Race to the Top assessment competition, in an attempt to provide both formative (i.e., timely and instructionally useful) information and the required summative information from a single assessment program. To date, many of those efforts have been limited to replacing the single end-of-year state summative test with the traditional interim assessment model in which all standards are assessed on a short test administered three or four times per year, but some states are attempting to better synchronize the sequence of standards tested throughout the year with instruction or to closely connect the state assessment with the taught curriculum (Powell et al., 2022).

Using information from a single assessment event for both formative and summative purposes poses a significant challenge to the interpretation and use of through-year assessment models for summative accountability purposes (Dadey et al., 2023; Gong, 2021). Some states and state assessment programs, such as Smarter Balanced Assessment Consortium, have responded to this not by changing the summative assessment, but by offering optional interim assessments of varying lengths (full comprehensive assessments, interim assessment blocks, or focused interim assessment blocks, depending on how many standards are assessed) aligned to the state summative assessment. Teachers can choose to administer and use these interims for formative purposes and even create their own from item banks. In other words, Smarter Balanced has responded to this pressure on summative assessment by shifting resources to interim assessment (Smarter Balanced, 2019).

ASSESSING LEARNING TRAJECTORIES FROM CLASSROOM LESSONS TO SUMMATIVE

The assessments described in the previous section were measures of performance or learning status at single points in time, and this evidence about achievement status was what was leveraged to inform teaching and learning. In contrast, the assessments described in this section offer information for informing teaching and learning by looking at student achievement trajectories. This work represents a distinction from assessments in the previous section in two ways: It looks at performance over time and it is theory based—in contrast with any growth modeling using the more traditional measures.

Learning implies growth or change. Growth or change can be measured or indicated in several different ways: as trend lines, pre–post (or pre–mid–post) designs, or progress on a map of development in a domain of learning. Different assessment methods have been applied to show learning spans or trajectories, and three of these are described in this section. In this chapter, the generic term *assessment of learning spans or trajectories* is meant to include any assessment method based on trajectories. The term *learning progressions* has come to be applied to one particular method, described below in the section “Assessment Based on Learning Progressions.” However, the idea of learners progressing from naive to expert, or from novice to mastery, in a particular domain of content underlies all three of the assessment methods in this section. Assessments of trajectories spanning from classroom lessons through summative (outcome) achievement rely on individual measures taken over time. Inferences are then made from students’ trends or growth, as well as the final outcome or level achieved, and this trend information is used to inform teaching and learning.

Assessing trajectories of student achievement fits with the formative assessment cycle as described by the question loop in Table 15.1: Where are we going? Where are we now? How will we get there? Assessments that focus on learning trajectories ask those same questions, but in terms of a bigger developmental picture than when those questions are used for classroom formative assessment of small sequences of lessons. In both, the emphasis is on the formative, on “getting somewhere.” Unlike state standards or classroom learning goals, learning trajectories describe both the destination and the way to get there. This makes learning trajectories potentially a rich source of formative information.

This section considers three assessment methods focused on learning spans or trajectories. Curriculum-based measurement (CBM) has the longest history of the three, in both research and practice. Student learning objectives (SLOs) date from the recent standards-based accountability era and arose in a practical context. Assessments based on learning progressions seek to connect theory about how students learn various topics or concepts with their assessment. Learning progressions are the subject of several ongoing research agendas.

Curriculum-Based Measurement

CBM is an approach to measuring the academic growth of individual students during instruction toward a general outcome of interest (Deno, 2003a). The measurement process is based within the curriculum, and the measures themselves are carefully constructed measures of that general outcome (i.e., the endpoint), rather than being drawn from or based on a particular curriculum. Repeated measurements of student achievement of the general outcome provide information to the teacher regarding a student's progress toward the ultimate learning goal, signaling whether changes to instruction are needed.

Figure 15.1 shows a sample graph of CBM measures collected over 27 weeks of instruction, with an instructional change occurring after Week 16 (Espin et al., 2018). Key components of the CBM progress-monitoring graph include: (a) baseline data, representing the student's current level of performance; (b) peer data, representing typical performance and reflecting the discrepancy between the student and peers; (c) a goal line, representing the expected rate of growth and end-of-year level of performance; (d) data points, representing the number of correct and incorrect responses on weekly probes; (e) slope or growth lines, representing the student's rate of growth over time; and (f) solid vertical lines, representing instructional changes. The slope of the student's performance during a particular instructional intervention provides feedback to the teacher of the success of that instructional approach for the student.

Purpose and Uses of CBM

CBM was developed in the 1980s to support the instruction of individual students with disabilities (Deno, 1985, 2003b). CBM was developed as a means “for teachers to use technically sound, but simple, data in a meaningful fashion to document student growth and determine the necessity for modifying instructional programs” (Stecker et al., 2005, p. 795).

Since its initial development as a tool for elementary school teachers of students with disabilities, the applications and use of CBM and progress monitoring have expanded to other grade levels and multiple content areas, general education, and other uses, such as program evaluation (Allen & Smith, 2022; Jenkins & Fuchs, 2012). A major application of the principles of CBM has been as part of the large-scale Response-to-Intervention program (Fuchs & Fuchs, 2007; National Center on Response to Intervention, 2010). The use of CBM for program evaluation and large-scale screening programs such as Response to Intervention is not directly related to the use of assessment information collected during instruction to inform instructional decisions and therefore is not a focus of the discussion of CBM in this chapter.

Design of CBM

From its inception, CBM has focused on the frequent collection of student performance on a general outcome measure linked to students' overall proficiency on long-term goals (Deno, 1985, 2003a; Stecker et al., 2005). The purpose for using the general outcome measure, rather than more discrete measures tied to individual standards or particular

knowledge and skills, was to provide teachers with clear evidence of student progress toward the desired goal, that is, the level of proficiency desired at the end of the year or other defined instructional period (Fuchs & Deno, 1991). The goals are specific to the content area assessed and the grade level of the students. The general outcome measures are intended to focus on those academic performances that represent “vital signs of educational development” (Deno & Mirkin, 1977, p. 14).

The vital signs measured on individual assessments used in CBM are to be regarded as indicators of student performance within a domain, rather than as direct measures of specific knowledge and skills within the domain, in some ways consistent conceptually with the manner in which state summative tests are designed to provide an indicator of students’ overall proficiency and not a measure of student mastery of individual standards (Fuchs, 2016). Central to the vital signs approach to measurement in CBM is the belief that (a) teachers, in many cases, have no simple indicators with which to monitor the effects of instruction and (b) information that teachers are more likely to have, student mastery of individual standards or skills, is not necessarily evidence of increasing student proficiency on the general outcome (Deno, 1993).

A progress-monitoring graph depicting student performance over time, like the one in Figure 15.1, is one of the fundamental components of CBM (Espin et al., 2018).

FIGURE 15.1

Sample Graph of Curriculum-Based Measurement (CBM) Measures Collected Over 27 Weeks of Instruction, With an Instructional Change Occurring After Week 16

Note. From “Curriculum-Based Measurement Progress Data: Effects of Graph Pattern on Ease of Interpretation,” by C. A. Espin, N. Saab, R. Pat-El, P. D. M. Boender, and J. van der Veen, 2018, *Z Erziehungswiss*, 21(4), 767–792. <https://doi.org/10.1007/s11618-018-0836-9>. Copyright Creative Commons Attribution 4.0 International License. Reprinted with permission. (<http://creativecommons.org/licenses/by/4.0/>).

To evaluate the effectiveness of instruction for a particular student, the teacher examines the graph to determine whether the student is progressing at the desired rate of growth and whether the student will achieve the goal (van den Bosch et al., 2017).

By comparing the slope of the line depicting student progress to the line representing anticipated growth over time toward the long-term target, teachers can determine whether an instructional change is warranted (Stecker et al., 2005). Consistent below-target performance is regarded as evidence that a change in instructional program might be needed. Consistent above-target performance may suggest that the teacher consider raising the long-term goal. In addition to information about an individual student's progress toward the long-term goal, teachers may also consider normative information (e.g., student progress relative to others in the class) or group-level information (e.g., median student progress in a class).

Measurement Considerations in CBM

The quality of CBM information is enhanced by the use of technically sound assessment instruments developed for particular grade levels, content areas, and skills (Stecker et al., 2005; Marston, 2012). Each assessment probe is developed to be a measure of the same overall performance and equal in difficulty to all other probes measuring that area of proficiency. A critical component of CBM, therefore, is the selection or development of multiple alternate forms of an assessment instrument, each of which is a sufficiently reliable indicator and supports valid inferences of students' overall proficiency. Consequently, true applications of CBM cannot rely on teacher-made assessments unique to an individual teacher or group of teachers or on the ad hoc selection of commercially developed assessment instruments. CBM requires the use of assessments that have been empirically selected to meet the technical requirements outlined in this paragraph (Deno, 2003a,b).

An extensive body of research describes the type and technical quality of measures used in various content areas: reading (Fuchs, 2004; Miura Wayman et al., 2007; Tindal, 2013); writing (McMaster & Espin, 2007; McMaster et al., 2011), and mathematics (Foegen, 2008; Fuchs, Fuchs, Compton, et al., 2007; Fuchs, Fuchs, & Hollenbeck, 2007; Gersten et al., 2011). Research also describes measures used with various groups of students, for example, students at secondary levels (Espin et al., 2018; J. Shin & McMaster, 2019), English learners (H. Campbell et al., 2013), and students who are deaf or hard of hearing (Lam et al., 2020).

Fuchs (2004, p. 189) described two approaches to the task of identifying "measurement tasks that simultaneously integrate the various skills required for year-end performance" as (a) identifying tasks that "correlate robustly (and better than potentially competing tasks) with the various component skills constituting the academic domain" and (b) a "systematic sampling of the skills constituting the annual curriculum to ensure that each weekly CBM represents the curriculum equivalently." Tasks at early elementary grades

are more likely to reflect the first approach and tasks at upper elementary and secondary grade levels are more likely to reflect the second approach (Allen & Smith, 2022).

Although linked directly to students' overall proficiency on the desired construct, the vital signs approach of CBM relies heavily on the use of the predictive validity of the measures and has given less weight to issues related to alignment of the individual measures to specific content standards (Deno, 2013), raising concerns and criticisms about the appropriateness of the measures. CBM assessment probes used at higher grade levels in general education classrooms and in content areas other than reading have focused more on alignment to content standards (Allen & Smith, 2022; Fuchs, 2004; Morton, 2013). Recent research has focused on the alignment of CBM measures to state content standards and has used performance on state assessments as a criterion for evaluating the technical adequacy of CBM measures (Shriner & Thurlow, 2012; Tindal, 2013).

Implementation of CBM in Practice

After the selection of assessments, the key steps in the CBM process are regular administration of the assessments, scoring and graphical depiction of student performance, and appropriate interpretation of student progress toward the long-term goal. From its beginnings, an important feature of CBM was the use of assessment instruments that were short, easy to administer, and easy for teachers to score. Such features were intended not only to increase the reliability of scores, but also to increase the utility of the process; that is, such features were considered critical to enhancing the likelihood that teachers would administer the assessments and collect data on student performance on a regular basis.

CBM arose from a different view of teaching and learning than classroom formative assessment, one more focused on affecting teacher instructional adjustments and thereby enhancing student achievement (Stecker et al., 2005), similar in focus to formative evaluation for mastery learning (Bloom et al., 1971) rather than informing students' regulation of learning directly. Although described as a tool to support data-based or data-driven decision-making (Fuchs & Deno, 1991; Hosp & Hosp, 2012) the development and implementation of CBM is not a product of the accountability-centered data-driven decision-making models described as a policy theory of action (Shepard et al., 2017). Rather, with its foundations in special education and the instruction of individual students by special education resource teachers, CBM is more aptly classified as an application of single-subject research design or time series design (Marston, 2012).

In contrast to the data-driven decision-making models assumption that teachers will know how to help students (Shepard et al., 2017), CBM is based on the assumption that a teacher does not know in advance whether, or how well, a particular instructional intervention will work for an individual student. In their Data-Based Program Modification manual, a precursor to CBM, Deno and Mirkin (1977, p. 22) offered the following as two fundamental assumptions of Data-Based Program Modification:

Assumption 1: At the present time we are unable to prescribe specific and effective changes in instruction for individual pupils with certainty. Therefore, changes in instructional programs which are arranged for an individual child can be treated only as hypotheses which must be empirically tested before a decision can be made on whether they are effective for that child.

Assumption 2: Time series research designs are uniquely appropriate for testing instructional reforms (hypotheses) which are intended to improve individual performance.

The theory of action for CBM, therefore, can be described as experimental teaching or data-based instruction in which the teacher takes an active role in verifying that an instructional strategy is effective for the individual student (Fuchs & Bradley, 2012). The fundamental assumption of CBM is

successful intervention required that teachers receive clear and unambiguous feedback regarding the general effects of their instructional efforts. If teachers are either uncertain about the overall effects of their efforts, or believe they have been successful simply because a student learns the specific content that has been taught, their efforts to improve growth will be unsuccessful. (Deno, 2003a, p. 6)

In early applications of CBM, individual teachers were required to create their own progress-monitoring graphs, but with the assistance of computer-based applications to generate the graphs, the focus of teacher assessment literacy needs has shifted to the ability to read and interpret the information provided by the graphical depiction of student progress (Fuchs & Fuchs, 2007). This requires a basic understanding of how to interpret fluctuations in student performance over shorter time intervals in relation to changes in performance over larger time intervals (van den Bosch et al., 2017). With training, teachers, on average, become fairly proficient in reading the data on CBM graphs, but there is variation in the ability of individual teachers (Espin et al., 2017). Further, teachers have greater difficulty in interpreting the data on the graphs, particularly ambiguous data, and linking it to instructional decisions (van den Bosch et al., 2017). Although studies have shown that students make more progress in achievement when teachers use graphs than when they simply record data (Fuchs & Fuchs, 1986), the recent research on teachers' ability to read and interpret graphs highlights the need for professional development in interpreting CBM data and using it in conjunction with other data about instruction and student performance to inform instructional decisions. A meta-analysis of the impact of professional development on teachers' knowledge, skill, and self-efficacy in data-based decision-making (Gesel et al., 2021) found that professional development supports could have a positive impact on teachers' data-based decision-making skills.

Impact of CBM on Learning

Relatively few studies have directly examined the impact of the use of CBM on student learning (Deno, 1985). Stecker et al. (2005, p. 795) stated, "The hope was that by responding instructionally to students' poor patterns of performance, teachers should

be able to enhance student achievement.” Two studies that synthesize the research studies that have been conducted in this area indicate that the proper use of CBM by teachers as part of instruction can have a positive impact on student learning (Jung et al., 2018; Stecker et al., 2005). Both studies, however, describe significant challenges to teachers implementing CBM with fidelity and using the results of measurement to inform modifications to instruction.

Stecker et al. (2005) described research with students with disabilities from the initial development of CBM in the 1970s and research conducted with students in general education settings that began in the 1990s. Critical variables examined in the studies reviewed include the use of data-based decision rules, the inclusion of a skills-analysis component to the reporting of CBM results, and the provision of recommendations for next steps by teachers. Across the studies for students with disabilities and in general education settings, Stecker et al. (2005) found that the use of CBM alone did not have a significant positive impact on student learning (i.e., progress monitoring without making use of the data), but that significant gains in student achievement were attained under the following five conditions: (a) teachers respond to the CBM data to tailor instruction to student needs; (b) a preestablished data-decision framework is adhered to; (c) computer applications are used to improve the efficiency of all aspects of the CBM process; (d) skills analysis, in conjunction with consultation, is provided; and (e) some form of recommendations for next steps are provided. Studies conducted in general education settings also demonstrated that instructional modifications based on class-wide CBM data, rather than data for individual students, could be used to produce gains in student achievement and that with training, CBM data could be used successfully by students in peer-tutoring contexts to improve student achievement.

Jung et al. (2018) conducted a meta-analysis of the effects of CBM, under the generic label of data-based individualization (DBI), on the performance of students with intensive learning needs. They examined the effect of teachers’ use of DBI on student achievement and the factors that influence the strength of effects of DBI. Of the 14 studies included, 6 were conducted after the original Stecker et al. (2005) review. Overall, Jung et al. (2018) found that the use of DBI alone and the use of DBI with additional information or supports, DBI Plus, had significant positive effects on student achievement compared to a “business-as-usual” control. Consistent with the findings of the earlier review, they found that providing teachers with some type of support for the interpretation and use of the progress monitoring data to make instructional modifications had a significant impact on the efficacy of using DBI to improve student achievement.

The findings from both reviews on the impact of CBM on student learning is consistent with the definition of formative assessment adopted by the authors for this chapter, that is, that a practice is formative to the extent that the evidence about student achievement is not only elicited, but also interpreted and used by teachers and students to make decisions about instruction. Research on the impact of CBM on student learning

is also consistent with the findings elsewhere in this chapter that additional research is needed on teacher assessment literacy, and additional ongoing support is needed for teachers' use of data to inform instructional decisions.

Evaluation of CBM Informing Teaching and Learning

CBM is supported by an extensive body of research compiled over more than 3 decades since its inception (Allen & Smith, 2022; Espin & Wallace, 2004; Stecker et al., 2005; Tindal, 2013). Much of the research on CBM can be classified into three categories that are critical to developing a validity argument for its use to inform teaching and learning (Fuchs, 2004): (a) research on the technical adequacy of the measures and scores produced from each assessment, (b) research on the technical features of the slope (i.e., student performance over time) to determine whether increasing CBM scores are in fact associated with improvement in overall competence in the academic domain, and (c) studies concerning instructional utility to determine whether practitioners can use the CBM information to improve instructional decisions and student achievement. This third category of research is particularly relevant to the use of CBM to inform teaching and learning.

Tindal (2013) described the dual focus of the CBM research as grounded in a “measurement paradigm” and focused on a “training in data use and decision-making paradigm”; although the former is an essential foundation for the use of CBM to inform teaching and learning, the latter is critical to ensuring that it can and will be used appropriately to inform teaching and learning. As with formative assessment processes, a long-acknowledged threat to the use of CBM to improve teaching and learning is that when the data indicate that a change in instructional intervention is needed, teachers do not know how or what to adjust in their instruction (Fuchs et al., 1989; Stecker et al., 2005). Recent research has identified teachers' aforementioned difficulty in reading and interpreting CBM graphs (Espin et al., 2017; van den Bosch et al., 2017) and teachers' insufficient professional development in making instructional decisions based on data as two additional threats to the use of CBM to inform teaching and learning (Espin et al., 2021).

Student Learning Objectives

SLOs arose at the local level in the context of teacher evaluation policy, giving teachers some say in the measures for which they would be held accountable. The locus of SLO shifted to the state level when teacher evaluation based on teachers' impact on student learning became a federal requirement for states receiving Race to the Top funding or NCLB waivers. Using SLOs meant teachers of subjects that were not represented in state accountability tests could be held accountable for student progress in their subjects. This brief section on SLOs is included in the chapter for the sake of completeness because the intent of SLOs is that student learning will be affected. However, there is little evidence to date that student learning is in fact affected.

Purpose and Uses of SLOs

SLOs—also referred to as student learning goals, student learning outcomes, student learning measures, and student growth objectives—delineate a process designed to integrate assessment and instruction for the purpose of improving student learning. Typically, teachers and building principals together negotiate the measures to be used for the SLO process in teacher evaluation (New York State Education Department, 2014; Texas Education Agency, 2021). The SLO process is intended to include (a) developing carefully planned learning goals for what students will learn over a given period of time and (b) evoking critical, evidence-based thought about student progress and growth through instruction (Community Training and Assistance Center [CTAC], 2018).

Initially used as part of innovative pay-for-performance compensation programs (CTAC, 2004, 2013), SLOs were developed as a school improvement tool to be implemented collaboratively by administrators and teachers at the local district and school levels (Diaz-Bilello & Thompson, 2019). SLOs gained popularity as they were adopted by many states as the primary method for evaluating teachers' impact on student learning in content areas and grade levels in which there was not a state assessment (Marion & Buckley, 2012) in response to federal requirements under Race to the Top and NCLB waivers (Briggs et al., 2019).

Design of SLOs

The use of the SLO process as a tool for school improvement has been described as a school-based application of the management-by-objectives model (Chapman, 2014). The design and implementation of individual SLOs by teachers under the CTAC (2013) model is driven by six elements: (a) learning content (what will be learned), (b) instructional strategies (approach to teaching), (c) interval of instruction (time frame for teaching), (d) assessment (measures of learning), (e) student growth targets (numeric goals for learning), and (f) student population (who is included).

Those elements are then implemented in a cyclical process that includes periods of instruction, assessment, and adjustment. A common SLO cycle might include the following steps (Diaz-Bilello et al., 2016; Diaz-Bilello & Thompson, 2019): identify the learning goal, develop or select assessments, analyze baseline data, establish targets, analyze a cycle of instruction and assessment, revise targets when appropriate, analyze a cycle of instruction and assessment, and complete the SLO evaluation. Each cycle of instruction would also include the use of formative assessment procedures and adjustments to instructional strategies, as needed.

Measurement Considerations for SLOs

A critical distinction between SLOs designed for accountability and SLOs designed for improving instruction is the focus on comparability across districts, schools, and

teachers, as evidenced by the level of autonomy allowed in two critical aspects of the SLO process: the development and selection of assessments and the establishment of growth targets (Cushing & Meyer, 2014; Diaz-Bilello & Thompson, 2019). It is less important for SLOs designed to improve teaching and learning than for SLOs for teacher evaluation to be comparable across contexts (Lane & DePascale, 2016). Even when SLOs are used for teacher evaluation, however, there is a large degree of variation across states in how SLO performance targets have been established (Crouse et al., 2016).

Using SLOs requires a basic understanding of reliability of observed scores, in general, and difference scores, in particular. Decisions made about individual students' meeting their growth target will be affected by error in the pretest and posttest scores. For example, a common approach to setting growth targets for SLOs is referred to as the "half-the-distance" method, in which the growth target on a posttest is defined as the score that is halfway between the student's baseline score on a pretest and either a specified criterion score or the maximum score on the posttest (i.e., a perfect score; Austin Independent School District, 2015; Missouri Department of Education, 2015). The use of approaches such as half-the-distance can produce different results based on the level of student performance and the design and type of assessments used (Austin Independent School District, 2015) and can produce results that are not acceptable within the given context, such as target scores that are below the accepted passing score on the posttest (English et al., 2015).

Implementation of SLOs in Practice

When implemented with fidelity, the SLO process should provide feedback to teachers, administrators, and students about the specific learning content and growth targets expected to be achieved during the interval of instruction. It also should provide feedback to teachers and administrators about the instructional strategies teachers will use to support student learning and attainment of growth targets. At the end of the SLO process, teachers and administrators receive summative feedback on whether a SLO or multiple SLOs implemented by individual teachers have been met. That decision is usually based on the percentage of students included in the SLO process who met their individual student goal (Hall et al., 2014).

The SLO process requires a high level of training and support at the district and school levels and is difficult to implement without an extended commitment to the process (Schneider & Johnson, 2018). In addition to general assessment literacy, specific teacher needs include the ability to clearly specify measurable objectives that are also primary curriculum goals and to select or create assessment tools whose results are valid, reliable, and fair indicators of those goals. Teachers and administrators need the ability to analyze and interpret assessment results against both student learning goals and teacher professional goals for purposes of high-stakes decision-making.

Impact of SLOs on Learning

Few research studies have been conducted examining the extent to which the use of SLOs provides feedback that teachers use to inform their instructional strategies and decisions during the implementation of the SLO process. The limited number of surveys that have been conducted show mixed and/or conflicting results about the type of feedback received and used by teachers from the SLO process (Diaz-Bilello & Thompson, 2019; Lachlan-Hache et al., 2015). In preparing this chapter, the authors found no studies on the effects of using SLOs on student achievement.

Evaluation of SLOs Informing Teaching and Learning

SLOs are a process designed to integrate assessment and instruction. The process involves teachers and administrators agreeing on specific learning goals that the teacher will monitor and on selecting assessments to use as measures over time of student progress on those goals. The process was largely overtaken by the teacher accountability movement. Little research to date has focused on the effectiveness of SLOs for improving teaching and learning.

Assessment Based on Learning Progressions

The National Research Council (2007, p. 219), focusing on science education, defined learning progressions as “descriptions of the successively more sophisticated ways of thinking about a topic that can follow one another as children learn.” Corcoran et al. (2009, p. 8) used a more expansive definition: “Learning progressions in science are empirically grounded and testable hypotheses about how students’ understanding of, and ability to use, core scientific concepts and explanations and related scientific practices grow and become more sophisticated over time, with appropriate instruction.” In mathematics, the term *trajectory* has also been used, stemming from Simon’s (1995, p. 135) proposal of a “hypothetical learning trajectory” that referred to mathematics teachers’ expectations for how student learning might proceed for certain mathematical content. Work in learning progressions has developed in other countries as well, beginning as early as the 1980s.

Although more work on learning progressions has been done in mathematics and science than in other disciplines, the idea has been applied to many different disciplines. The appeal is that learning progressions can form the basis for the teacher’s instructional decisions (Deane et al., 2015), improving teaching and learning. In fact, some definitions of learning progressions include not only progressions in students’ thinking but also progressions in instructional experiences that might help students move along, and the relative lack of attention to including the latter in progressions is one of the current criticisms of learning progression research (Mosher, 2022).

All definitions of learning progressions envision learning as growth in sophistication of understanding, not solely a body of content to be covered, and envision progress as growth in understanding not referenced to age or grade level (Heritage, 2008). Learning progressions describe typical development of expertise in a domain for most, but not

all, students. They are not rigid; a student's level on a learning progression may fluctuate as learning is taking place. In many domains, learning progressions may describe building blocks that lead up to more complete understandings. In science, lower levels on a particular learning progression may also describe commonly held facets or naive conceptions that students must abandon as their learning progresses (Alonzo, 2018). Since students learn in the context of instruction, learning progressions are not independent of curriculum sequence (Wiliam, 2018b).

Many—if not most—sets of content standards and curricula are built on a logical, developmental progression of knowledge, skills, and competencies across grade levels (e.g., Common Core Standards Writing Team, 2019; Confrey et al., 2014; National Centre, 2020) and certainly qualify as progressions in the plain English sense of the word. However, the empirically developed and validated learning progressions defined and described in this section represent something beyond this; while acknowledging a relationship with students' educational experiences, the assessments based on learning progressions described in this section also seek to detail cognitive growth in a more theoretical way.

Purpose and Uses of Assessment Based on Learning Progressions

Learning progressions are a hypothesized vehicle for making assessment more useful for informing teaching and learning, whether at the classroom or the large-scale level, and especially to guide teachers' formative assessment practices (Alonzo, 2018). Teachers need to have a conception of what comes next in learning to respond effectively to students' work. It is for this reason that informing teaching and learning seems the most salient purpose for learning progressions and assessments based on them. However, a learning progression framework can also be used to describe student performance summatively.

Design of Assessment Based on Learning Progressions

There are different approaches to constructing learning progressions as a priori, theoretical statements about how learning takes place in a domain. In general, such approaches are based on the work of human panelists (as opposed to data mining) and can be categorized as top-down, beginning with the ideas of experts in the domain, or bottom-up, beginning with the ideas of curriculum content experts and teachers about what is best taught when (Heritage, 2008). Learning progressions can be big, encompassing K–12 learning in a broad domain (e.g., writing), or relatively small, describing the acquisition of understanding on a single topic.

A true learning progression—as opposed to, for example, a curriculum scope and sequence or a simple rubric—requires empirical evidence or validation, or what Graf and van Rijn (2016) have called *empirical recovery*. If learning progressions are a representation of a theory about how children learn and develop in a domain, they should be empirically verifiable (Denvir & Brown, 1986; Graf & van Rijn, 2016).

Therefore, design concerns for assessment based on learning progressions include both verifying the progression and designing and validating measures to assess them. Confrey (2019) cautioned that studies need to distinguish between the learning progression and its measures. Evidence for the former must verify the constructs in the progression, while evidence for the latter must validate a scale for measuring student progress on the progression. When the two are conflated, what results is much like the validity evidence for any other educational measure. When the two are distinguished, research on the progression can inform research on the measure and vice versa.

Learning progressions design work is done in a content area, because learning progressions are content specific, and most often requires partnerships between researchers and educational practitioners. The result is often assessment that is neither completely classroom based and teacher developed nor completely externally developed, as for large-scale assessments. This hybrid development is a hallmark of assessments based on learning progressions, at least to date, and foreshadows some future possibilities as technology makes possible the coordination needed for this kind of assessment.

Measurement Considerations for Assessment Based on Learning Progressions

Some learning progressions are constructed to help teachers create or select classroom-based tasks and progressions, and some are constructed to serve as the basis for externally developed tasks and questions that teachers can use in the classroom. Content-related evidence for the validity of the progression has been reported for the former (Furtak, Circi, & Heredia, 2018; Hess & Kearns, 2010, 2011). A wider range of validity evidence has been reported for the latter, including content-related evidence as well as evidence of whether measurement models fit assessment data as predicted. It is worth noting that studies do not always support hypothesized learning progressions, or do not support them completely (e.g., Pham et al., 2021). Examples of how several different programs of research have treated validity and validation follow.

One of the more influential frameworks for the design of learning progressions (Duschl et al., 2011), especially in science, is the BEAR Assessment System (Berkeley Evaluation and Assessment Research Center; Wilson, 2009; Wilson & Sloane, 2000). The BEAR Assessment System is based on four principles, each with accompanying building blocks for the assessment system (Wilson et al., 2016, pp. 7–8):

- (1) Assessment should be based on a developmental perspective of student learning; the building block is a *construct map* of a progress variable that visualizes how students develop . . .
- (2) There must be a match between what is taught and what is assessed; the building block is the *items design* . . .
- (3) Teachers must be the managers of the system, with the tools to use it efficiently and effectively; the building block is the *outcome space*, or the set of categories of student responses that make sense to teachers . . .
- (4) There is evidence of quality in terms of reliability and validity studies and evidence of fairness, through the data analytics; the

building block is an algorithm specified as a *measurement model* that provides for a visual representation of the students and the items on the same graph (called a “Wright Map”) and a number of other data analytic tools.

The BEAR Assessment System, then, creates a priori learning progressions based on research and uses researcher-developed measures in a system managed but not authored by teachers (Black et al., 2011; Wilson & Scalise, 2016; Wilson & Sloane, 2000). The measures may be based on multiple-choice or open-ended items. Classroom teachers use the system during instruction. Validity can be supported if the instruments reflect the expected characteristics of learning described in the progressions. Construct maps can be used to study this match (Black et al., 2011), and statistics from unidimensional or multidimensional item response theory analyses can be offered as evidence for appropriate internal structure and reliability. Assessment results are used to adjust both the learning progression and the items (e.g., Schwartz et al., 2017). Table 15.3 shows an

Table 15.3 Construct Map Showing a Learning Progression for Student Understanding of Earth in the Solar System

Level	Description
5 8th grade	Student is able to put the motions of the Earth and Moon into a complete description of motion in the Solar System which explains: the day/night cycle the phases of the Moon (including the illumination of the Moon by the Sun) the seasons
4 5th grade	Student is able to coordinate apparent and actual motion of objects in the sky. Student knows that: the Earth is both orbiting the Sun and rotating on its axis the Earth orbits the Sun once a year the Earth rotates on its axis once per day, causing the day/night cycle and the appearance that the Sun moves across the sky the Moon orbits the Earth once every 28 days, producing the phases of the Moon Common error: Seasons are caused by the changing distance between the Earth and Sun. Common error: The phases of the Moon are caused by a shadow of the planets, the Sun, or the Earth falling on the Moon.
3	Student knows that: the Earth orbits the Sun the Moon orbits the Earth the Earth rotates on its axis However, student has not put this knowledge together with an understanding of apparent motion to form explanations and may not recognize that the Earth is both rotating and orbiting simultaneously. Common error: It gets dark at night because the Earth goes around the Sun once a day.

(continued)

Table 15.3 (continued)

Level	Description
2	Student recognizes that: the Sun appears to move across the sky every day the observable shape of the Moon changes every 28 days Student may believe that the Sun moves around the Earth. Common error: The Sun travels around the Earth. Common error: It gets dark at night because the Sun goes around the Earth once a day. Common error: The Earth is the center of the universe.
1	Student does not recognize the systematic nature of the appearance of objects in the sky. Students may not recognize that the Earth is spherical. Common error: It gets dark at night because something (e.g., clouds, the atmosphere, “darkness”) covers the Sun. Common error: The phases of the Moon are caused by clouds covering the Moon. Common error: The Sun goes below the Earth at night.
0	No evidence or off-track

example of a construct map that functions as a learning progression for student understanding of the Earth in the solar system (Wilson, 2009, p. 720).

Confrey and her colleagues (Confrey & Toutkoushian, 2019; Confrey et al., 2020) created Math Mapper 6–8, a digital learning system used in middle-grades mathematics classrooms. Multiple forms of assessment are used, including multiple choice, multiple select, numeric, one letter, and open ended. Like the BEAR system, Math Mapper 6–8 is based on a priori learning progressions derived from research, but it uses a different validation framework. The validation process is iterative: Results from the digital learning system are used to adjust the learning trajectory, and vice versa. Evidence is sought that the assessment taps domain knowledge (cognitive evidence), that the assessment is aligned to the curriculum and opportunity to learn and is used to inform teaching and learning (instructional evidence), and that the assessment reliably yields model-based information about student performance (inferential evidence; Pellegrino et al., 2016). Both quantitative (e.g., from empirical studies of model fit) and qualitative (e.g., observation-based design studies) evidence are sought.

Pham et al. (2021) studied three learning progressions for formative assessment in middle school mathematics. They, too, used a priori learning progressions derived from research to describe three related progressions—equality and variable, linear functions, and proportional reasoning—and created items to measure them. They used item response theory to investigate whether student response

evidence supported claims about the order of levels within each progression and multidimensional item response theory to investigate whether student response evidence supported predicted relationships across pairs of progressions.

In language, Bailey and Heritage (2014) use a more descriptive and qualitative approach to validation of learning progressions in the Dynamic Language Learning Progression project. The project collected a body of elementary school-age children's oral and written language (including from English learners and children with a range of language experiences) and from this corpus created learning progressions illustrating how children's use of language in school becomes gradually more sophisticated over time. Validation included a study of students' oral explanations (both procedural and conceptual) of mathematics problems. The language samples are searchable online. The language learning progressions are intended for use with both regular and English learner students and eventually are intended to inform interim and summative assessment, as well as formative assessment and classroom instruction (Bailey & Heritage, 2014) and student self-assessment (Goral & Bailey, 2019).

One critique of the learning progressions approach is that cognitive understanding is not quite as linear as learning progressions may suggest (Shavelson, 2009). Several research agendas have used nonlinear cognitive models or maps that relate knowledge components within a content area. Automated methods for cognitive diagnostic modeling are often used to create these cognitive maps (Goldin et al., 2016). Wilson et al. (2016) saw a place for exploratory automated methods as well as confirmatory methods such as those used in the BEAR system, partly depending on how much is already known about learning in an area. However, some argue that even in well-researched areas such as mathematics learning, automated methods help with the diagnostic precision needed for teachers to make decisions about next instructional moves (Kingston & Broaddus, 2017; R. Liu & Koedinger, 2017).

For example, R. Liu and Koedinger (2017) showed that most students who can calculate the area of a two-dimensional shape given its sides can also calculate the sides, given the area, and human experts most often consider calculating area of a shape to be one skill. However, cognitive modeling showed that this is not true for all shapes: for example, calculating from the radius to the area of a circle is a different skill from calculating the radius given the area. R. Liu and Koedinger (2017) showed that is probably because of the use of the square root. This additional precision about student understanding has obvious utility for informing teaching and learning.

Another example of using automated techniques for cognitive mapping is the Dynamic Learning Maps project, which uses diagnostic classification modeling to create the learning maps (Kingston et al., 2016). Originally applied to alternate assessment of state standards, Dynamic Learning Maps can support formative assessment and instructional decisions about typical educational standards as well (Kingston & Broaddus, 2017) and allows for representing finer grained, more diagnostic information for content standards than that produced by large-scale, standards-based tests.

In sum, to date, much of the measurement consideration for assessment based on learning progressions has focused on the development and validation of the learning progressions themselves. Relatively little research has focused on traditional measurement considerations related to their use by teachers, schools, and districts for various formative or summative purposes. Learning progressions may eventually provide a framework for the design of assessment systems, for example, district assessment systems, that include both classroom and large-scale assessment (Duschl et al., 2011). The most effective assessment systems will relate formative and summative measures in coherent, comprehensive, and continuous ways (Wilson & Draney, 2004) that most current assessment systems do not.

Implementation of Assessment Based on Learning Progressions in Practice

Learning progressions and assessment based on them are still very much in the developmental or small-scale implementation phase. Such development and implementation almost always involves a research–practitioner partnership of some sort. Even so, teachers do not always use learning progressions as intended (Alonzo & Elby, 2019).

Australia has been an early adopter of this approach, beginning work on what they called “subject profiles” in 1988 (Rowe & Hill, 1996). Subject profiles are vertical maps of achievement in a domain that can be used as a framework for assessing student work. The work in Australia was conceived in a summative context, looking for ways to record and report student growth. Currently, it is also used formatively, illustrating the aforementioned trend toward assessment being called on to inform teaching and learning that is happening all over. Australia currently uses a learning progression approach to student growth in reform efforts aimed at both curriculum and assessment, for both formative and summative purposes (Commonwealth of Australia, 2018; Confrey, 2019).

Furtak and Heredia (2014; Heredia et al., 2016) showed that the design and use of common formative assessments using a learning progression can inform how teachers interpret student thinking (Furtak, Circi, & Heredia, 2018) and adjust instruction. Furtak, Circi, & Heredia (2018) showed that a group of science teachers were able to design formative assessment tasks generally aligned with multiple learning progressions in high school biology, specifically in the area of natural selection, with some gaps and variations and associated uneven student learning gains across the learning progressions. In this research agenda, implementation can also proceed through the external development of curriculum-embedded assessments of learning progressions (Briggs & Furtak, 2020), including performance-based tasks and labs, phenomenon-based item clusters, and conceptually oriented multiple-choice questions.

Math Mapper 6–8 (Confrey & Toutkoushian, 2019; Confrey et al., 2020) provides teachers with assessments designed to give immediate, actionable feedback to both

teachers and students. Teachers are allowed to use the assessments as they see fit during their instruction. Confrey and Toutkoushian (2019) found that teachers vary in their use of the assessments; most measure students' progress about two thirds of the way through an instructional unit, when there is still time to adapt instruction.

Black et al. (2011) described a broad model of pedagogy based on teachers' understanding "road maps" or progressions toward curricular learning goals and using classroom assessment strategies that provide feedback to students. Wilson and colleagues applied this model in the BEAR Assessment System by working with content area researchers in various disciplines. Work has been conducted in the areas of science (Wilson & Draney, 2004; Wilson & Sloane, 2000), scientific argumentation (Yao et al., 2015), structure of matter (Morell et al., 2017), data science (Arneson et al., 2019), and statistical reasoning (Lehrer et al., 2014; Wilson & Lehrer, 2021). The BEAR Assessment System embeds assessment in the classroom teaching and learning context. Teachers are involved in managing the way the assessment system is used in their classrooms, collecting and scoring student work, interpreting the results in instructional terms, and using the results in instructional decision-making. To facilitate this, the BEAR Assessment System provides a single scoring guide for each variable in the progression; teachers do not need to use a new scoring guide for each assessment. In so doing, the assessment gives direct evidence of students' location on the progression and implications for instruction. Looking beyond the development of assessments, Lehrer et al. (2014) developed an approach that integrates the learning progression for an instructional program in middle school statistics with predeveloped items and teacher-managed formative assessment. This approach has been expanded to incorporate a mobile device-based system for recording teachers' daily observations of their students in alignment with the postulated learning progression (Lehrer, 2021; Wilson, 2021, 2023).

Impact of Assessment Based on Learning Progressions on Learning

Most studies of the effectiveness of learning progressions have studied the learning progressions themselves, seeking to confirm that students do in fact demonstrate thinking as described in the levels, or studied their measures, seeking to validate that performance on a measure reflects the levels described in the learning progressions. Some have studied the effects of using learning progressions, or of professional development using learning progressions, on the alignment of teacher-created formative assessment tasks, teachers' interpretation of student work, or instructional decision-making (Alonzo & Elby, 2019; Furtak, Bakeman, & Buell, 2018; Heredia et al., 2016); in other words, these studies investigated how learning progressions might inform teaching.

Furtak, Circi, & Heredia(2018) showed that students whose biology teachers participated in professional development using learning progressions, designed formative

assessment, used it with their students, and reflected on next steps in instruction did increase along the learning progression as measured against their own baselines.

A few studies have used experimental designs. Wilson and Sloane (2000) used an experimental design to evaluate the initial work of the BEAR Assessment System in the context of middle school science. Results demonstrated that students whose teachers used the assessment system improved their learning—with both statistically and educationally significant effects—beyond that of students whose teachers were in either of two control groups: teachers who participated in professional development but were not required to use the assessment system and comparison teachers who taught the regular middle school science curriculum. More recently, BEAR Assessment System work in the context of middle school statistics also showed statistically and educationally significant results in a controlled experiment using a change score approach (Gochyyev & Wilson, 2021; Wilson & Lehrer, 2021).

Some experimental studies have investigated the impact of using cognitive tutoring systems based on cognitive maps and found the effect to be strong and positive (Ritter et al., 2007). R. Liu and Koedinger (2017) compared achievement of students who used a cognitive tutor with that of students who used the cognitive tutor redesigned with adjustments to the cognitive map based on the results of data mining. Students in the redesigned condition had significantly higher posttest scores than control students, even after controlling for pretest scores, which they interpreted to mean that the quality of the cognitive map had improved and made a difference in the effectiveness of the tutoring system.

Evaluation of Assessment Based on Learning Progressions Informing Teaching and Learning

The idea of learning progressions has both theoretical and intuitive, practical appeal. Logically, learning progressions should help address the known difficulty teachers have deciding precisely what feedback or next instructional moves would help learners the most in moving toward learning goals (Heritage et al., 2009; Ruiz-Primo & Furtak, 2006, 2007; Ruiz-Primo & Li, 2013; Schneider & Gowan, 2013; see the “Formative Assessment” section above). Teachers demonstrably do need some way to conceptualize “what’s next” to adjust their teaching.

The current state of the field of assessments based on learning progressions shows some promising proofs of concept. Most of these projects leverage the recent increase of technology in the classroom to support classroom-based formative assessment with deep pockets of external research and methodological capability. Several projects leverage teacher professional development and external research support, some with and some without large-scale measurement methodology. At present, it is difficult to imagine enough of these resource-intensive projects to cover the curriculum (also see Baird et al., 2017). When these projects talk about going to scale, they usually mean involving more classrooms in a computer-based tutoring or assessment system, rather than being generally or routinely used in the educational landscape.

Work on assessment based on learning progressions does illustrate the major theme of this chapter, the trend toward the formative. Learning progressions research continues the shift from the focus on groups and aggregate scores to the focus on individuals. Yet several of the research programs described in this section show how difficult it is to apply a particular learning progression to an individual student, even if it is clear what “typical development” looks like.

Work on learning progressions also highlights the role of learning theory in assessment and assessment design. Most of the learning progression research described in this section is theory driven, with the progression distilling research on how students learn particular content into a developmental path. This section shows that personalized learning and assessment system design fueled by data science also has the potential to be driven more by data than by theory. The balance of theory and data science in future learning progression development is likely to be quite interesting.

FUTURE DIRECTIONS

The concepts of teaching and learning continue to evolve, and the pace of change appears to be increasing (Bennett, 2014). In a historical sense, the inseparable connection between teaching and learning is still relatively new, with research on teaching that focused on the student dating only to the last quarter of the 20th century (Peterson, 1979; Rosenshine, 1979; Shulman, 1986) and the current focus on student-centered assessment emerging around the same time (Chappuis, 2022; Stiggins, 1994). The definition and scope of learning—and student-centered education in particular—continues to expand, redefining nearly all aspects of teaching and learning: what is taught, how it is taught, why it is taught, who is taught, and by whom (Carter & Darling-Hammond, 2016; Cochran-Smith & Lytle, 1999; Faltis & Valdés, 2016). As previously described, this shift from “instructivist” (Box et al., 2015, p. 972) or “social efficiency” (Shepard, 2000, p. 4) teaching focused on delivering content to learners to teaching that supports students as they construct their own meaning has fueled the press for all assessment to be formative. The argument will be summarized in more detail in the “Conclusion” section; here, it is enough to note the growth in interest and use of formative assessment methods (classroom formative, interim, and common formative), the use of summative assessment methods (grading and state accountability assessment) for formative purposes, and the development of assessments focused on trajectories that describe the process as well as the final outcome of learning.

In addition, the introduction of technology into almost every aspect of schooling, from record keeping to communication, to curricular and instructional resources, to instruction itself, is changing the nature of teaching and learning (Bennett, 2015, 2018; see also Bennett et al., this volume). Information technology is advancing rapidly, including the availability of computers and other devices in the classroom, as well as Internet and communications technology linking students in classrooms to external information sources and to other students. The rapid growth of information technology has generally

changed most aspects of schooling—for better or worse—and has the potential to both support and shape the ongoing transition to more learning-oriented assessment.

It is within this fluid environment that the future of assessment to inform teaching and learning will be determined. The argument throughout this chapter has been that usefulness of assessment in informing teaching and learning is directly related to its proximity to learning, factors such as the timing and nature of the content assessed and the manner in which it is assessed, the nature of the information the assessment provides as feedback to teachers and students, and the type and level of pedagogical skill needed to effectively use the information provided. It is inevitable that the nature of assessment information will change as the understanding of teaching and learning evolves (Mislevy, 2018a; Pellegrino, 2014; von Davier et al., 2019; Wilson & Scalise, 2016) and the constructs that are valued and measured shift to meet societal needs (L. Liu et al., 2017; Stoeffer et al., 2020). It is likely that prevailing measurement models and measurement principles will be adapted or replaced as the field expands its view of what is important to measure (Mislevy, 2018b; Taylor et al., 2018). And it is possible that the very nature of assessment will change as technological advances, including advances in artificial intelligence, increasingly reshape education and all aspects of life (Bennett, 2018; von Davier et al., 2021; Wilson et al., 2015).

The Future of Assessment Information

In the third edition of *Educational Measurement*, Bunderson et al. (1989) outlined a four-generation framework to describe the effect that ongoing advances in technology would have on educational assessment.

- *Generation 1. Computerized testing:* administering conventional tests by computer.
- *Generation 2. Computerized adaptive testing:* tailoring the difficulty or contents of the next item or an aspect of the timing of the next item on the basis of test takers' responses.
- *Generation 3. Continuous measurement:* using calibrated measures embedded in a curriculum to continuously and unobtrusively estimate dynamic changes in the student's achievement trajectory and profile as a learner.
- *Generation 4. Intelligent measurement:* producing intelligent scoring, interpretation of individual profiles, and advice to learners and teachers, by means of knowledge bases and inferencing procedures (Bunderson et al., 1989, p. 368).

Further, Bunderson et al. characterized a “shift in emphasis from institutional purposes [of educational measurement] to individual purposes” as characterizing “the distinction between the first two and last two generations of educational measurement” (p. 369). It is such a shift in emphasis in the purpose of educational measurement that is likely to move the field from Generation 1 and 2 assessments, designed to provide information about groups of students to support policy decisions about institutions, to a much greater focus on Generation 3 and 4 assessments, designed to produce

information about individual student performance and growth to inform teaching and learning. For example, Zheng et al. (2019) showed that formative assessment information embedded in MATHia, an intelligent tutoring system for middle and high school blended learning, can predict state test scores beyond the ability of a prior-year test.

As demonstrated throughout this chapter, in the time between the third and fifth editions of *Educational Measurement*, the shift in demands on assessment from serving institutional purposes to serving individual purposes has begun and is exerting growing pressure on Generation 1 and 2 assessments and their stakeholders. While many classrooms currently use Generation 1 and 2 assessments, Generation 3 and 4 assessments are being gradually introduced in research projects such as the ones described in the section on “Assessment Based on Learning Progressions” and require partnerships between schools and external organizations. Generation 3 and 4 assessments are not yet the common practice—but then, not that long ago, neither were Generation 1 and 2 assessments.

Although the field as a whole has progressed through the framework over the 30 years since the framework was published, the past decade has seen significant movement in K–12 assessment. Advances in the capabilities and availability of technology have fueled widespread adoption of computer-based assessment and rapid acceleration from Generation 1 (computerized testing), through Generation 2 (computerized adaptive testing), to the cusp of Generation 3 (continuous measurement). Computerized adaptive testing is well established as the primary mode of testing for interim assessments and has been accepted as a viable option for state summative assessment (Bennett, 2015).

It is in the classroom, however, that there is most likely to be an emergence of Generation 3 assessment—the use of calibrated measures embedded in a curriculum to continuously and unobtrusively estimate dynamic changes in the student’s achievement trajectory and profile as a learner (Bennett & Gitomer, 2009; Scalise & Wilson, 2011; Wilson & Sloane, 2000). This brings with it implications for privacy rights and responsibilities, teacher assessment literacy, and school technological capacity and policies.

Constructs

The constructs measured by assessments designed to support teaching and learning are likely to shift in two areas. The first shift involves measuring content in currently measured academic areas to a much greater depth and measuring additional areas that are not currently a primary focus of K–12 educational measurement. The second shift involves measuring process as well as outcomes in each of those areas.

The first shift—driven by academic content, curricular, and instructional changes—involves the use of assessments designed to measure students’ higher order thinking skills via performance on complex tasks. The first shift also includes measurement of other skills not currently a primary focus of K–12 educational assessment. Those include

so-called 21st-century skills such as communication, teamwork, and collaboration, as well as constructs such as social-emotional learning and student engagement. While these types of changes in assessment are already being driven by the development of new content standards in the core areas of English language arts, mathematics, and science, it is likely that similar changes will also be seen in other content areas. These changes may bring with them long-standing generalizability issues related to performance assessment because responses to complex tasks are subject to a large person-by-task interactions (Gao & Baxter, 1994; McBee & Barnes, 1998).

The second shift involves increased interest in and capacity to measure process in addition to student outcomes. Computerized assessment has provided the opportunity to efficiently collect process data such as time spent completing an item or progress through an instructional unit, intermediate steps or pathways, and changes to responses, as well as student outcomes. Including such process data in measurement has the potential to improve significantly the quantity and quality of information about student thinking that can be derived from assessment. As discussed previously, for formative assessment the main goal is not measurement of student achievement of a learning goal, but rather a description of the status of student understanding on the way toward a learning goal; the main information sought is an understanding of the nature of student thinking, not the correct answers that thinking will generate (Heritage & Heritage, 2013).

The availability of additional data alone, however, is likely to do little to improve the ability or use of assessment to inform teaching and learning. It will be necessary to process that wealth of data to produce Generation 3 and 4 type information that helps teachers understand students' achievement trajectories and interpret individual student profiles or offers instructional advice to learners and teachers. Generating that type of information will require the expansion of current measurement models, as well as the development of new models, and will likely incorporate long-standing and emerging work and modeling in the areas outside traditional psychometrics and assessment, such as computer-assisted instruction, intelligent tutoring, and data mining (Gobert et al., 2013; Koedinger et al., 2018; Ritter et al., 2007).

Measurement and Other Models

Since the NCLB era began in 2001, the design and development of K–12 large-scale summative and interim assessments has relied on the application of unidimensional measurement models such as the Rasch model and a variety of one-, two-, and three-parameter item response theory models. The use of these models has served the field well for accomplishing the institutional purposes of educational measurement (i.e., providing comparable estimates of students' overall ability across a variety of alternate test forms administered within and across years). As discussed in the sections of this chapter on state summative and interim assessment, these models have been less useful in providing information to inform teaching and learning, particularly at the individual student level.

As the focus of educational measurement has shifted to the classroom and individuals, new models and different applications of current models have emerged to inform the design of assessments intended to inform teaching and learning and support formative assessment. (See Cai et al., this volume, for a discussion of modeling for different types of assessment.) Theory-driven applications of the traditional unidimensional and multidimensional Rasch models have been used to help define, describe, and measure student performance along learning progressions with the specific intent of providing information to inform teaching and learning (Black et al., 2011; Briggs & Alonzo, 2012; Shepard, 2018; Wilson, 2012). As discussed in the section on learning progressions, to date, much of the innovative research in this area is still being conducted in close partnership between researchers and local educators. Widespread application of this emerging work at scale has yet to be accomplished.

While the unidimensional and multidimensional applications of the Rasch model have been useful in describing relatively simple linear progressions, new models or modeling approaches are needed to support the development of assessments to measure and support the development of complex learning progressions/trajectories or learning maps (Confrey et al., 2014; Toutkoushian, 2019; Kingston & Broaddus, 2017; Kopriwa et al., 2016). In addition, latent class models such as cognitive diagnostic models and hierarchical diagnostic classification models have applied a multidimensional approach to describe more fine-grained profiles of student performance and estimates of mastery (Bradshaw et al., 2014; Templin & Bradshaw, 2014). In addition to these models focused on outcomes for individual students interacting with items and tasks, new measurement models are being developed to provide information for new types of assessment designed to measure 21st-century skills such as collaboration.

Computational psychometrics is described as

a blend of stochastic processes theory, computer science–based methods, and theory-based psychometric approaches that may aid the analyses of complex data from performance assessments, including collaborative assessments. This discipline organically developed around the complex next-generation learning and assessment systems that include performance tasks, such as collaboration, games, and simulations. (von Davier, 2017, p. 3)

Computational psychometrics combines theory-based psychometrics and computer science–based methods to develop a model that incorporates process and outcome data into information about student performance on complex tasks.

The computer science–based methods employed in computational psychometrics, such as machine learning and data mining, can also be applied on their own without theory-based psychometrics to develop models of student learning and achievement. Such models fall under the broader category of learning analytics, which may incorporate data mining, machine learning, artificial intelligence, and other data science techniques in an attempt to provide information to inform instruction. Although instructional

theory, learning theory, and measurement theory are not necessary aspects of learning analytics, it is expected that the most effective use of learning analytics to inform teaching and learning will involve an iterative process in which theory and empirical data are used to guide the collection and analysis of data and transform data into understanding that is useful to teachers and students (Wong et al., 2019). As Wilson and Scalise (2016, p. 2) noted, “applying learning analytics to educational assessment therefore requires negotiating a key intersection, which is at the interface of measurement technology and information technology.” At a minimum, it should be expected that the dissemination of information and feedback to teachers and students from learning analytic models and any of the models described above will be based on a solid theoretical foundation.

Nature of Assessment

As described throughout this chapter, the nature of formative assessment to inform teaching and learning is distinctly different from the nature of summative and interim assessment designed primarily to serve institutional purposes. By their nature, the process of formative assessment, and therefore the tools to support formative assessment, are most effective when they fit the Generation 3 description of measures that are embedded in a curriculum to estimate, continuously and unobtrusively, dynamic changes in the student’s profile as a learner. At this time, however, the field of educational measurement has not yet reached the point where technology can support continuous and unobtrusive assessment in the classroom. The role of the student in technologically based measurement also bears investigation. As advances in technology progress, it can be expected that some aspects of teacher and student activities and interactions in the classroom will be more likely candidates for continuous and unobtrusive data collection than others. As assessments and measurement models are built from that data, it will be critical to ensure that the data collected from the classroom are the most relevant data to inform teaching and learning and that they are representative of the interactions among teachers and students.

Assessment Literacy Requirements in the Future

Teacher assessment literacy requirements for the effective use of assessment information will remain centered on deep content knowledge and the attendant understanding of how to select learning targets and success criteria, communicate them to students, and accurately recognize how students are thinking from the evidence in their work. Teachers will benefit from deeper content and pedagogical knowledge as content, curriculum, and instructional changes focus teaching and learning on more complex cognitive processes and greater individualization and personalization.

An additional assessment literacy demand is likely, namely, that teachers will have the skills needed to filter more data and information than is currently normally available for individual students. At this time, teachers are often asked to make sound instructional decisions based on sparse evidence. As information technology makes

the collection, processing, and storage of data from the classroom feasible, teachers will have to evaluate multiple sources of information and data, identify relevant information, and combine multiple pieces of data to make informed decisions. They will need supports to do this (U.S. DOE, 2009). An alternative view, from the artificial intelligence research, is that the teacher's job becomes simpler, with the technology doing the interpretation and presenting the teacher with a simple set of options (Hamilton et al., 2023). The authors doubt that this will be the case. As teaching has become more and more complex, the central role of the teacher as the most influential factor in students' learning has been demonstrated over and over (Hanushek, 2011; Ker, 2016; Oppen, 2019).

As the field transitions from Generation 3 to Generation 4 measurement and the information provided from assessment becomes more prescriptive, some assessment literacy demands placed on teachers may be reduced; however, demands for skills in other areas are likely to increase. Teachers will need to be able to judge the quality of the information provided and determine the basis of the information: Was it customized for an individual student or generic for a wide variety of students? Was it based on learning theory or solely on probability?

Student assessment literacy requirements will remain focused on the ability to understand learning targets and criteria, compare work to criteria, and use different types of feedback to improve. As instruction becomes more personalized through the use of technology, students are likely to be required to process feedback from sources other than their teacher. Similarly, an increased focus on collaborative skills may require students to process real-time feedback from their peers in the course of completing performance-based activities.

Advances in ways researchers and educators can work together to determine what data to collect, what information to convey to teachers and students, and the best ways to convey that information will be critical to advancing the assessment literacy of teachers and students and improving the usefulness of information from assessment to inform teaching and learning.

CONCLUSION

The chapter has explored eight general types of assessment—classroom formative assessment, interim assessment, common formative assessments, grading, state summative assessment, curriculum-based measurement, student learning objectives, and assessments based on learning progressions—each used in different ways to inform teaching and learning. These types of assessment vary in the nature of the assessment information they provide, their effectiveness in terms of improvements in teaching and learning, the quality of the assessment process and information, and assessment literacy requirements. Expectations about the future of assessment to inform teaching and learning suggest that these types are changing and will continue to change.

All told, descriptions of these eight types of assessment work together to demonstrate the movement that Bunderson et al. (1989) anticipated and recent history has borne out. The arc of the history of assessment is moving from institutional purposes and bending toward assessment to inform teaching and learning.

At this time, the argument is not that the formative trend in assessment is largely successful in informing teaching and learning. The chapter has documented both progress and significant challenges. Rather, the argument is that assessments are being pressed to do so. Four of the types of assessment discussed in this chapter—classroom formative assessment, curriculum-based assessment, common formative assessments, and assessments based on learning progressions—were developed specifically to inform teaching and learning. Interest in classroom formative assessment especially is growing, and research suggests that, when done well, it can be highly effective. The other four types—student learning objectives, interim assessment, grading, and state summative assessment—were developed for more institutional purposes and bent toward the purpose of informing teaching and learning as a response to stakeholder and public demand. As the chapter has shown, that bending produced some cracks in validity and reliability, and efficacy research, where available, has shown that the latter four types of assessment are less effective for producing learning gains than are the types of assessment designed for that purpose.

Nevertheless, both educators and the public now believe that wherever information about student achievement is available, it should be harnessed in the service of teaching and learning, and they press for that at every turn. This chapter has discussed some of that pressure, including pressure on tests at all levels to produce formative information, the relatively recent development of adding a layer of district-mandated assessment (e.g., interim and common formative assessment) in order to have more assessment information, and the rise of a grading reform movement that for the first time explicitly states that grading should support learning. The conviction that assessment should inform teaching and learning is expressed on state and district websites and materials, in meetings at all levels of educational administration, in the classroom, and in communication with parents and caregivers.

Related to this movement toward the formative, assessment to inform teaching and learning is moving toward more student involvement. Pressure toward more student involvement comes from the advent of more situated, sociocognitive, and sociocultural views of learning, as well as concerns for students' social-emotional well-being, social justice, and fairness. As it has become clearer that students construct knowledge with the help of teachers, peers, and materials, and that students regulate their learning, it follows that students need to be involved in the generation and interpretation of evidence of that learning. Research has affirmed this general trend to be useful for informing teaching and learning. For example, feedback research has shown that elaborated feedback on which students can build is generally more effective than simple knowledge of results. Formative assessment research also has shown that students do better

when they understand the criteria by which they will be evaluated and use them as learning is taking place.

Therefore, informing teaching and learning means designing, administering, and using information that is, to the extent possible, student specific, producing valid and reliable information about individual learners as well as groups; pedagogy and content specific, producing information at instructionally actionable grain sizes; and situation specific, producing information relevant to a learning community, most often a classroom. This is not to say that assessment should not continue to serve institutional, accountability, or administrative purposes or produce valid and reliable data for groups relevant to administrative decision-making—for example, schools, districts, or states and demographic groups within those. The research reviewed in this chapter suggests that those purposes are being—and should be—overtaken, not eliminated, by purposes about supporting teaching and learning. This is happening in both effective and ineffective ways, as the reviews above described. The field of educational measurement needs to understand this phenomenon and continue to work to support quality assessment in a world where the balance of assessment information tips toward assessment to inform teaching and learning.

Points from this review may suggest ways to do this. However, these changes are not guaranteed, or even likely, to occur without concerted and coordinated effort among measurement professionals, content specialists, learning theorists, practicing educators, and others. As this review showed, progress is being made, but it is not easy, quick, or without challenges. With this caution, this review suggests three potential ways forward toward the intelligent assessment Bunderson et al. (1989) and others aim for.

First, the nature of assessment information needs to be understood in broader terms than conventional scales. At least one type of assessment, classroom formative assessment, includes verbal information, in the form of feedback comments, that is important for teaching and learning. In addition, verbal descriptions add meaning to performance levels in rubrics and developmental levels in learning progressions. Learning analytics can add process information, and such multiple measures can contribute to more precise estimates of student learning. This attention to meaning is not a new concept in educational measurement. The importance of inferences, interpretation, and the utility of tests and test scores has been a central tenet of educational measurement for decades. However, the movement toward the formative increases the importance of the underlying meaning of assessment information and the necessity of connecting interpretations of assessment results to understandings of content and pedagogy.

Second, attention to both the quality of the assessment process and the quality of the information will help with understanding and improving assessment to inform teaching and learning. Formative assessment, on the one hand, typically emphasizes the process, and more attention to the quality of the questions or discourse used in the formative assessment process might improve its effectiveness. Interim assessment, on the other

hand, typically emphasizes the quality of the information and has not yet really found an effective process for using that information in the service of teaching and learning. More work on this point may lead to diminished interest in interim assessments or more effective processes or designs for their use in teaching and learning. Currently, assessments or assessment systems that show promise for continuous or intelligent assessment are demonstration projects or successful research projects that explore assessment processes and tools that are far from commonplace in schools. In any case, insistence on quality of both process and information for all assessment information can be expected to improve teaching and learning.

Third, the more assessment turns away from institutional purposes and moves toward assessment to inform teaching and learning, the more assessment literacy demands rise for educators and students. In large-scale testing for institutional purposes, educators and students are consumers, and the bulk of assessment literacy requirements reside with test developers. As the trend moves toward assessment to inform teaching and learning, assessment users—educators and students—have a larger role to play and thus greater assessment literacy needs. This is the case even with professionally developed assessments that are used to inform teaching and learning, because the teachers and learners become the owners of the information and its use and consequences. It is even more the case with educator-developed assessments that are used to inform teaching and learning, for example, classroom formative assessment, common formative assessments, and grading. As the connection between assessment and the teaching and learning process expands, assessment literacy expands to include deep content knowledge and an understanding of how learning happens, in general and for specific concepts.

As assessment to inform teaching and learning evolves in these ways, as the chapter sections have suggested, advances will be required in validity theory and methods, measurement models and methods, technology, and assessment literacy. This is a broad list offering a wide array of productive opportunities for scholarship and practice and is not offered lightly—as this chapter shows, bumps in the road may be expected and collaborative work will be needed.

Finally, it is important to note that this chapter about assessment to inform teaching and learning has been written from an assessment point of view. The reviews have described scholarship and practice in eight types of assessment, described a broad assessment trend toward the formative, and derived three assessment-related sub-themes. The authors envision a companion chapter that could have been written by experts in teaching and learning, from a teaching and learning point of view. In other words, given the trend toward the formative, assessment to inform teaching and learning will also need to be understood from a learning point of view. Some of the research agendas reviewed have already resulted in partnerships with instructional experts and learning theorists. Advances in this kind of work may truly be the future of assessment to inform teaching and learning.

ACKNOWLEDGMENTS

The authors express sincere gratitude to Drew Gitomer, Dylan Wiliam, and Mark Wilson, whose thoughtful reviews helped us immensely. The reviewers were instrumental, especially in organizing and presenting the vast amount of material covered in this chapter and in contributing suggestions from their deep subject matter expertise. We would also like to thank the editors of this volume, Linda Cook and Mary Pitoniak, for their wise leadership and guidance throughout this enormous undertaking.

Test-Based Accountability in K–12 Education

Andrew D. Ho

Harvard Graduate School of Education

Morgan S. Polikoff

University of Southern California

Over the past several decades, K–12 educational tests have served a variety of roles in formal and informal accountability policies at the student, teacher, school, district, state, and federal levels. The use of tests for accountability places a considerable burden on those seeking validity evidence (see Lane & Marion, this volume, for a discussion of validity and validation). While a canonical user of a test score may draw an inference about a single student, accountability systems often incorporate many actors, and many derived scores, at many levels of an educational system. Who is holding whom accountable? By what mechanism? Using which scores? For what purpose?

In the face of such complexity, the measurement field has sometimes treated accountability as a distinct second-stage consideration. A developer may first gather validity evidence for a student score interpretation and then leave those who wish to use scores in an accountability system to gather validity evidence for such uses. This two-stage formulation risks isolating measurement experts and measurement expertise in the first stage, when recent history has shown that the second stage often follows the first. A modern approach to analyzing tests from a measurement perspective is integrated. It anticipates the likely use of scores for accountability and aims to document and prevent the bias, variance, and unintended consequences that such uses can impart.

Our chapter extends the significant contribution by Koretz and Hamilton (2006) in the fourth edition of *Educational Measurement*. The first three editions of *Educational Measurement* had no stand-alone chapter on accountability. Koretz and Hamilton provided an extensive treatment of the validity of inferences under high-stakes conditions. Their treatment, further developed by Koretz (2008), convincingly demonstrates how validity evidence gathered under low-stakes administration conditions is inadequate to support the use of tests for accountability. We extend their framework and principles to the wide range of derived scores common in modern accountability systems.

Koretz and Hamilton (2006) also provided a comprehensive history of large-scale testing in the United States, including the increasing use of assessments for accountability from the 1980s through the initial years following the No Child Left Behind Act of 2001 (NCLB). We summarize and extend their history through three additional discernible national accountability policy periods, the Growth Model Pilot Program (GMPP) of 2005, the “waiver” period beginning in 2011, and the Every Student Succeeds Act of 2015 (ESSA). We emphasize how each period brought accompanying measurement challenges, including the measurement of growth, the measurement of college and career readiness, and score comparability across states and over time.

The COVID-19 pandemic closed U.S. schools in early 2020 and disrupted assessment and accountability systems worldwide. The pandemic coincided with the development of this chapter, and our perspective on pandemic-era accountability is limited. While we treat this recent period simplistically as a pause and return of ESSA accountability policies, we acknowledge that states varied considerably in their responses to the pandemic, and current accountability policies are even more varied across states than they were prior to the pandemic. We look forward to future research that summarizes the history and impact of this period of volatility in educational accountability policies.

Our chapter complements others in this volume. Our focus is on assessment for accountability in the United States, including the low-stakes, but not no-stakes, National Assessment of Educational Progress (NAEP). In contrast, Braun and Kirsch (this volume) focus on large-scale assessments in other countries, including cross-national monitoring assessments like the Programme for International Student Assessment (PISA) and the Trends in International Mathematics and Science Study (TIMSS). Our focus is on assessment for accountability across multiple levels, including the nation, state, district, school, classroom, teacher, and student levels. Brookhart and DePascale (this volume) cover student-level assessment for purposes like orienting diagnostic feedback and informing pedagogical decisions, and Margolis et al. (this volume) cover assessment for licensing and certification. Our focus is also on school environments in K–12 grade levels. Camara et al. (this volume) cover assessment in the context of higher education. Finally, our focus is on cognitive constructs related to academic content, whereas Kyllonen and Zu (this volume) cover issues related to assessments of social and emotional learning and nonacademic outcomes.

THE LOGIC AND HISTORICAL DEVELOPMENT OF K–12 TEST-BASED ACCOUNTABILITY

Accountability testing uses formal or informal policies and mechanisms to encourage or require actors to use test scores. Five questions can help to distinguish among different approaches to “assessment for accountability”: (1) Who is holding whom accountable? (2) By what mechanism? (3) Using which scores? (4) For what purpose? (5) With what unintended negative consequences? Figure 16.1 provides an overview of these questions asked and answered at different levels of K–12 educational systems. We explain the vertical and horizontal dimensions of Figure 16.1 here and return to this framework throughout the chapter.

The vertical dimension distinguishes among levels of the educational system, answering Question 1, “Who is holding whom accountable?” At higher levels of aggregation, national, state, and district leaders hold lower level leaders accountable to educational progress in the interest of the general public. At lower levels of aggregation, schools and teachers use tests to hold students accountable to learning. We reference “general public interest” and “general parent interest” at higher and lower levels of the educational system, respectively, to indicate that justifications for accountability emphasize more benefits to the general public at higher levels and more benefits for parents and their children in specific classrooms and schools at lower levels. These interests also interact, where parents serve in general public roles and can be a strong advocacy group at higher levels of educational systems.

The horizontal dimension of Figure 16.1 contains four columns, each of which addresses the remaining four questions in turn, about accountability mechanisms, score types, purposes, and unintended negative consequences, respectively. The first column lists accountability decisions and mechanisms that test scores serve at different levels

**FIGURE 16.1****A Framework for K–12 Test-Based Accountability Purposes and Mechanisms**

of the system. For example, at higher levels of aggregation, publicly reported aggregate scores for the nation, states, districts, and schools can act as a form of “public accountability” (Hutt & Polikoff, 2020), where transparency about aggregate scores and progress can theoretically inform the general public and inspire educational improvement. Policies can also establish funding or program enrollment for higher scoring or lower scoring schools, teachers, and students. These policies have higher or lower stakes depending on the consequence of the policy, the individuals or groups it targets, and the relative weight of test scores in the policy decision.

The second column describes the types of scores that usually support these decisions and mechanisms. Emphasizing score types and uses is particularly essential for accountability testing because intended uses are often at different levels of aggregation, or scores are “adjusted” or “combined” in various ways to serve accountability purposes. These “derived scores” have properties that can both serve intended purposes and create unintended consequences (Haertel & Ho, 2016). Chapter 13 of the *Standards for Educational and Psychological Testing* (Standards; American Educational Research Association [AERA] et al., 2014) also discusses these issues in the context of “accountability indices.”

The third column of Figure 16.1 describes “indirect” or “influencing” purposes of accountability testing that also serve as broad justifications for accountability. Haertel (2013) distinguished these indirect purposes of testing as mechanisms, including incentives and messaging, that influence actors without directly using their test scores. For example, a goal of test-based graduation policies is to direct student and teacher effort, and a goal of school accountability policies is to signal worthy curricular goals

and levels of proficiency. Both intended effects occur as the result of the policy, not as a result of interpretations or uses of any particular scores themselves. Indirect purposes are usually but not necessarily explicit in the logic of test-based accountability policies. Validity evidence supporting indirect test uses includes quasi-experimental analyses that estimate the effect of the test-based accountability policy over a counterfactual policy with less testing or accountability.

The final column of Figure 16.1 lists common unintended negative consequences of test-based accountability policies at different levels of educational systems. These can include common responses like inflation that derive from incomplete or unrealistic goal structures (Koretz, 2008). Additional unintended consequences of accountability testing include “deficit interpretations” of students or groups where users interpret low scores or averages as irreparable or innate student or group deficits for themselves or for others. For example, recent empirical evidence suggests that “achievement gap” framing affects teacher support for policy solutions and general public beliefs about racial stereotypes and causes of disparities (Quinn, 2020; Quinn et al., 2019). Professional testing standards are explicit about the importance of anticipating, documenting, and minimizing unintended negative consequences in test-based accountability (AERA et al., 2014).

Avoiding unintended consequences requires resolving a central tension in test-based accountability: on the one hand, between incentivizing achievement of students, teachers, and school leaders to meet test-based goals and, on the other hand, formalizing the responsibility of school, district, state, and federal actors to provide the capacity and opportunity for this achievement. Elmore (2004) laid out five guiding principles for designing fair accountability policies that attempt to resolve this tension: (a) there should be empirical evidence that goals are achievable, (b) measures should be sufficiently accurate and precise for their purposes, (c) students should be held accountable only to what they have had the opportunity to learn, (d) schools should be held accountable only to the value they add, and (e) the performance that a policy requires should be reciprocated by the responsibility of the system to provide that capacity.

Implementing these principles is challenging in part because test-based measures cannot on their own distinguish between a low score that reflects a lack of individual commitment to achievement and a low score that reflects a lack of systematic support for achievement. A lack of individual commitment might suggest that stakes should be higher, whereas a lack of systematic support suggests that support should be stronger. This fundamental ambiguity in test score interpretation enables actors at different levels of the accountability system to use the same test score data to ask more from each other. Higher level actors use policy and authority to require more of lower level actors. Lower level actors can use mechanisms of public accountability (Hutt & Polikoff, 2020) to require more assistance or support from higher level actors.

These mechanisms are not equal in power. Because of this asymmetry, particular care is required to ensure that the system is beneficent in providing opportunities to accelerate learning without reinforcing existing inequalities and power structures. Toward

the end of this chapter, we review recent movements that attempt to rebalance power toward holding systems accountable to learners, including systems of equity indicators (National Academies of Sciences, Engineering, and Medicine [NASEM], 2019), sociocultural assessment (Shepard, 2021), and indigenous data sovereignty and policy (Walter et al., 2021).

Balance between stakes and supports among actors, mechanisms, scores, and purposes has evolved through the history of U.S. federal educational policy. In the remainder of this section, we review five phases in rough chronological order: the Tyler rationale, program evaluation and monitoring, programmed instruction, minimum competency testing, and the standards movement. Our review draws from similar reviews of history relevant to accountability testing, including those by Haertel and Herman (2005), Koretz and Hamilton (2006), and Madaus et al. (1983). Like Shepard et al. (in press), we also update this history by describing recent waves of federal accountability policy, including NCLB and ESSA.

The Tyler Rationale

The Tyler rationale (Tyler, 1949) forms the basis of many modern models for improving curriculum and instruction. Tyler drew lessons from the “Eight-Year Study” (E. Smith & Tyler, 1942) conducted from 1933 to 1941. The original study investigated whether students in 30 high schools with relaxed college-preparatory course requirements had different outcomes than students in high schools that maintained the strict curricular sequences of that era.

Tyler (1949) distilled four principles from the study: (a) define appropriate objectives, (b) design educational experiences aligned to objectives, (c) organize educational experiences for effectiveness, and (d) evaluate whether objectives have been attained. As Haertel and Herman (2005) noted, Tyler and his colleagues also articulated clearly that tests served multiple purposes beyond evaluation. These purposes included focusing student and teacher effort and providing “a sound basis for public relations” (E. Smith & Tyler, 1942, p. 10) through evidence about outcomes. The use of tests to focus the system and shape public perceptions would grow in the decades to come (Haertel, 2013).

Programmed Instruction and Criterion-Referenced Testing

From the 1950s through the 1970s, Tyler’s principles undergirded the rise of programmed instruction, a model that shifted Tyler’s emphasis on measurable objectives from the program level to the classroom level. Psychologists at the time envisioned a well-crafted sequence of curricular topics, with tests that guided and sometimes determined subsequent instruction. Propelled by behaviorist theories (Skinner, 1953), these systems included tests to check understanding and provide immediate feedback to reinforce desired behaviors.

To support these uses, tests had to support inferences about what students could do. Glaser (1963) coined the term *criterion referenced* to describe tests designed to assess

“the degree to which the student has attained criterion performance” (p. 6). This set up a useful contrast to *norm-referenced tests* that have a primary purpose of differentiating among test takers relatively, often for the purpose of selection into competitive programs. Although well-designed tests can support scores that have criterion-referenced and norm-referenced interpretations (AERA et al., 2014), essentially all modern accountability tests claim to be criterion referenced to emphasize that the primary scores of interest indicate what students know and can do against an absolute standard. The term also suggests the appealing theoretical possibility that all test takers can achieve a given criterion level.

To support or operationalize decisions in programmed instruction, practitioners and systems use established cut scores or set them on the basis of what students know and can do. Bloom’s popular “mastery learning” model (1968), for example, included end-of-unit tests with cut scores that distinguish between students who are and those who are not ready for the next unit. Cut scores on criterion-referenced tests should enable teachers to describe a student who scores at or above a cut score in terms of their absolute knowledge and skills, without reference to any norm or reference group.

Tests in this era became much more focused on fine-grained objectives that developed along continua. Score reporting turned to support interpretations of specific criteria, knowledge, skills, and abilities. Programmed instruction also raised the stakes on potential instructional decisions for students, including remediation and repetition of previous instruction. And the use of tests to reform and improve instruction, both directly by providing data and informing decisions and indirectly by focusing the system, continued to rise.

Testing for Monitoring and Program Evaluation

As programmed instruction was increasing the role of testing in classroom instruction, the 1960s saw an increase in the role of testing in federal programs and surveys. The Elementary and Secondary Education Act of 1965 (ESEA) included a required, annual, measurement-based evaluation of Title I programs under the Title I Reporting and Evaluation System. The National Science Foundation began to require the use of educational tests in evaluations of funded curricula. And the headline findings from the Equality of Educational Opportunity Survey (Coleman et al., 1966) were drawn from standardized achievement tests. Extending the Tyler rationale, educational testing began to be a default requirement for federal programs, a signal of rigor, transparency, and public accountability.

Planning for NAEP also began in the 1960s, and the first NAEP assessments were administered in 1969–1970 (Jones & Olkin, 2004). Early NAEP testing did not report scale scores and was instead inspired by the same objectives-oriented theories that guided programmed instruction. In a 2004 reflection, Cronbach compared the reporting goals to those of opinion polling, where results consisted of numerous percentages of correct answers to specific questions, disaggregated by groups. He also notes, “There was interest in making the results comprehensible to teachers in terms that they could

put to use in their teaching” (Cronbach, 2004, p. 141). However, the reports were unwieldy and made it challenging to measure progress over time. We reserve a fuller review of NAEP and its significant and growing role in educational accountability for the section “NAEP and a Theory of Public Accountability”. Here, we observe the growing pains of early NAEP as an example of a continuing tension between designing diagnostic tests for instructional guidance and designing monitoring tests for large-scale educational progress.

Minimum Competency Testing

In the 1970s, concern about youth unemployment, low graduation standards, and intractable achievement gaps helped to spur a “back to basics” movement (Haertel & Herman, 2005). In response, district and state policies known as *minimum competency testing* began to spread, typically taking the form of making high school graduation and, in some cases, grade promotion contingent on students scoring above selected score thresholds on standardized tests. Statewide minimum competency testing requirements existed in at least 29 states by the end of the decade.

Minimum competency testing built on the theoretical foundations of educational psychologists from previous decades, including the use of tests that measured specific competencies and the use of a criterion-referenced cut score for “minimum competency.” However, a dramatic extension from previous decades was the use of large-scale educational policy to articulate a clear and high-stakes decision rule, in this case with direct consequences for students. The rhetoric of the movement has largely faded in favor of an emphasis on high standards and higher-order thinking skills. Nonetheless, the movement helped to advance a more substantial state role in educational testing, as well as the use of criterion-referenced tests and cut scores for high-stakes decisions (Koretz & Hamilton, 2006).

With low cut scores and numerous opportunities to retake exams, Catterall (1989) summarized the scholarly consensus that “the competency test was legislated as a lion but implemented as a lamb” (p. 4). As we review federal and state accountability policies for schools and students over the next decades, this pattern recurs: initially unrealistic political rhetoric and goals are followed predictably by increasing flexibility.

The Birth of the Standards Movement

The 1980s began with a more centralized and data-driven effort than the previous decade to signal a crisis that required national educational reform. The influential 1983 report *A Nation at Risk* (National Commission on Excellence in Education, 1983) used a range of indicators, including international comparisons from the International Association for the Evaluation of Educational Achievement (Bloom, 1973), results from the SAT (formerly Scholastic Aptitude Test), and NAEP results to argue that “the educational foundations of our society are presently being eroded by a rising tide of mediocrity that threatens our very future as a Nation and a people” (National Commission on Excellence in Education, 1983, p. 5). The report called out the shortcomings of

minimum competency tests specifically, arguing that “the ‘minimum’ tends to become the ‘maximum’ thus lowering educational standards for all” (p. 20). The report instead called for “more rigorous and measurable standards, and higher expectations, for academic performance” (p. 27). The report specified that tests “should be administered at major transition points from one level of schooling to another” and “should include other diagnostic procedures that assist teachers and students to evaluate student progress” (p. 28).

The coming years continued to clarify the logic of modern large-scale accountability testing: aligned tests, higher standards, and transparent reporting helped to focus and improve teaching and learning (Resnick & Resnick, 1992; Smith & O’Day, 1991). The state and federal roles in accountability testing also continued to rise. Responding to requests from some governors in 1984, Secretary of Education Terrel Bell prepared a one-page “wall chart” of state educational outcomes, including graduation rates and SAT and ACT (formerly American College Testing) scores. Once planned for release in a small press conference in the secretary’s office, the wall chart resulted in the largest press conference in the Department of Education’s history (Ginsburg et al., 1988). Later that year, the Council of Chief State School Officers passed by a vote of 27 to 12 a report supporting improved measurement of educational indicators across states, with a closer 20–19 vote that avoided the deferral of a key section of the report about comparable outcomes (Toch, 1984). The report noted that, “on a technical level, state-to-state comparisons are problematical for a variety of reasons . . . on a political level, however, the attention given to the Secretary’s ‘wall chart’ makes inevitable future state to state comparisons on outcome measures” (Council of Chief State School Officers, 1984, p. 3). This articulates a theory of public accountability that we develop in the next section, where transparent reporting of comparable outcomes signals worthy goals, creates competition, and draws public attention, even without explicit consequences or rewards for scores.

In addition to higher performance standards as exemplified by “proficiency,” reports from this era emphasized complex, higher-order thinking skills and attempted to distinguish clearly between performance standards and content standards. Content standards referred to “the knowledge, skills, and other understandings that schools should teach in order for students to attain high levels of competency in challenging subject matter,” and performance standards “define various levels of competence in the challenging subject matters set out in the standards” (National Council on Education Standards and Testing, 1992, p. 13). The National Council on Education Standards and Testing was convened to explore the possibility of a national system of standards and tests, with candidate sets of content standards like those by the National Council of Teachers of Mathematics in 1989 and the American Association for the Advancement of Science in 1993.

An ambitious effort known as the New Standards Project was a joint effort of the University of Pittsburgh’s Learning Research and Development Center and the National Center on Education and the Economy. The project attempted to operationalize higher

order content standards in the form of performance assessments. The project had 17 states and 6 urban districts signed on at its peak. It ultimately faced a number of challenges, including state resistance to standards that were not “home grown” and apparent underestimation of the amount of time and money it takes to produce performance assessments that support accountability decisions at scale (Hoff, 2001). Koretz et al. (1994) summarized similar tensions among affordability, score precision, and instructional relevance in Vermont’s portfolio assessment system.

The 1990s also saw the rise of explicit school-level stakes. Whereas minimum competency testing had direct consequences on students, the logic of standards-based reform focused on incentives at the school level. The popular Quality Counts series published by *Education Week* reviewed state educational reform plans annually, including a grade for states on multiple indicators related to standards-based reform. By 1999, the report found that 36 states had committed to transparent reporting of report cards for schools, with 19 issuing overall performance-based ratings (Jerald, 2000). In addition, 16 states had the legal authority to reconstitute schools that failed performance measures, and 13 states offered monetary rewards to successful schools. These state systems established the precedent for the explicit school sanctions that would be required of all states by NCLB in the years to come.

The NCLB Era

The NCLB Act, passed in 2001, was a bipartisan triumph of the standards movement in education. NCLB represented a reaction to federal discontent over the progress of school reform throughout the 1990s, most specifically the slow and weak implementation of the prior ESEA reauthorization, the Improving America’s Schools Act (McDonnell, 2005). NCLB also grew out of state-level reforms, primarily in Texas, that seemed to be boosting student performance (Deming et al., 2016; Grissmer & Flanagan, 1998).

The NCLB suite of reforms was premised on a straightforward theory of change (Porter & Polikoff, 2007). First, establish clear, grade-level content standards in the core academic subjects (mathematics and English language arts, though science was also included in the law). Second, create aligned assessments to measure student performance against those standards and inform the public and educators of that performance. Third, through accountability policies, hold schools and districts accountable for student performance against the standards and offer interventions in schools where the standards are not met. Fourth, disaggregate all results for key student groups of interest to ensure high average performance does not mask low-performing student groups. With these policies in place, the thinking went, teachers (supported by school and district leaders) would be incentivized to align their instruction with the challenging academic content standards, student opportunity to learn would improve, and achievement would rise. In schools where achievement was not rising, public school choice (enabled by the public release of school performance data) would put additional market pressure on schools to improve, while supplemental education services would provide additional support to students and teachers. The design of the accountability

systems broadly aligned with this theory of change, though we discuss the effectiveness of these policies in the section “The Impact of Accountability Policies”.

School accountability under NCLB was based on a straightforward set of measures: student proficiency rates on state tests, student participation rates on state tests, and an additional state-selected indicator (high school graduation rates and, typically, attendance rates for elementary and middle schools). For student proficiency, states were required to establish proficiency rate trajectories for each tested subject and grade. These trajectories began from baseline proficiency rates set in 2002 based on the distribution of student performance in the state to the target of 100% proficiency by 2014. Each year’s target was called an annual measurable objective (AMO), and meeting all AMOs was necessary to make adequate yearly progress (AYP) and avoid consequences. In other words, the NCLB accountability system represented a conjunctive approach to combining multiple measures—schools had to cross each AMO bar overall, and for all student groups—high performance in one area could not offset low performance in another.

The consequences for failing to meet AYP escalated with the number of years of failure, beginning with labeling, then public school choice, then supplemental tutoring, and finally the possibility of state intervention (including school closure, charter conversion, state takeover, or other significant turnaround efforts). States were allowed to set different trajectories for different grade levels and subject areas, but they were required to have the same targets for all student groups (NCLB required states to disaggregate data for, at minimum, student groups based on race/ethnicity, socioeconomic status, disability status, and English proficiency). To ensure that schools were not selectively excluding low-performing students from taking tests, the law also required 95% of each student group to participate in each exam.

While these test-based performance measures seem straightforward and comparable across states, in practice, state decisions about the construction of their systems dramatically affected how many and what kinds of schools would be subject to accountability pressure. These decisions are described well elsewhere (Davidson et al., 2015; Polikoff & Wrabel, 2013; Porter et al., 2005), but we briefly summarize some of the relevant key decision points here.

One decision point states were allowed to make under NCLB was about student group size. This was the minimum number of students required in a particular student group for that student group to count toward accountability. The modal subgroup size under NCLB was 30 (Polikoff & Wrabel, 2013), meaning that if a school had 29 low-income students, that student group would not count as its own group for accountability purposes, whereas if it had 30 or more, it would. (The students would count in the overall school average regardless.) However, minimum group sizes ranged considerably across states (from a low of 5 to a high of 100; Davidson et al., 2015). Smaller student group sizes can dramatically affect the number of students who are included in student group accountability measures. An analysis of California data (Polikoff et al., 2018), for instance, found that moving from their old group size of 100 to a group size of 30

increased the average number of accountable student groups in schools from 3.65 to 5.44. This had the effect of dramatically reducing the number of students who were in groups not reported or used for accountability (for instance, under the previous system, 80% of multiple-race students were in schools where that group was not large enough to be reported, but under the new system it was just 28%). Of course, there are trade-offs of changes in student group size rules: With smaller minimum group sizes, reliability will be lower (year-to-year fluctuations will be higher), but there will be greater incentive for educators to attend to student group performance if the school is accountable for more student groups.

Second, as described by Polikoff and Wrabel (2013), the law allowed states to use a variety of alternative methods in determining whether schools' and districts' proficiency rates were above the performance target. By far the best known of these was the Safe Harbor provision, where schools were given credit for meeting a proficiency target if the percentage of students scoring below *Proficient* decreased by 10% (not 10 percentage points) from the previous year. These alternative methods had the effect of sometimes dramatically lowering the proficiency threshold. For instance, consider a school with 100 students, of whom 50 are *Proficient* (50% proficiency rate) against an AYP target of 75%. This school would need to get just 5 more students over the proficiency threshold in the next year to meet the AYP target, even though the proficiency rate of 55% would fall far below the actual target for that year.

Third, as described in detail by Davidson et al. (2015), states also could use statistical adjustments to their accountability results in making accountability decisions. Specifically, states were permitted to adjust targets based on confidence intervals, in essence allowing states to say, "we will only hold your school accountable if we are extremely confident your school's performance is below the proficiency threshold." Confidence intervals were defined in terms of sampling variance of proportions, but were applied in an unusual way. Instead of indicating the precision of the parameter estimate, they were used to lower targets in proportion to imprecision. Importantly, confidence intervals and Safe Harbor could be layered on top of one another. In the previous example of the 100-student school in California, it would actually only need to get 2 more students over the proficiency line, because California applied a 75% confidence interval to the 5-student Safe Harbor target.

Fourth, states had leeway over a variety of technical decisions about which students would count for accountability and how to aggregate their scores. For example, states applied variable rules around the inclusion of students with certain kinds of disabilities and varied in their selection of student racial/ethnic groups (Davidson et al., 2015). States could set their own rules about student enrollment, with some states requiring students to be enrolled in a school for an entire year to count for accountability purposes and others requiring just a few months' enrollment (the former approach excluding highly mobile students). And states could decide how to aggregate results across grades and subjects, whether by first aggregating results and then comparing these to AYP targets or by comparing results to targets separately by grade and subject.

Finally, states were allowed to set nonlinear performance trajectories from the 2002 starting point to the 2014 100% proficiency target (Porter et al., 2005). Some states set “straight-line” targets, expecting a constant annual increase in the percentage of students scoring *Proficient*. Other states set more back-loaded targets, with smaller annual increases in the earlier years of the law and larger increases in the later years.

These state policy decisions—some of them seemingly modest—had profound effects on the number and type of schools identified as failing to meet NCLB proficiency targets. For instance:

- Porter et al. (2005) found early in NCLB that Kentucky’s design decisions (using a large student group size of 60 and confidence intervals) resulted in 75% fewer schools failing to meet their accountability targets than had the state made more stringent decisions.
- Polikoff and Wrabel (2013) found that two thirds of California schools used Safe Harbor to meet at least one AYP AMO in 2011.
- Davidson et al. (2015) documented the complex and interacting effects of state accountability policy decisions on failure rates, suggesting that school failure under NCLB was as much about minor differences in the ways state policy makers interpreted and implemented the law as it was about actual school performance.

As the NCLB era drew toward its conclusion, there was widespread dissatisfaction with NCLB accountability systems, with specific focus on (a) the unreasonableness of 100% proficiency targets (though again, in practice there were many ways to make AYP without hitting 100% proficiency), (b) the use of status measures of performance without considering growth, (c) the narrowing effects of the law resulting from its near-exclusive focus on English language arts (ELA) and mathematics test scores, and (d) the perceived ineffectiveness of NCLB’s mandated interventions.

The ESEA Waivers

It was in this context that in 2011 (already 4 years after the original intended ESEA reauthorization), the U.S. Department of Education began offering states flexibility waivers from some provisions of NCLB’s accountability rules. The waiver accountability policies were broadly aligned with NCLB policies and the NCLB theory of change, but offered some technical fixes aimed to address the shortcomings of NCLB accountability systems.

In place of NCLB’s AYP rules, the waivers had several requirements for state accountability systems. First, state AMO targets had to be revised, with the waivers offering states two options: AMOs that increase in equal annual increments to 100% proficiency by 2019–2020 or reduce by half the percentage of *Below Proficient* students in the “all students” group and in each student group within 6 years. These tweaks were offered to reduce the pressure of the impending 100% proficiency deadline, which was then just a couple years off. Second, states were required to include a measure of student growth

in their accountability rules to address the widely known concerns about student proficiency rates as a measure of school performance. Third, states were mandated to identify at least 15% of schools for intervention, with 10% of schools identified as “focus” schools (intended to be schools contributing to state achievement gaps) and 5% of schools identified as “priority” schools (intended to be the state’s lowest-performing schools). This provision offered states some relief in terms of the number of schools and districts they would have to identify and work with, but it also introduced a norm-referenced approach into what was originally intended to be a criterion-referenced policy system based on schools meeting targets. Though the waiver accountability systems were in place for only a few years, there are generalizable lessons in the revisions about how to set realistic targets and establish consistent definitions to avoid perverse incentives.

Waiver accountability systems represented important improvements over NCLB systems in some ways, but less so in others. Polikoff et al. (2014) reviewed these improvements and missed opportunities, which we summarize here. First, waiver accountability systems offered flexibility to include measures beyond test scores, responding to earlier critiques of NCLB as narrowly focusing on ELA and mathematics proficiency at the expense of all other measures of school effectiveness. States used this flexibility to include a variety of measures like graduation rates, attendance, school climate, and opportunity-to-learn measures. Only five states used just test scores in identification of their priority schools, and most states used at least one nontest measure in their identification of focus schools. Waiver plans also often included additional tested subjects in accountability (e.g., science, which was required to be tested but was not used for accountability under NCLB), further broadening the measures against which schools were evaluated.

Second, when waiver accountability systems did rely on test scores, they included measures that experts argued were superior to proficiency rates in terms of measuring and incentivizing school effectiveness (e.g., Ho, 2008; Linn, 2003; Polikoff & Wrabel, 2013; Ryan, 2004). About half of states used a measure of individual student achievement growth, and about a quarter used different status-based measures of performance, such as performance indices where students scoring *Basic* earned half a point and those scoring *Proficient* earned a full point (Polikoff et al., 2014). Third, waiver plans made more stable classifications—identifying schools and working with them for at least a few years before moving on to a new set of schools. This has two potential benefits: It reduces the extent to which ephemeral fluctuations in performance drive school classifications and it ensures more sustained intervention and support in struggling schools.

However, researchers also raised concerns about the design of waiver accountability systems. These concerns were along a number of dimensions. For example, in some states the state would use one approach to rate schools on, say, an A–F composite index, but then use a different approach altogether to identify schools for intervention. This created a lack of consistency that might cause unnecessary confusion. As another example, while nontest measures were included in many states’ accountability systems,

proficiency rates based on state tests still dominated accountability classification rules in nearly all states, raising all of the same issues as discussed in the NCLB era. And finally, some were concerned about the use of so-called super-subgroups, which combined the performance of multiple groups of students, rather than fully disaggregating results as under NCLB (e.g., R. A. Hernández, 2013). There was concern that this approach to aggregating student groups could mask the performance of the disaggregated groups and therefore diminish attention to supporting these student groups.

Overall, the waiver period represented a controversial but important transition from NCLB-style accountability to ESSA accountability. The waivers clearly broadened the measures against which schools were evaluated, a transition from the nearly exclusive test-based focus of NCLB. The waivers narrowed attention to a small proportion of the lowest-performing schools, moving away from NCLB's extraordinarily high school failure rates and toward a more norm-referenced approach to school accountability. The waivers encouraged innovation in the use of student achievement test scores, including a move away from proficiency-based status measures and toward true student growth measures. These innovations carried over when ESEA was finally reauthorized as the ESSA in 2015.

The Every Student Succeeds Act

The ESSA passed in 2015, finally reauthorizing ESEA and updating requirements and expectations with regard to state accountability systems. The act's accountability provisions continued and expanded on some of the main innovations of the waiver era and continued the rollback of NCLB-era sanctions. The proportion of schools subject to accountability sanctions was reduced to just the bottom 5% (plus high schools with low graduation rates), and the sanctions were made much less prescriptive (with a focus instead on district creation and implementation of evidence-based plans for school improvement).

The statute describes five types of indicators that must be included in school accountability systems (Marion, 2016): first, an indicator of academic achievement; this can be as simple as percent *Proficient*, but ESSA also allows for states to use other status measures of performance (e.g., average scale scores, index-based approaches); second, another “valid and reliable academic measure,”¹ often a measure of either growth or achievement gaps; third, graduation rates, including extended (i.e., 5- or 6-year) graduation rates; fourth, progress toward English language proficiency for English learners; and fifth, another indicator of school quality or success that meaningfully differentiates and is valid, reliable, and comparable (in the text of the law, they list as options measures of student engagement, educator engagement, student access to and completion of advanced coursework, postsecondary readiness, and school climate and safety). In terms of actual accountability classifications, the statute also says that states must measure school performance against state-determined status and improvement goals in at least the areas of academic achievement, graduation rate, and student groups that are behind (Marion, 2016). Drawing on the waivers, the law requires that states produce

at least every 3 years a list of schools for comprehensive support and improvement, including (a) the lowest 5% of Title I schools, (b) high schools with graduation rates below 67%, and (c) schools with low-performing student groups (thus including both norm- and criterion-referenced approaches to school identification).

How did states implement these requirements? The approved state ESSA plans varied along every dimension, so characterizing them concisely is difficult. Indeed, if there is one way to characterize state ESSA accountability systems, it is that they are incredibly variable in form and content. But a few trends emerged in the many external reviews that were produced.

With regard to student achievement measures, many (but not a majority of) states use status measures of student performance that move beyond percent *Proficient* (e.g., average scale scores or “indices” that use a fuller range of student scores rather than a binary *Proficient/Nonproficient* distinction) and many also include achievement in subjects other than mathematics and ELA as another indicator of school quality or student success (English, 2017). Virtually all states (47 + Washington, DC; Education Commission of the States, 2018) include measures of student achievement growth in their ESSA systems, a sharp departure from waiver policies (American Institutes for Research, 2017; English, 2017). States also include test participation in their achievement measures, most commonly by assigning a score of zero to nonparticipants on state tests (English, 2017). The story for achievement measures at the high school level is even more variable from state to state; see Petrilli et al. (2016a, 2016b).

State goals and approaches also vary considerably with regard to graduation rate and other high school measures. State 4-year graduation rate goals range from a high of 100% (South Dakota) to a low of 84% (Nevada, Virginia), with the most common levels being 90% or 95% (21 and 10 states, respectively; Hackmann et al., 2019). States also include a wide variety of “college- and career-readiness” (CCR) measures, mostly at the high school level, but sometimes at lower levels. The most common of these are Advanced Placement/ACT/SAT/International Baccalaureate exam scores, industry-recognized credentials, Career and Technical Education (CTE) course sequence completion, advanced diploma completion, and other measures of course taking (for a full list, see Hackmann et al., 2019). In most but not all states, these measures are reported overall and separately for student groups. In many states, these diverse measures are aggregated into a single index (e.g., in Arizona, students can earn fractions of a CCR point for various accomplishments, with those student scores averaged across the state). In most states, the aggregated CCR measure is then combined with other measures to create an overall summative rating.

Another important trend is with regard to the “other academic indicator.” While 33 states include the CCR measure as part of their other indicators (Education Commission of the States, 2018), many alternative accountability measures are also included, representing a continued growth in the number and variety of nontest measures that began under the waivers. For instance, the majority of states include chronic absenteeism as a measure (English, 2017), which is important because absenteeism is highly predictive of other long-term student outcomes (Ansari & Pianta, 2019; Liu et al.,

2021). Other measures in this area include conditions of learning or school climate, some measure of the well roundedness of students' education, and credit accumulation.

Student groups continue to play an important role in accountability systems, but perhaps less so than under NCLB. Although ESSA requires states to continue to report student group performance, it does not require a particular approach to the use of student group performance for accountability purposes. Some states under ESSA are using a variant on super-subgroups that began under the waivers, most often simply a group defined by the lowest-performing students (English, 2017). But other states combine low-performing student groups into a demographically defined student subgroup. Furthermore, state minimum subgroup size rules continue to decrease under ESSA, with a median and modal value of 20 (Alliance for Excellent Education, 2018).

Finally, a large majority of states combine multiple measures in some way to produce a summative rating of some kind. Thirty-six states use an A–F grade, a descriptive rating system (e.g., *Needs Improvement, Average, Good, Great, Excellent*), or a numerical index system (e.g., 1–10, 1–100; Education Commission of the States, 2018). These indices vary along every conceivable dimension in terms of how they aggregate and weight their various component measures.

While most reviews of ESSA accountability plans view those plans positively, there are some concerns that are commonly raised. The most common critiques have to do with the treatment of student groups. While NCLB was critiqued by some for its overly harsh attention to student groups (its conjunctive approach meant that a single group failing a single AMO would lead to the whole school failing), ESSA may have swung the pendulum far in the opposite direction. Independent reviews suggest that most state plans give almost no attention to the performance of student groups, with school ratings being determined on whole-school performance (Bellwether Education Partners, 2017). Advocates for students with disabilities have expressed similar concerns, worrying that these students will fall through the cracks of the 33 state accountability systems that do not explicitly take student group performance into account in rating schools (National Center for Learning Disabilities, 2018). Another critique is that states' composite indices may appear transparent on the surface, but actually are overly complicated in ways that make their results confusing to educators and the general public (Bellwether Education Partners, 2017). There are also continued concerns about high school accountability, which is heavily reliant on graduation rates (a status-based measure of performance) and lacks the growth-based approach used when student-level longitudinal test score data are available. It is also not fully clear in many state plans how states actually plan to intervene in and improve their lowest-performing schools (though the literature does not exactly offer a road map for school improvement at scale).

The overall takeaway from ESSA plans can be summarized as follows. These plans expand on some of the trends that began under the waivers. In most cases, they dramatically increase the types and number of measures to be used in accountability, but proficiency rates in mathematics and ELA still play a major role and may drive educators' actions. They more appropriately measure student achievement status and

almost universally include measures of student achievement growth as well. However, they take some of the pressure off for school improvement (which is by design and a reaction to NCLB), substantially decreasing the number of schools that are likely to feel meaningful accountability pressure. The changes to student group reporting and accountability requirements may reduce awareness about the average achievement and progress of historically underserved students when these populations are small.

There are two other ESSA-era trends that are worth mentioning here. The first concerns changes in the high school summative assessment. As of 2019, half of the states were including either or both the SAT and the ACT as a high school summative measure (Olson, 2019). This change was allowed under the law's provisions for "a nationally recognized college entrance exam," and states were enthusiastic about the opportunity to adopt assessments that could serve multiple purposes. There are continued concerns about the alignment of the tests to state standards (e.g., National Council on Measurement in Education, 2019), but the Department of Education approved the use of the tests for statewide summative purposes regardless.

Second, as ESSA accountability systems were being implemented, the COVID-19 pandemic gripped America's schools in the 2019–2020 academic year. There were important implications of the pandemic on assessment and accountability. For instance, the Department of Education authorized states to extend the testing window, shorten assessments, and give assessments remotely (U.S. Department of Education, 2021). The Department of Education also allowed states to waive the 95% participation rate rules and to apply for waivers to the requirements for school identification. The Department of Education has been returning to ESSA accountability rules as the pandemic abates.

NAEP AND A THEORY OF PUBLIC ACCOUNTABILITY

Public accountability includes policies and commitments for reporting test data without predetermined stakes attached to results (Hutt & Polikoff, 2020). As Figure 16.1 indicates, proponents of public accountability assert or assume that publishing test score data can signal worthy goals, improve commitment to those goals, spur competition toward those goals, encourage actors to learn from organizations that are successful at achieving those goals, and align the system toward those goals. This logically requires appropriate measures that communicate effectively to intended audiences. The reasoning also requires that actors are motivated by public transparency without any automatic sanctions or rewards attached to results.

This section reviews the rise and species of "report cards" that represent the linchpin of test-based public accountability. We begin with the assessment known as the Nation's Report Card, NAEP (<https://www.nationsreportcard.gov/>), which was introduced briefly in the previous section. NAEP remains the foremost national and cross-state example of test-based public accountability. This section continues with a discussion of audiences and effects of public reporting.

The Rise of NAEP as a Mechanism for Public Accountability

NAEP had its origins in the federal Office of Education under the leadership of Francis Keppel in 1969. The earliest NAEP assessments that year tested citizenship, science, and writing skills of 9- 13-, and 17-year-olds, debuting technical features like matrix sampling. Over subsequent years, new innovations were included, such as comprehensive content frameworks, state comparisons, and, later, large urban district comparisons. In 1986, Secretary Bennett formed a study group chaired by Tennessee governor Lamar Alexander and Spencer Foundation president H. Thomas James to explore state comparisons using NAEP (Alexander et al., 1987). The resulting report compared NAEP to a weather map that only provided weather for the nation as a whole. The report described state-to-state comparisons as “the single most important change recommended by the Study Group” (p. 11). This recommendation was fiercely debated and ultimately included in the 1988 amendments of ESEA as a trial state assessment program beginning in 1990 that would be voluntary for states (Vinovskis, 2001). Later, NCLB required states to participate in NAEP biennially as a condition of receiving Title I funds.

NAEP also illustrated the value of compelling reporting metrics for public accountability by adopting the criterion-referenced score metric, “percent *Proficient*.” The 1987 Alexander–James report included a published commentary by a National Academy of Education review committee chaired by Robert Glaser, the same scholar who coined the term *criterion-referenced testing* 24 years prior. Although the Alexander–James report did not mention criterion-referenced score reporting, the commentary does:

We recommend that, to the maximal extent technically feasible, NAEP use descriptive classifications as its principal reporting scheme in future assessments. For each content area NAEP should articulate clear descriptions of performance levels, descriptions that might be analogous to such craft rankings as novice, journeyman, highly competent, and expert. Descriptions of this kind would be extremely useful to educators, parents, legislators, and an informed public. (Alexander et al., 1987, p. 58)

The subsequent 1988 legislation created the independent NAGB to oversee NAEP policy and assigned to NAGB the responsibility of “identifying appropriate achievement goals for each age and grade in each subject area to be tested” (PL 100-297, Part C, Section 3403(6)A, 1988). Shortly thereafter, in 1989, President George H. W. Bush convened all 50 governors in an education summit to achieve consensus on broad educational goals for the year 2000. In 1989, the National Governors Association established Goal 3: “American students will leave grades four, eight, and twelve having demonstrated competency in challenging subject matter” (National Governors Association, 1990). A year later, in May 1990, the newly formed NAGB voted to establish three achievement levels for each grade and subject, with a central level of *Proficient* including the same descriptor: “Students reaching this level have demonstrated competency over challenging subject matter.” Although the NAGB process for setting performance

levels for “proficiency” faced considerable scrutiny and controversy through the 1990s, (Shepard et al., 1993; Vinovskis, 1998), a 2017 evaluation concluded, “Through 25 years of use, the NAEP achievement levels have acquired a ‘use validity’ or reasonableness by virtue of familiarity” (NASEM, 2017, p. 11). The apparent interpretability of the 0- to 100-scaled percent *Proficient* statistic would help it to become a central feature of test-based public accountability policies in the decades to come, despite its technical flaws (Ho, 2008; Polikoff, 2016).

Although official reporting of NAEP scores includes states and participating large urban districts (from 6 in 2002 to 27 in 2019), NAEP data form the basis of a number of aggregate mapping efforts that represent a form of public accountability. The National Center for Education Statistics has regularly published a mapping of state performance standards to the NAEP scale (e.g., Bandeira de Mello et al., 2009; Ji et al., 2021), revealing wide variation in the rigor of proficiency standards across states under NCLB. These mappings show the rise and convergence of proficiency standards through the ESSA era. NAEP scores also form the basis of linking efforts that attempt to map school and district test scores to a common national scale for aggregate research and public engagement (Reardon et al., 2021). These secondary research efforts extend the reach of test-based public accountability even as they lag years behind the time of testing.

NCLB and ESSA required states to participate in only two NAEP subjects, reading and mathematics. Additional NAEP subjects have included science, economics, arts, foreign language, civics, geography, and technology and engineering literacy, all typically reported at the national level only. NAGB interest and budgetary constraints have led to less frequent testing in these subjects in recent years. This is consistent with a theory of public accountability: Absent required participation, competition, and alignment with state goals, tests at other levels of the system will be less effective at inspiring progress.

Hutt and Polikoff (2020) distinguished between a range of variables for public accountability, not only test-based variables but also curriculum materials, budget, and salary data. They classified NAEP as relatively inactionable compared to other variables because of NAEP’s high level of aggregation and delayed reporting schedule. In the remaining subsections, we review other audiences for public accountability that might use report cards like NAEP but at different levels of aggregation and for different purposes.

Forms of Report Card Accountability

There is a long history of states implementing report card accountability, where they publish publicly available report cards of school performance indicators. These report cards are intended to provide information to parents and stakeholders to both inform parent choices and encourage external pressure for schools to improve and meet benchmarks. These “public accountability” systems began to be implemented in the mid-1990s (Hanushek & Raymond, 2005), such that by the onset of NCLB in 2002, about

20 states had report card–style accountability systems without attaching consequences. (Of note, early research on report card–style accountability systems found they did not have the same positive effects that consequential systems did; Hanushek & Raymond, 2005). Of course, states with consequential accountability systems might also put out report cards, and indeed, this became required under NCLB.

Under ESSA, all states have accountability report cards that summarize school and district performance and compare them to state benchmarks. State (and Washington, DC) report cards and dashboards vary tremendously in the ways in which they present accountability data. Of the 51 report cards produced, 26 have some form of summative rating. Of these, 12 give schools a letter grade, 8 a numerical score, 7 a categorical label (e.g., “*Commendable*”), and 5 a star rating (some states give schools multiple summative ratings). The Data Quality Campaign (2019) offers a high-level overview of progress on state accountability report cards each year. In their report, they highlighted strengths and weaknesses of report cards across the nation. Strengths include that the majority of state report cards are easily found through Internet searches, are in formats that are useful to parents (PDF and mobile friendly), and include downloadable data. Weaknesses include that most state report cards do not offer translation to any language other than English, include text at too high a reading level, lack disaggregated data for at least one federally required student group, and lack reporting on important measures like college enrollment and teacher demographics and effectiveness. In addition, the Education Commission of the States (2014) offered a more detailed summary of the similarities and differences in report cards as of that time.

Another form of reporting educational data is through public-facing “dashboards,” which display school and district performance along multiple dimensions. California adopted a school dashboard, which they have modeled on dashboards from other jurisdictions (Darling-Hammond et al., 2014). In California’s dashboard (Polikoff et al., 2018), schools are given ratings for “status” and “change” on each of several dimensions (including ELA and math achievement, chronic absenteeism, suspension rates, and English learner progress) on a five-point color-coding rating scheme. These public-facing dashboards are intended to drive parent decisions and involvement in states’ (nonconsequential) public accountability system, the Local Control and Accountability Plans, but evidence suggests that few access these data (Polikoff et al., 2018) or participate in these processes (Marsh & Koppich, 2018).

How Parents Use Accountability Data

One of the main targets of accountability data is parents. Providing accountability data to parents could affect performance in several ways. For an individual parent, receiving accountability data and using it to select more effective schools for their child could result in improvements in that child’s performance. Accountability data use by parents could also affect the broader system. Or if enough parents made school choices based on accountability data, they could drive systemic improvements in school

performance by leading to the growth of more effective schooling options or the closure of less effective ones (for more on this topic, see the literature on “exit” and “voice,” for instance, Hirschman, 1970; for a recent critique of the theory by which public accountability of this form can result in educational improvement, see Hutt & Polikoff, 2020). And, of course, individual parents might also use their child’s state test results to press for educational improvement for their individual child (e.g., needed instructional supports, acceleration opportunities).

School accountability report cards themselves have not been the subject of much empirical study, but there are a few exceptions. A study by the Institute of Education Science’s National Center for Education Evaluation and Regional Assistance (2019) tested the impact of five different features (e.g., the balance of numbers and graphs, the ordering of schools by distance or performance, and whether district averages were included) on school report cards on parents’ knowledge, satisfaction, and school choices in an experimental simulation study. They found evidence that these features matter (though to a fairly modest extent), with each feature mattering in different ways. For instance, they found that presenting accountability results as numbers only increased parents’ ability to accurately answer factual questions about school performance indicated on the report card, but presenting numbers and graphs increased parent satisfaction. They also found that including parent satisfaction in accountability report cards boosted parents’ satisfaction, but slightly diminished their knowledge. Finally, they found that adding more information to the presented results boosted parents’ satisfaction but may have led them to select fewer effective schools. The Education Commission of the States (2014) also analyzed parents’ preferences with regard to school report cards and accountability data, finding that ease of interpretation, thoroughness of data (including nontest measures), and ability to compare schools were especially important in parents’ evaluations of report card quality. Finally, Jacobsen and colleagues (2014) tested certain features of accountability report cards more formally, finding that the form by which results are reported (e.g., A–F, proficiency rate) substantially affects voters’ satisfaction with high- and low-performing schools (for instance, letter grades widened the perceived quality gap between high- and low-performing schools as compared to proficiency rates).

There is also more general literature on how parents evaluate schools. This literature is not necessarily about accountability reporting per se, but their results speak to the kinds of measures that might be valued by parents on accountability report cards. Haderlein (2022) divided these literatures into stated preferences and revealed preferences. Stated preferences research relies on parent self-reports about the factors they think are most important in evaluating schools. Revealed preferences research estimates parent preferences without explicitly asking them (i.e., by analyzing their behaviors).

Survey studies of parents suggest that they value academic quality measures the most when evaluating schools. The particular academic quality variables range by study, but include teacher quality (Schneider et al., 1998), curriculum quality (Van Dunk

et al., 1998), and academic outcomes such as test scores (Armor & Peiser, 1998). Some studies suggest that there are heterogeneous preferences for these factors (with low-income and less-educated parents expressing even stronger emphasis on academic measures; Schneider et al., 1998). There is also some evidence that school demographics may play a role in parents' decisions, especially for White parents (Holme, 2002; Roda & Wells, 2013).

Revealed preferences research generally relies on housing data, school choice preference data, or experimental data (Haderlein, 2022). Housing studies confirm that parents are willing to pay more for access to schools that have higher average academic achievement (Bayer et al., 2007; Black, 1999; Figlio & Lucas, 2004). Further, Figlio and Lucas (2004) found that accountability report card results affect housing values, with parents willing to spend more money to live on the boundary of an "A" school versus a "B" school. In the school choice context, studies using parent choice data reveal that parents value a variety of factors, including average student achievement, growth in student achievement, proximity to home, racial demographics (preferring schools with demographics closer to their own), and other nonacademic factors like extracurricular activities (Glazerman & Dotter, 2017; Harris & Larsen, 2017; Hastings et al., 2009). Recent evidence suggests that parents' perceptions of school effectiveness may actually be proxied by their perception of students' peer quality (Abdulkadiroglu et al., 2017). Finally, experimental survey studies show that parents value demographics when making school decisions, but that academic achievement levels and growth are the two most important factors (Billingham & Hunt, 2016; Haderlein, 2022). A recent and innovative study by Haderlein (2022) tested parents' choices in three ways, finding that the ways they evaluate school quality do not always line up with how they make choices among schools. In particular, parents value academic achievement growth the most when choosing among schools even though the factors contribute equally to their rating of school quality. Nontest measures also matter in parents' decisions, though more so in their rating of schools than in their selection of schools.

Taken together, the existing literature clearly demonstrates that school accountability data are important for affecting parents' evaluations of school quality. Parents clearly seem to value student performance data, including both achievement status and growth. They also seem to value nontest measures to the extent they are available, especially information on teacher quality and instructional programs. In addition, parents seem to respond to student demographics by choosing schools that are more racially similar to their own race/ethnicity. While there is a very small literature on the ways in which accountability data are presented and the impacts of that presentation on preferences and decisions, that literature does suggest that key features of data presentation matter for parents' judgments, perhaps especially at the tails of the performance distribution. Unfortunately, research also suggests that more advantaged parents are more likely to access and use accountability data, implying that more needs to be done if the data are to be useful to diverse audiences.

How Teachers Use Accountability Data

Accountability data could also be used by teachers to improve instructional quality and, through it, student performance. For example, receiving data on student performance could help teachers identify gaps in performance that need to be addressed (e.g., topics or skills where students are performing poorly or well). These data could also be used to group students (heterogeneously or homogeneously) or to target interventions. There is a growing body of literature on “data-driven decision-making”—the ways that educators use data for instructional improvement (see Marsh et al., 2006, for an early review or Marsh & Farrell, 2015, for a more recent summary). This section does not review this entire body of literature, but rather summarizes some of the key findings as they pertain to the role of state accountability performance data in teachers’ decision-making.

There is broad agreement that state-level achievement data often arrive too late to be instructionally useful (see Marsh et al., 2006). This has led to a proliferation of district-level assessment systems that are intended to provide more actionable evidence about student performance on a timeline that is more usable by educators; these are very widely adopted now, especially in urban districts (Burch, 2010). Indeed, the creators of summative state tests have recognized the importance of (and market for) aligned interim assessments. This has led to, for example, the Smarter Balanced Assessment Consortium creating and offering interim assessments that are more seamlessly integrated with summative state tests.

More generally, researchers have identified the key factors driving the use of educational data by educators. As just mentioned, one dimension is timeliness—if the data do not arrive sufficiently quickly, they cannot inform instructional decisions. Other key dimensions include the following (Marsh et al., 2006):

- accessibility of data, including technological capacity;
- quality of data, including both the reality and the perception of data quality (i.e., whether results accurately reflect performance);
- motivation to use data, including both internal and external forms of motivation;
- educator capacity to understand and use data, including the degree to which educators have been sufficiently supported on data use;
- educators’ other beliefs and values, including their beliefs about the abilities of their students (Bertrand & Marsh, 2015);
- organizational culture and leadership, including school norms, presence of collaborative opportunities, and leadership modeling effective data use;
- organizational barriers, including pressures from the curriculum and adequate time to interpret and use data; and
- local and state context, including the history of data use and accountability.

State summative accountability results may be less useful for educators than more locally developed performance data because of their timeliness and their perceived distance from instruction.

The use of performance and accountability data by teachers can also have unintended consequences (these are discussed below in the section on accountability effects).

Whether in the context of state summative assessment data or interim/benchmark data, the results of these assessments can sometimes be used to “game” accountability systems by targeting students who are close to accountability thresholds. These so-called bubble kids are the ones whose performance is most likely to drive accountability ratings, so it is a rational (if potentially pernicious) response for educators to attend to them. There is some evidence that these responses are widespread (Booher-Jennings, 2005; Marsh et al., 2006), though the actual impact on student performance of these kinds of approaches is unclear. We discuss other unintended instructional responses in the section “The Impact of Accountability Policies”.

How Researchers and Policy Makers Use Assessment Data From Accountability Systems

Assessment data from state accountability systems offer comparable performance metrics across school systems and over time. This comparability enables researchers to link relative improvements in test scores to resource allocations and policies. Phillips et al. (2018) laid out a typology of different uses of assessment data for research and policy. One type of use is to inform service provision, including to help coordinate services across government agencies (e.g., schools, social work). Another type of use is to generate descriptive evidence to support continuous improvement efforts (for example, see the University of Chicago Consortium on Schools research that has informed Chicago Public Schools’ policies and practices for several decades, e.g., Allensworth & Easton, 2005; Roderick et al., 2014). A third type of use is to identify schools or districts that are performing particularly well or poorly and use them to inform improvement efforts more broadly (e.g., Cannata et al., 2017). Fourth and finally, state longitudinal data systems have been used to conduct large amounts of quantitative research evaluating specific policies and programs, ranging from teacher evaluation to accountability and curriculum reforms.

Several states have been national leaders in the creation and dissemination of educational data for research, and as a result these states are overrepresented in the literature using statewide longitudinal data systems to evaluate policy. Phillips et al. (2018) summarized these states, which include Florida, North Carolina, Texas, and Washington. State creation and maintenance of longitudinal data systems grew sharply under the Obama administration, which used Race to the Top and substantial federal dollars to incentivize states to beef up their data systems (Howell, 2015).

Another potential use of accountability data by policy makers is for continuous improvement; this is a focus of policies like California’s Local Control and Accountability Plans. Hough et al. (2018) identified three key issues in the use of educational data for improvement processes. First, data use for improvement is different from data use for accountability purposes. In particular, educational data must be a part of a change-oriented pathway, which involves school and district leaders evaluating changes, running predictive analytics, and establishing priorities (Yeager et al., 2013). Second, data use for improvement must be embedded in an aligned improvement process. This includes

attention to establishing cycles of inquiry; building norms, culture, and mindset; and fostering organizational capacity (Marsh et al., 2006). Third, the specific data needed for continuous improvement vary by user and phase of the improvement process. State accountability data are not nearly enough to drive improvement in this context—more and different kinds of data are needed, and they must be provided in usable forms (The Victorian Quality Council, 2008).

In general, for data to be more useful for research and policy, Phillips et al. (2018) suggested that several factors are important. First, data are more useful to the extent that they are well linked over time and across agencies (e.g., across agencies at a given age level and longitudinally from early childhood through higher education and beyond). Second, data are more useful to the extent that they are clean and straightforward to use. Third, data are more useful to the extent that political barriers do not get in the way of their use. For instance, laws that prohibit the connection of student data with individual teacher identifiers (as in California) will limit the ability to conduct analyses related to teacher policies. Fourth, data are more useful if there are not too many administrative and bureaucratic requirements that limit the ability of researchers to publish their results (e.g., onerous data use agreements).

STUDENT AND TEACHER ACCOUNTABILITY IN K–12 EDUCATION

At lower levels of the system in Figure 16.1 are student and teacher accountability systems. These systems contrast with school accountability policies and public accountability strategies by using student test scores to inform decisions with direct impact on individual students and teachers. The intended direct mechanisms include matching students and teachers with curricular or professional experiences appropriate for their current skills (e.g., sorting students or teachers, assigning them to programs, awarding them credentials). Their intended indirect mechanisms include directing student and teacher effort toward desired goals, as well as indicating who holds responsibility, management, and control over key outcomes (Airasian, 1987).

The Main Types of Student Accountability Policies

Broadly, there are two main types of high-stakes student accountability assessments in use across the United States in the early 21st century: high school exit exams (HSEEs), which are sometimes delivered as comprehensive exams covering multiple subjects and sometimes delivered as end-of course (EOC) exams, and grade promotion exams.

High School Exit Exams

HSEEs are a policy by which students must pass one or more standardized tests to receive a high school diploma. Exit exams have evolved over time from the minimum competency testing (MCT) movement of the 1970s (Chudowsky et al., 2002). Like those tests, cut scores were set at a low level of difficulty and were more often used

to identify and remediate low-performing students (Dee, 2003; Jacob, 2001). As the standards movement grew in the 1990s and into the 2000s, more states began implementing HSEEs, and those with MCTs began increasing the rigor of these assessments. By the resurgence of the movement around 2010, the majority of states had implemented high-stakes HSEEs (Center on Education Policy, 2012). These exams were especially common in states serving larger proportions of non-White students—in 2011–2012, for instance, 85% of Hispanic students attended school in states requiring HSEEs, as compared to 69% of students overall. Since that time, the number of states requiring an exam to graduate has declined—at last count for 2018–2019, just 13 states still had a traditional exit exam in place (Gewertz, 2020).

Even as cut scores have risen above historical levels, they remain at relatively low levels of difficulty, often representing middle school or early high school content (Achieve, 2004). Furthermore, the vast majority of exit exam policies have come with numerous escape valves or alternative methods to pass the assessments. All states that had exit exams offered students the opportunity to retake the exams if they failed, with states allowing anywhere from 2 to 12 retakes (Center on Education Policy, 2009, 2012). More than 80% of states also offered alternative pathways to meet the standards—for instance, many states allowed test scores from other tests such as SAT or ACT to count, permitted students to use portfolios or projects to substitute for test scores, or offered waivers or appeals for students who met other requirements. Finally, nearly all states specifically offered alternative pathways for students with disabilities (Center on Education Policy, 2009, 2012). Given these alternative pathways, the actual impact of the test itself on students' graduation may have been moderated somewhat (Harris et al., 2020).

Beginning late in the NCLB era and continuing to the present, states began to move toward EOC exams to replace more traditional exit exams, recognizing that student pathways are increasingly differentiated in high school. EOC exams differ from traditional exit exams (which are sometimes referred to as “comprehensive” exit exams) in two key ways (Center on Education Policy, 2008; see also Domaleski, 2011, for a comprehensive discussion of EOC exams). First, EOC exams are intended to assess student mastery over specific course content, as opposed to providing a more general assessment of student knowledge across subjects. Second, EOC exams are given to students when they complete particular courses, rather than at a fixed point (i.e., most exit exams are given starting in 10th grade).

An analysis by Tyner and Larsen (2019) documented the rise of EOC exams across the United States. In 1996, just 2 states had EOC exams. Over the next 12 years, the count rose an average of 1 state per year to 14 states by 2008. The next 9 years saw more rapid spread, with 30 states having adopted one or more EOC exam by 2017. Since then, the count has ticked down to 26 states (not counting any COVID-related pauses). Importantly, EOC exams are widely used for both student and school accountability, and their school accountability uses (i.e., as part of high school accountability metrics) outnumber their student accountability uses.

Early advocates for EOC exams tended to emphasize that they were more appropriate than HSEEs as tools for accountability because they were better aligned with the high school curriculum (Center on Education Policy, 2008). Furthermore, they offered the opportunity to provide feedback to teachers and students about student performance to drive targeted supports and remediation activities to students. Indeed, in some states EOC exam scores are factored into students' course grades instead of or in addition to students being required to pass the exam to receive credit (Domaleski, 2011). Still, these exams are broadly based on the same theory of action that more traditional comprehensive exit exams are based on.

Early evaluations of HSEEs describe the motivations behind the policies (Chudowsky et al., 2002). One overriding motivation is to provide some assurance that the high school diploma “means something”—that it signifies that the diploma recipient has indeed demonstrated sufficient attainment of some body of knowledge and skills needed to succeed beyond high school. By establishing clear expectations and ensuring that students must meet those expectations to receive the diploma, the HSEE should ensure at least a minimum standard has been obtained. If the standard is sufficiently rigorous, another motivation for HSEEs is that they could boost the rigor or quality of the education students are provided (i.e., setting a baseline beneath which high school teaching and learning will not fall). Third, HSEEs are seen as motivating individual students to work harder, and indeed there is evidence that high school students in the United States have not felt sufficiently challenged (Boser & Rosenthal, 2012). Fourth, HSEEs that are well aligned to state standards can provide additional weight behind standards-based reform policy, driving high schools to better align instruction to standards. Fifth, these exams could have formative uses if their results are used to identify students falling below the target and provide them support or remediation to succeed. And last, HSEEs are seen as possibly strengthening college applicant pools or providing a new source of assessment data that is better aligned with the high school curriculum than are the SAT and ACT. Advocates also note that many competitor countries in Europe and Asia have high-stakes student-level exit exams.

Grade Promotion Exams

A second main type of assessment for student accountability is the grade promotion exam. Grade promotion exams are used by states and districts to hold individual students accountable for meeting performance thresholds to be promoted to the next grade. The most common type of grade promotion exam is the third-grade reading exam, which was used by 17 states and the District of Columbia as of the 2018–2019 school year (National Conference of State Legislatures, 2019). Third-grade reading is seen as especially consequential for students' future success, with evidence that the large majority of students who eventually drop out were struggling readers by the time they were in third grade (D. J. Hernandez, 2012). Eight other states allowed the use of state tests for third-grade retention purposes but did not require it. And there are a number of large urban districts that now use or have in the past used third-grade reading

assessments for this purpose (e.g., Chicago, New York). Importantly, there are very few states or localities that do not offer numerous exemptions to the test-based promotion rules. These so-called good-cause exemptions include students with limited English proficiency (typically 3 or fewer years in an English language acquisition program); special education students; participating in an intervention; parent, principal or teacher recommendations; previous retention; demonstrating proficiency through a portfolio (student work demonstrating mastery of academic standards in reading); or passing an approved alternative reading assessment. While well intentioned and aligned with best practices in test use, recent research found that these exemptions are inequitably applied, with children of more educated mothers substantially more likely to obtain exemptions (LiCalsi et al., 2019).

There are also some test-based promotion policies at other grade levels, though it is harder to get an accurate count on the prevalence of these kinds of policies. For instance, Chicago's test-based promotion policy that began in the 1990s included promotion tests in third, sixth, and eighth grades (Jacob & Lefgren, 2009; Roderick & Nagaoka, 2005), and New York City's included Grades 3 through 8 (Mariano & Martorell, 2013).

The theory of action behind grade promotion exams is typically twofold. First, grade promotion exams are generally tied to specific remediation and intervention programs, such as summer school, assignment to a high-quality teacher, or extended reading instruction (Ozek, 2015; Winters & Greene, 2012). Through this path, the exam identifies students who need additional support, and the policy responds by providing that support. If the support is effective, student abilities and skills will increase, producing long-lasting effects. Second, like exit exams, promotion exams are thought to have motivational effects on students. Indeed, a common complaint from teachers about most state tests under standards-based accountability is that students do not have much incentive to try hard because there are few consequences for individual students; promotion exams address this concern and may also cause students to work harder in their learning. We discuss the literature on the impact of these student accountability systems in the section "The Impact of Accountability Policies".

TEACHER ACCOUNTABILITY POLICY SYSTEMS

A relatively recent target of test-based accountability is individual teachers. The Obama administration's Race to the Top and ESEA flexibility waiver initiatives dramatically changed the way that teachers around the nation were evaluated. These changes were in response to two streams of research. First, a variety of studies provided compelling evidence that teachers have large effects on students' achievement (e.g., Rivkin et al., 2005; Rockoff, 2004). Subsequent research has deepened this literature and also extended it to teacher impacts on nontest measures (e.g., Blazar & Kraft, 2017; Chetty et al., 2014a; Jackson, 2018). Second, academic research (Almy, 2011; Donaldson, 2009; Sartain et al., 2011; Sinnema & Robinson, 2007; Stronge & Tucker, 2003; Toch & Rothman, 2008; Tucker, 1997) and one high-profile report (Weisberg et al., 2009) suggested that

teacher evaluation systems largely failed to differentiate teachers or to provide useful feedback to improve their teaching.

As a result of Race to the Top and the waivers, states substantially redesigned their teacher evaluation systems. The main features of these revised teacher evaluation plans included (a) the use of multiple measures of performance to evaluate teachers, (b) the inclusion of student outcomes (measured most often by state test scores or student learning objectives) in evaluation, (c) the use of three or more levels of ratings (i.e., not just “*Pass/Fail*”), and (d) the attachment of consequences to results of evaluations (Steinberg & Donaldson, 2016).

In terms of the component measures of new teacher evaluation systems, by far the most common measure—appearing in every state and district plan analyzed in a 2016 survey of 50 states and 25 large districts—was classroom observations (Steinberg & Donaldson, 2016). Observation-based ratings of effectiveness also comprised the largest portion of teachers’ overall evaluation scores, on average representing a bit more than half of the total rating. About one fifth of states and half of large districts also included a separate, but very lightly weighted (about 2%–5%, on average) measure of teachers’ professional conduct. Measures of student learning were also an essential part of teacher evaluation systems postwaiver/Race to the Top (RTTT). Test-based measures—value-added models or student growth percentiles, which we discuss later—were part of 80% of states’ and large districts’ evaluation systems. In other states and districts, or in nontested grades, the most common measure of student performance was student learning objectives. Finally, some districts and states included other measures in teacher evaluation systems. For instance, 26%–30% of states and districts included schoolwide achievement data in individual teachers’ evaluations, and about one in six states and districts included results from student surveys.

There were a number of important technical challenges in the design and implementation of these systems. One of the major challenges was in including measures of student learning that could be applied to all teachers. The large majority of teachers do not teach in subjects and grades for which student growth models can be calculated from state tests (i.e., all teachers below Grade 4 and above Grade 8, teachers of any subject other than mathematics or ELA). For these teachers, alternative measures of student learning could sometimes be computed. But these could sometimes result in seemingly nonsensical and indefensible measures being used, such as the art teacher who is evaluated in part by the growth in students’ mathematics achievement (Jacobs, 2015). Another common approach for these teachers was individualized “student learning objectives,” which were widely used but lacked standardization and adherence to psychometric standards (Buckley, 2015). They also ultimately do not seem to have resulted in meaningful instructional improvement (e.g., Lachlan-Haché, 2015).

Research has begun to shed light on the implementation and effects of these teacher evaluation policies. First, just as before these systems were implemented, very few teachers seem to be rated as needing improvement—a study of 24 state evaluation systems found fewer than 5% of teachers rated as needing improvement (Kraft & Gilmour,

2017). Second, the low percentage of teachers rated as needing improvement does not comport with district leaders' subjective ratings of teacher performance (i.e., when asked directly, leaders rate far more than 5% of teachers as *Below Proficient*; Kraft & Gilmour, 2017). Third, teachers' overall ratings in evaluation systems are highly sensitive to these systems' design decisions (Steinberg & Kraft, 2017). For instance, the greater the weight on student achievement and other norm-based measures of performance, the larger the proportion of teachers deemed *Not Proficient*. Finally, where there is a large literature on achievement-based measures of teacher performance, researchers have argued that relatively less is known about the properties of nontest measures of performance, such as teacher observations (J. Cohen & Goldhaber, 2016).

What we do know about nontest measures suggests that they may have many of the same challenges as test-based measures. For instance, there is evidence that the attachment of stakes to evaluation scores can change the distribution of those scores (Liu et al., 2019) and that there are racial gaps in teacher effectiveness ratings that are driven by school-level demographic differences (Steinberg & Sartain, 2021). Teacher observation scores can have substantial measurement error unless they are averaged over multiple lessons and raters (Ho & Kane, 2013). However, findings from randomized studies also suggest that observation scores can be unbiased estimates of instructional quality (Bacher-Hicks et al., 2017). Summarizing the impact of the Obama-era push for teacher evaluation reform, a recent national study found precisely zero effect on student achievement nationwide (Bleiberg et al., 2024).

THE IMPACT OF ACCOUNTABILITY POLICIES

What have been the effects of accountability on key teacher and student outcomes? This section reviews the available literature on these impacts, focusing on the effects on (a) student achievement as measured by standardized tests; (b) longer term outcomes, including graduation, college, and outcomes beyond college; (c) teacher outcomes, including their instruction; and (d) unintended consequences. This section draws on several recent reviews of accountability and its effects (Figlio & Loeb, 2011; National Research Council, 2011; Polikoff & Korn, 2020). First, we discuss the evidence focused on school accountability systems and then teacher and student accountability.

Effects of School Accountability on Student Achievement

There are several main methods that have been used to estimate the impact of school accountability policies on student achievement on state tests. The most prominent studies have used state-level data to compare changes in achievement levels and trends between states that implement new accountability systems and those that already had existing systems in place (using difference-in-differences or comparative interrupted time series methodologies). Investigating the impact of NCLB on student achievement, two studies (i.e., Dee & Jacob, 2011; Wong et al., 2015) used analyses of this type on data from NAEP. Both studies found evidence of positive to null effects, depending

on grade and subject. Dee and Jacob found achievement impacts of around a quarter of a standard deviation in elementary mathematics. Wong and colleagues found similar impacts in elementary mathematics, as well as statistically significant impacts in middle school mathematics and marginally significant impacts in elementary reading. Interestingly, these positive effects come despite the fact that NCLB's consequences were largely ineffective—supplemental education services saw low participation and ineffective program design (Heinrich et al., 2010), and vanishingly small numbers of students participated in public school choice, often because there were no options available (Lauen, 2008). Earlier studies similarly leverage variation among states in either the timing or the strength of accountability in attempts to isolate a causal effect; these studies generally find positive achievement effects of similar magnitude (e.g., Carnoy & Loeb, 2002; Hanushek & Raymond, 2005).

Another common approach to estimate the impact of accountability is to leverage within-state variation in state or district policies. Figlio and Loeb (2011) grouped these studies into three categories: (a) studies that look within states or districts over time (e.g., Jacob, 2005; Klein et al., 2000); (b) studies that compare districts that implement accountability policies to those that do not (e.g., Ladd, 1999; S. S. Smith & Mickelson, 2000); and (c) studies that examine the differential responses of schools subject to and not subject to accountability pressure using regression discontinuity design (e.g., Rockoff & Turner, 2010). They concluded that there is evidence of a positive relationship between school accountability and student achievement, but that this relationship is not universal and varies in magnitude.

The designs of most state accountability systems are well suited to the use of regression discontinuity designs, with schools just above and below the threshold functionally similar except for their accountability classification. Studies in North Carolina (Ahn & Vigdor, 2014), Wisconsin (Chakrabarti, 2014), and Kentucky (Bonilla & Dee, 2020) found positive effects of accountability on student achievement. In contrast, Dee and Dizon-Ross (2017) found null effects in Louisiana, Hemelt and Jacob (2020) found essentially null effects in Michigan, and Atchison (2020) found null to negative effects in New York State. A study of New York City school grades by Winters and Cowen (2012) also used regression discontinuity (RD) designs at the C/D and D/F thresholds. That study found heterogeneous effects, with positive impacts at the D/F margin but negative impacts at the C/D margin.

Studies have also investigated the heterogeneous effects of accountability policies on different types of students, often with a focus on the impact of accountability on student achievement gaps. This is an important area of research, because NCLB and other accountability policies generally aim to close racial and socioeconomic achievement gaps. One study of achievement gaps in North Carolina found that NCLB accountability narrowed the Black–White test score gap by around 4%–10% of the baseline gap in both mathematics and reading (Gaddis & Lauen, 2014). Other studies also provided evidence of achievement gap effects by showing that accountability affected subgroup achievement differently, again generally leading to a modest narrowing of gaps (e.g., Dee

& Jacob, 2011; Figlio et al., 2009; Lauen & Gaddis, 2012). Pre-NCLB accountability studies found mixed effects, with Hanushek and Raymond (2005) finding a narrowing of the White–Hispanic gap and Harris and Herrington (2004) finding no impact of accountability on performance gaps.

None of the above-cited studies is generalizable unconditionally, but the results taken together demonstrate that school accountability policies often have a positive impact on average student achievement. These effects may be concentrated in mathematics and in the early grades. And the effects on achievement gaps are modest, at best. The impacts of accountability appear not to be uniform, however, because there is evidence that these effects are stronger for the lowest-performing schools (Figlio & Rouse, 2006; Jacob, 2005), in states with higher proficiency standards (Wong et al., 2015), and in states with greater degrees of local autonomy (Loeb & Strunk, 2007).

Our conclusion about the impact of accountability aligns with that of Figlio and Loeb (2011), who said, “Taken as a whole, the body of research on implemented programs suggests that school accountability improves average student performance in affected schools, at least in general” (p. 410). And our conclusion is more positive than that of the National Research Council (2011), which noted,

Test-based incentive programs . . . have not increased student achievement enough to bring the United States close to the levels of the highest achieving countries. When evaluated using relevant low-stakes tests . . . the overall effects on achievement tend to be small and are effectively zero for a number of programs. Even when evaluated using the tests attached to the incentives, a number of programs show only small effects. (p. 4)

The differences between our conclusion and that of the National Research Council may have to do with at least two factors. First, the literature on this topic has grown dramatically in recent years, with many of the positive effects coming in more recent studies using more advanced methods. And second, the difference hinges on the definition of “small” as pertains to the magnitude of accountability effects. We agree with Kraft (2020) that effects of even just .2 standard deviations in performance are not small, even though they pale in comparison to the magnitude of performance gaps and are clearly insufficient to narrow gaps with higher performing nations. This is especially the case insofar as the effects were cumulative across grades and years—the resulting long-term impacts could indeed be quite large.

Despite the positive evidence overall, there appears to be very modest evidence of any significant gap-closing effects of accountability systems. This is notable insofar as student group accountability is intended to drive educators to work to narrow these gaps—that portion of the theory of change clearly appears to be failing. Furthermore, concerns about accountability policies are often driven by equity issues—that standards-based accountability undermines possibilities for culturally relevant pedagogy (Royal & Gibson, 2017), leads to proceduralized instruction in classrooms serving historically marginalized youth (Polikoff & Struthers, 2013), and overall undermines

educational opportunity (Rebell, 2008). At the very least, it is by now clear that performance gaps will need to be closed with other policy levers rather than through test-based accountability.

Effects of School Accountability on Longer Term Student Outcomes

Much less is known about the long-term effects of accountability or the effects on outcomes besides student academic achievement. In large part, this is due to data limitations that may be addressed as new state longitudinal data systems mature. There are two exceptions to this pattern. A study using longitudinal graduation rate data from before and after the NCLB era found that the introduction of accountability systems coincided with a significant bump in high school graduation rates equal to about one fifth of the descriptive increase over that time (Princiotta, 2019). A second study, by Deming et al. (2016), explored the effect of Texas high school accountability policies during the 1990s on college attainment and future earnings. They found that schools on the threshold of a *Low Performing* label increased student achievement on high-stakes exams, which led to higher rates of college enrollment and completion and higher salaries at age 25. In contrast, they found a negative effect of accountability in higher performing schools, which they attributed to the reclassification of low-performing students into categories exempt from taking state tests (e.g., special education). There is a great need for further research on the impact of accountability on longer term outcomes.

Effects of School Accountability on Instruction and Teacher Outcomes

The theory by which accountability policies boost student achievement operates through these policies' effects on teacher behaviors. The effect of accountability on teacher practice and other teacher outcomes is even more difficult to estimate. This is primarily because there is a lack of high-quality measures of teachers' instruction at the kind of scale needed to conduct causal analyses. However, there are many correlational and descriptive studies that explore teachers' instructional responses to school accountability, especially focusing on teachers' instructional alignment to standards. The results of this work generally suggest modest instructional change in the direction of the standards, as called for by the theory underlying standards-based accountability.

A large number of self-report studies using surveys or interviews indicated that teachers believe they practice aligned instruction and are making efforts to increase the alignment of their instruction with standards and assessments (see, for instance, Hamilton, 2012; Pedulla et al., 2003). However, when teachers' practice is assessed by external means, such as through observation, it often appears less aligned to the intent of standards than teachers think (see, for instance, D. K. Cohen, 1990; H. C. Hill, 2001; McDonnell, 2004; Spillane, 2004). Still, there is evidence that the quality of instruction

and school goals for student performance have improved over the early years of the accountability era (Hunter, 2019; Lee & Lee, 2020).

A different approach to studying alignment involves surveying teachers about the content of their instruction and then using alignment methods (discussed in more detail in the section “Methods of Measuring Alignment”) to compare these survey responses to content analyses of standards and assessments (see Polikoff, 2012a; Porter, 2002). These approaches make it less likely that social desirability and other self-report issues could bias the results. Several studies that use these techniques find that: (a) the alignment of instruction to standards is low, much lower than reported on other kinds of surveys; (b) instructional alignment generally increases over time, especially in mathematics; and (c) some state policy features and characteristics of teachers predict stronger instructional alignment (Polikoff, 2012a, 2012b, 2013). Still, the findings taken together indicate significant gaps in the extent to which teachers are implementing standards in the classroom, even decades into the standards era and with considerable accountability pressure.

There is also some evidence that accountability affects various dimensions of teachers’ working conditions, though these effects seem modest and mixed in direction. Two studies of NCLB, for instance, found contrasting effects. Grissom et al. (2014) found that the law had no impact on teachers’ hours worked, job satisfaction, or commitment to teaching; had small negative effects on teachers’ perceptions of cooperation; and had small positive effects on teachers’ perceptions of classroom control and administrator support. Dee et al. (2013) found that the law increased teachers’ salaries and teacher-reported student engagement. Two other studies have found that accountability decreased teachers’ job security (Reback et al., 2014), increased the frequency of involuntary school transfers, and decreased the frequency of involuntary attrition (Sun et al., 2017). And a more recent study on just the impact of grade-level accountability testing requirements found no impact on teacher attrition (Fuchsman et al., 2020). In sum, the effect of accountability on teacher working conditions appears mixed and modest.

Unintended Consequences of School Accountability

As indicated in Figure 16.1, there are also a number of well-documented unintended consequences of accountability policies, which arise when teachers and schools strategically seek to maximize their scores and avoid accountability consequences. One type of gaming behavior is through the reallocation of instructional time. For example, schools have been shown to allocate instructional time away from nontested subjects and toward tested ones (Dee et al., 2013; Judson, 2013). Another variant on this is the allocation of instructional time to specific test-taking strategies (for instance, using class time to take practice tests, teach strategies for completing specific types of test items, or narrowly focus on content that is expected to be assessed; Jennings & Bearak, 2014; Jennings & Sohn, 2014). There is ample evidence that these behaviors have taken place under recent accountability regimes. Thus, positive effects that are measured on state

tests should generally be cross-validated with lower stakes exams like NAEP (Koretz, 2008).

Another type of strategic manipulation is when educators narrowly target resources and instructional efforts on the students who matter the most for accountability ratings. Under NCLB, for example, school performance was determined by the percentage of students scoring above a proficiency cut point on the state test. This creates incentives to target efforts on students just below the proficiency cut point (often referred to as bubble kids), since improving those students' scores would be more likely to boost a school's performance rating. There is some evidence that teachers diverted attention to bubble kids (Booher-Jennings, 2005; Jennings & Sohn, 2014), including evidence that positive effects of accountability were concentrated on students close to the proficiency cut score (Neal & Schanzenbach, 2010). However, other studies have not replicated the bubble kids finding using achievement data (e.g., Cronin et al., 2005).

The most damaging and pernicious unintended consequence of accountability policies is perhaps their effect on teacher cheating, which can be enabled or even encouraged by school and district leaders. High-profile cheating scandals have emerged in some places, and these scandals have often been blamed on the intense pressure associated with accountability policies. For example, an Atlanta cheating scandal ended in 11 teachers being convicted on racketeering charges (Blinder, 2015). A study in Chicago used unusual test score patterns and identified that approximately 5% of teachers had likely cheated on the state exams (Jacob & Levitt, 2003). Cheating-type behaviors have also been reported in nontest outcomes, such as graduation rates (Edwards & Mindrila, 2019).

Effects of Student Accountability

Exit Exams

The literature on the impact of HSEEs on student achievement, high school graduation, and other desired outcomes consistently indicates that these exams do not lead to the outcomes desired by their proponents (Holme et al., 2010). At the same time, the worst fears of HSEE opponents—that they would lead to large-scale reductions in opportunity, especially for disadvantaged groups—appear not to have materialized given that graduation rates have trended upward for decades and, prepandemic, stood at all-time highs overall and for all racial-ethnic groups (Harris et al., 2020).

A number of studies using quasi-experimental designs have examined the impact of HSEEs on student achievement (Grodsky et al., 2009; Jacob, 2001; Reardon et al., 2010), graduation/dropout rates (O. Baker & Lang, 2013; Dee & Jacob, 2006; Hemelt & Marcotte, 2013; Ou, 2009; Papay et al., 2010; Polson, 2018; Reardon et al., 2010), and labor market outcomes (Baker & Lang, 2013; Warren et al., 2008). In general, these studies have been focused on comprehensive exit exams rather than EOC exams. Some studies estimate the causal impact of just passing the exam compared to the counterfactual of just failing. Other studies estimate the causal impact of a policy year that includes an exit exam compared to the counterfactual of a policy year that does not.

Broadly speaking, this literature produces several clear conclusions (for a comprehensive review of evidence on exit exams, see Holme et al., 2010). First, exit exams seem to have no effect on student achievement as measured by standardized tests (Grotsky et al., 2009; Jacob, 2001; Reardon et al., 2010). Second, exit exams do modestly decrease graduation rates and increase dropout rates, and these effects are concentrated among Black students and very-low-performing students and in states that have more rigorous exams (Baker & Lang, 2013; Hemelt & Marcotte, 2013; Jacob, 2001). And third, these exams have no appreciable effect on labor market outcomes (Baker & Lang, 2013; Warren et al., 2008). In response to these disappointing findings, there was mounting pushback against these exams starting in the mid-2000s. This pushback followed many researchers who opposed these exams from their onset; for a discussion see, for example, Warren & Grotsky (2009).

Promotion Exams

There is a large literature on the impact of test-based promotion policies on a range of short- and long-term outcomes for students, including student achievement in the tested grade (Winters, 2018); subsequent achievement and promotion (Greene & Winters, 2007; Mariano & Martorell, 2013; Mariano et al., 2018; Schwerdt et al., 2017); attendance, graduation, and other attainment measures (Eren et al., 2017; Jacob & Lefgren, 2009; Mariano et al., 2018; Schwerdt et al., 2017); and other outcomes like behavior, incarceration, and college enrollment (Eren et al., 2018; Ozek, 2015; Schwerdt et al., 2017). In general, this literature uses regression discontinuity methods to provide convincing causal estimates of the impact of these policies. However, there are methodological challenges in this work, especially in terms of choosing an appropriate comparison group, tracking impacts longitudinally, and separating out the effects of the retention policy from other portions of the intervention, like summer school prior to the retention decision (see Roderick & Nagaoka, 2005, for a discussion of these and other challenges).

In terms of short-term effects, studies found mixed evidence that the threat of retention induced by the policy boosts student achievement, with some evidence that it does, especially for the lowest-performing students (Winters, 2018). Subsequent to the retention decision, research suggests there are positive and substantial effects of retention on achievement, but that these effects depend on who retained students are compared against (same-grade vs. same-age peers; see Mariano & Martorell, 2013, for a good discussion of this issue; Greene & Winters, 2007; Schwerdt et al., 2017; Winters & Greene, 2012). There are some studies showing smaller positive or null effects (Jacob & Lefgren, 2004; Roderick & Nagaoka, 2005) and there is also evidence that test score effects may diminish over time (Schwerdt et al., 2017; Winters & Greene, 2012). Test-based retention policies seem to have null or perhaps modest negative effects on long-term outcomes like high school completion (Eren et al., 2017; Jacob & Lefgren, 2009; Mariano et al., 2018; Schwerdt et al., 2017), with evidence that retention policies that occur later in students' schooling may be especially harmful for the completion of the lowest-performing students (Jacob & Lefgren, 2009; Mariano et al., 2018). Research

on other outcomes found that test-based promotion policies can lead to increases in adult crime and student misbehavior (Eren et al., 2017, 2018; Ozek, 2015).

In short, the literature suggests that whatever benefits there may be from test-based retention and support in the early years, the long-term impacts of these policies appear to be close to zero and may in some cases be negative. These modest findings are notable given the large cost of student retention and its disproportionate effects on historically marginalized student groups (West, 2012). Importantly, the effects of test-based retention policies undoubtedly vary as a function of the rigor of the assessment and cut score, the nature of the interventions and supports that are paired with test failure, and the extent to which there are nontest alternatives available for students.

Special Considerations for High-Stakes Student-Level Accountability

In their review of high-stakes testing for student placement and promotion, Heubert and Hauser's National Research Council report (1999) identified three criteria for fair test use for students: psychometric adequacy, opportunity to learn, and educational benefit. The *Standards* (AERA et al., 2014) also have specific criteria listed for these tests in an illustrative example:

When tests are used for promotion and graduation, the fairness of individual score interpretations can be enhanced by a) providing students with multiple opportunities to demonstrate their capabilities through repeated testing with alternative forms or other construct-equivalent means; b) providing students with adequate notice of the skills and content to be tested, along with appropriate test preparation materials; c) providing students with curriculum and instruction that afford them the opportunity to learn the content and skills to be tested; d) providing students with equal access to disclosed test content and responses as well as any specific guidance for test taking (e.g., test-taking strategies); e) providing students with appropriate testing accommodations to address particular access needs; and f) in appropriate cases, taking into account multiple criteria rather than just a single test score. (p. 186)

Unlike Heuber and Hauser (1999), the *Standards* (AERA et al., 2014) do not count educational benefit to the marginal or average student as a criterion. As evidence continues to mount that these student-level accountability exams have no long-term positive effect for average or marginal students and are sometimes detrimental to historically marginalized groups (Penfield, 2010), the burden of proof should be considerable for current and new programs to argue that existing or proposed remediation strategies for failing students have a positive causal effect over social promotion. As we reviewed in an earlier section, tests serve political purposes as well as educational purposes, including signaling worthy goals and managing and controlling systems. It would be best if these purposes could be served with minimal detriment to students, including by following the guidance from the *Standards* and opening up multiple pathways to demonstrating readiness.

DERIVED ACCOUNTABILITY SCORES WITH A FOCUS ON GROWTH MODELS

As Table 16.1 indicates, the type of score creates opportunities to both achieve intended aims and inspire unintended negative consequences in accountability systems. The primary NCLB reporting metric was the percentage of proficient students, an aggregate status measure that was an obviously poor proxy for school quality because of its conflation with prior learning and other out-of-school opportunities to learn (Linn et al., 2002; Ryan, 2004). Proficiency percentages also exhibit deeply problematic properties when they become the basis of score trends and gap trends, where any group with proficiency percentages near 50% is expected to manifest greater trend magnitudes because of the density of the distribution local to the proficiency cut score (Ho, 2008; Holland, 2002). As we reviewed in previous sections, the statistic also enables gaming behavior related to triaging low-scoring students who may require greater effort to teach to proficiency. And it results in a considerable loss of information about differences and changes in student performance at other locations of the score scale. In these ways, the selection and properties of the derived score for any accountability purpose deserve scrutiny. In this section, we illustrate this by discussing the use of growth metrics for accountability purposes.

A debate about “status versus growth” motivated flexibility in the form of the GMPP (2005). In the GMPP announcement, Secretary of Education Margaret Spellings never defined what “growth” meant (U.S. Department of Education, 2005). The announcement insisted only that models adhere to seven “bright line principles,” such as “Ensure that all students are proficient by 2014,” and that the model “must track student progress.” Subsequent guidelines from the peer review panel similarly left latitude for growth definition and model specification (U.S. Department of Education, 2006).

The guidelines at the announcement of the Race to the Top competition seemed to be more explicit and defined growth as “the change in achievement data for an individual

Table 16.1 An Example of a Categorical Model From Delaware’s 2009–2010 School Year

	Year 2 Level				
Year 1 Level	Level 1A	Level 1B	Level 2A	Level 2B	Proficient
Level 1A	0	150	225	250	300
Level 1B	0	0	175	225	300
Level 2A	0	0	0	200	300
Level 2B	0	0	0	0	300
Proficient	0	0	0	0	300

student between two or more points in time” (U.S. Department of Education, 2009, p. 59742). However, it then continued, “A State may also include other measures that are rigorous and comparable across classrooms,” along with its motivations “to allow States the flexibility to develop data and assessment systems” (p. 59742). This left space for GMPP models to continue and effectively took no position on the definition of growth, a degree of flexibility that continues under ESSA.

As the final report of the GMPP described (Hoffer et al., 2011), states took a variety of approaches to operationalizing growth. Models continue to proliferate through the ESSA era, including renewed focus on “through-course” or “through-year” models that track growth from a fall test through a spring test. In this section, we review prototypical models and demonstrate that these models operationalize growth using related but fundamentally distinguishable approaches, and differently at the student level than at the aggregate level.

The proliferation of growth models in a policy space constructed deliberately to allow for flexibility has led to confusion among terms and definitions. We follow the general framework and nomenclature provided by Castellano and Ho’s *A Practitioner’s Guide to Growth Models* (2013a). In their guide, Castellano and Ho attempted to be explicit about each growth model and included its aliases and statistical foundations. In addition, they articulated the primary interpretations that models support in terms of three answerable questions: how much growth, growth to where, and what caused growth?

The gain-based model is an intuitive and largely straightforward model that requires a vertical scale, a challenging constraint with stringent requirements reviewed in Moses (this volume). The categorical model is a flexible framework that considers student status in a small number of categories (usually four to nine) and operationalizes growth in terms of transitions between categories (R. Hill et al., 2006). And conditional status models, including the student growth percentile model (SGP; Betebenner, 2009), express growth in terms of status beyond expectations given past scores. Value-added models are related to conditional status models and associate aggregate conditional status with the value that teachers and schools add to test scores.

Gain-Based Models

The first and arguably most intuitive growth model is a trajectory that each student has over time that can be described by a slope or a gain. The statistical foundation is the simple difference between two scores. Extensions are straightforward and can include estimating trajectories over more than two points in time or allowing for non-linear trajectories, in the tradition of longitudinal data analysis (e.g., Singer & Willett, 2003). Although gain scores are intuitive, they become problematic in that they rely on vertical scaling decisions, whereby expected gains may differ in magnitude across grades. Although average gains may be an accurate representation of the amount of learning in each grade on an absolute scale, this may be more attributable to the typical developmental trajectories of children than to schools. Straight comparisons of gains

on developmental vertical scales are thus inappropriate for comparing the amount of growth for which teachers and schools may be responsible.

Categorical Models

The categorical model, also known as the value table or the transition matrix model, divides each within-grade score scale into a smaller number of ordered categories (R. Hill et al., 2006). Table 16.1 shows Delaware's value table for the 2009–2010 academic year (Delaware Department of Education, 2010). A student who scores in Level 1A in Year 1 but Level 2A in Year 2 receives a growth score of 225, as shown, and the average across students in the school represents the school-level score. The model relies more than others on the selection of cut scores, where transitions between categories function as student growth data. Logically, the cut scores between Level 1B and Level 2A must have some basis for equivalence.

The categorical model is flexible in the sense that values for particular transitions between categories can be adjusted to user specifications. As R. Hill et al. (2006) demonstrated, careful selection of values for particular transitions can result in a pre-growth-era status model, where only proficiency is counted, or something that seems more gain based, where the gain is quantified as the number of levels that are gained or lost. The cost of this flexibility is the loss of information that comes with categorization, where the model cannot distinguish between the very highest and the very lowest scores in any given category. Although this may seem inappropriate for comparing growth for individual students, at the aggregate level, the errors due to coarse categorization are diminished, particularly as the number of categories increases. However, at a certain number of categories, judgments that support differing values become more difficult to distinguish and justify, and the model becomes likely to reduce to something similar to a gain-based model, with a number of categories approaching the number of score points.

The categorical model technically provides growth descriptions. However, the values that are selected for the categorical model may be motivated by inferences about whether a particular transition between categories is sufficient to warrant an “on-track” designation for students making that transition. To the extent that these inferences inform the choice and interpretation of values, the function of a categorical model is one of growth prediction, as well as growth description. In the case of some growth models, like Iowa's model under its GMPP (Hoffer et al., 2011), this took the form of values like those in Table 16.1, except any nonzero value was simply a 1. This was based in part on the argument that a gain in categories established students as being on track to *Proficient*. In this way, the categorical model can support both growth descriptions and growth prediction.

Conditional Status Models and the SGP Model

Betebenner (2009) introduced the SGP metric as a normative approach to describing student growth. The SGP metric uses nonlinear quantile regression to support

conditional status interpretations, where the current status of a student is referenced to expected percentiles given the score history of students. Although the name of the metric seems to indicate the percentile rank of a student's gain score, the statistical foundation is regression based, where a student's current status is considered in light of expectations given past scores.

Castellano and Ho (2013b) reviewed the SGP estimation procedure in detail. Fitting the statistical model can be time-consuming for large data sets and uses an open-source R library (Betebenner et al., 2023). The SGP is calculated by first estimating 100 nonlinear quantile regression manifolds, for quantiles from .005 to .995, where the outcome variable is the "current" score and the predictor variables are all prior-year scores. Castellano and Ho (2013b) demonstrated that this is practically similar to a straightforward linear regression model of current-year scores on past-year scores, where the SGP corollary is the percentile rank of residuals. The school-level SGP metric used most often in practice is the median SGP, which Betebenner (2008) argued for on the basis of the ordinal nature of percentile ranks. Castellano and Ho (2015) showed that means are superior, where medians require around three times the sample size for the same precision.

Value-Added Models for Teachers and Schools

As the focus in the 2000s shifted from proficiency to growth, value-added models (VAMs) rose as a candidate approach that unabashedly attempted to estimate the causal effect of a teacher or school on test scores, compared to a counterfactual average teacher or school. One set of questions concerned whether and how to estimate these causal effects, and another set of questions concerned whether and how to use them to hold teachers and schools accountable to student learning. High-profile consensus reports argued against (E. L. Baker et al., 2010) and for (Glazerman et al., 2010) the use of VAMs for evaluating teachers. The American Statistical Association (2014) offered a more neutral set of cautions that was rebutted by economists (Chetty et al., 2014b). And the American Educational Research Association (2015) listed limitations and specified eight technical requirements. We briefly review some of the technical issues here and reserve policy models for teacher and school evaluation for the next section.

Koedel et al. (2015) reviewed the substantial evidence about VAMs that emerged in this period. Using experimental evidence where students are actually assigned randomly to teachers, Kane and Staiger (2008) and Kane et al. (2013) estimated experimental causal effects and showed that nonexperimental VAM estimates are statistically indistinguishable from experimental estimates. Bacher-Hicks et al. (2014) and Chetty et al. (2014a) used a quasi-experimental approach to estimate causal effects of teachers from successive cohorts that have undergone staffing changes. They also found that VAM approaches recover these quasi-experimental estimates well. The upshot is that nonexperimental methods are good approximations of quasi-experimental and experimental results in the few studies we have. Further evidence of bias when test scores are high stakes would be useful.

Koedel et al. (2015) also reviewed the substantial evidence about VAM imprecision and intercorrelation, where the general finding is that VAM is positively but weakly correlated across subjects and years (Corcoran et al., 2011; Goldhaber et al., 2013; Lefgren & Sims, 2012; Lockwood et al., 2007). VAM estimates are also positively but weakly correlated across high-stakes versus low-stakes tests (Corcoran et al., 2011; Papay, 2011) and positively but weakly correlated with other evaluation measures like principal, peer, and student ratings (Kane & Staiger, 2012).

Koedel et al. (2015) established sensible technical recommendations for VAMs, including the use of student and school covariates, free estimation of coefficients for prior-year scores (instead of fixing coefficients to 1 to fit gain-based models), and corrections for measurement error (Lockwood & McCaffrey, 2014). They also noted that fixed-effects models (one-step estimation) are similar to averaging residuals (two-step estimation), with the latter approach benefiting from computational feasibility and separate inclusion of classroom and school covariates.

Suitability of Growth Metrics for Accountability Purposes

In test-based accountability systems, there are trade-offs among different growth models along dimensions of transparency, accuracy, and the potential for negative consequences (Ho, 2014). Gain-based models will seem transparent to users for individual reporting but create inequities in accountability models as a result of dependencies between initial status and expected growth. Categorical models may seem transparent to designers of accountability systems but reduce precision as a result of coarsening and confuse point-based aggregate policy goals with score-based individual learning goals. For student-level reporting, SGPs may seem like a black box, whereas at the aggregate level there may be insufficient control of sociodemographic variables for high-stakes purposes. And VAMs may be similarly imprecise and create incentives to artificially deflate test scores from prior years. In these ways, growth models illustrate the necessity of attending to the full complexity of Figure 16.1 by specifying the level of action, score type, and intended purposes, while anticipating predictable unintended consequences.

EVALUATING THE ALIGNMENT OF ASSESSMENTS FOR ACCOUNTABILITY

We next turn to a series of important technical issues underlying test-based accountability policies. There is no measurement concept more central to standards-based education policy efforts than alignment. Even the earliest versions of standards-based education reform in the 1990s had alignment at their core. (For instance, the text of the ESSA uses a form of the word “align” 72 times, demanding alignment among an array of policy instruments, including state content standards, state summative assessments, alternate assessments, English language proficiency assessments, and college entrance requirements.) A central goal of the standards movement is to get teachers to align their instruction with state content standards. To accomplish this, state policies

are meant to align challenging assessments with those standards and to support them through aligned curriculum materials and professional learning opportunities.

But what is alignment, and how has it been conceptualized and measured? This section draws on recent alignment reviews (Martone & Sireci, 2009; Polikoff, 2022) and discusses the role of alignment in accountability policy and the state of existing accountability assessments in terms of their alignment to standards.

Alignment and Validity

When assessments are to be used for accountability purposes, as has been required under federal law for several decades, it is imperative that those assessments align with the content standards they are intended to assess (and at the performance levels required) if the tests are to be used to gauge schools' contributions to student learning. This is certainly true from a policy design standpoint—aligned assessments send educators the message that the standards are important and should be well implemented, and they are at the heart of standards-based reform theory (M. S. Smith & O'Day, 1991). But it is also true from a validity standpoint—all of the inferences about student, teacher, and school performance that are made on the basis of assessment results rely to some degree on the extent to which those assessments align with the content standards they claim alignment to.

Consider the most common type of accountability use of assessments since the NCLB era—the rating of school performance based on its students' scores on state summative assessments. Setting aside policy design decisions about the construction of accountability metrics (e.g., status vs. growth and the use of nontest measures like attendance and graduation rates), the intended goal of these assessments is to gauge how effectively a school is educating children as to the content in state standards. Thus, to make valid inferences about school effectiveness, the assessments must measure student knowledge and understanding of the content and skills in those standards. Alignment is how we gauge the extent to which the assessments measure student knowledge and understanding of the standards. The argument is the same for teacher-level and student-level accountability assessments: To make valid inferences about teacher effectiveness or student mastery, the assessments must measure student knowledge and understanding of the standards.

Alignment is closely related to other terms—opportunity to learn, instructional validity, and instructional sensitivity. Opportunity to learn is a more general term that refers to “inputs and processes within a school context necessary for producing student achievement of intended outcomes” (Elliott & Bartlett, 2016). Alignment of instruction with standards can therefore be thought of as one component of opportunity to learn. For students to have the opportunity to learn the standards, they must (among other things) receive instruction that is aligned with the standards. For students to demonstrate their opportunity to learn the standards, the assessments must (among other things) be aligned to the standards.

Instructional validity and *instructional sensitivity* are other terms that have been used almost interchangeably with opportunity to learn. An assessment is instructionally

valid or instructionally sensitive to the extent that results on the assessment accurately reflect the content and/or quality of instruction students received (whereas some definitions of instructional validity only emphasize content, most implicitly cover both content and quality of instruction; see, e.g., D'Agostino et al., 2007). Presumably, a test could be aligned to standards and not instructionally valid (if, for instance, there were substantial gaps in the standards-aligned instruction students received). Instructional validity or sensitivity is more relevant to some uses of accountability tests than others (for instance, for a student promotion exam it might not matter how a student learned particular content, though it would matter tremendously that the student had the opportunity to learn it). For more on the distinctions among these terms, see Elliott and Bartlett (2016) and Polikoff (2010).

Methods of Measuring Alignment²

There are three main approaches to measuring alignment, but two of them are by far more widely used (Martone & Sireci, 2009). The most widely used procedure to investigate the alignment of state tests with state standards is the Webb approach. This approach compares tests with standards using four main criteria: categorical concurrence (agreement in coverage of broad content areas), depth of knowledge (agreement in coverage of depth or cognitive complexity), range of knowledge (breadth of coverage of the test relative to the standards), and balance of representation (even representation of content on the test). The Webb model also considers the source of challenge for test items (i.e., whether the source of challenge is construct relevant or whether the item is merely “tricky”). Expert raters analyze the content and cognitive complexity of each item on a test and use that information to calculate indices for each criterion. These indices are then compared with specified benchmarks to judge alignment along each criterion (see Webb, 1999, for more detail).

The second widely used alignment approach is based on the Surveys of Enacted Curriculum (SEC; Porter, 2002). Instead of directly comparing standards with assessments, this approach maps standards and assessments onto neutral content languages. These content languages, which define content at the intersection of specific topics (e.g., multiplying fractions) and cognitive demands (e.g., perform procedures), are intended to be exhaustive as to the content that would normally be taught in a particular grade and subject. Once multiple raters have coded the topics and cognitive demands in the standards and assessments, these codes are compared to one another by way of an alignment index that indicates the proportional agreement, as well as heat maps that graphically display areas of alignment and misalignment (Porter, 2002). Multiple alignment indices have been used in the literature (Polikoff et al., 2011). The SEC approach has also been extended to teacher surveys (e.g., Polikoff, 2012a, 2012b; Porter et al., 2011) and to curriculum materials (Polikoff, 2015), and similar alignment calculations have been done in those contexts.

The third most widely used approach was pioneered by Achieve to rate alignment of state tests with standards (Rothman et al., 2002). The Achieve approach rates the

individual test items on several criteria: confirmation of the test blueprint, the match of the content to its intended objectives, the match of the cognitive demand to what is called for by the objectives, the source of the item's challenge (whether it is the target objective or something construct irrelevant), and the overall level of cognitive demand. Then, it takes these item ratings and calculates holistic ratings for (a) level of challenge, (b) balance, (c) range, and (d) rigor (all but range are qualitative ratings; see Rothman et al., 2002, for a description of each dimension). Achieve differs from the previous two approaches by using a qualitative approach to holistic ratings—that is, relying on narrative summaries of the results rather than turning them into quantitative indices (Martone & Sireci, 2009).

There are also other approaches, which have been used more sporadically. For example, one approach has been recently created specifically for Common Core standards. This approach was used in a recent study of four assessment systems: the Partnership for Assessment of Readiness for College and Careers (PARCC), Smarter Balanced, ACT Aspire, and the Massachusetts Comprehensive Assessment System (MCAS; Doorey & Polikoff, 2016). This approach asks expert raters to analyze assessments against a large set of criteria that address both the content and the depth of the standards (for example, whether ELA items require students to read closely and provide evidence from the text, whether they use a balance of high-quality literary and informational texts, and whether they require a range of cognitive demand). These ratings are then rolled up to the whole test to indicate whether the assessment has a weak match, limited/uneven match, good match, or excellent match to the standards. This methodology has only been used in one study as of this writing, but it may be appropriate for more studies if the Common Core State Standards (CCSS) or similar standards remain in place. Other alignment approaches are summarized by Forte (2017).

There are strengths and weaknesses to each of these alignment approaches, and they are described in detail by Forte (2017). Some of the relevant distinctions include the following:

1. All of the methods are dependent on expert raters and are therefore time and labor intensive. The alignment ratings and their consistency across studies have sometimes been problematic (Herman et al., 2007).
2. While the Webb and Achieve approaches measure alignment along similar dimensions, Achieve is much more qualitative and rejects the consensus approach of the Webb methodology.
3. The Achieve approach also considers the role of test blueprints in translating standards into assessments, whereas the Webb and SEC approaches ignore blueprints.
4. The SEC approach is the only approach that can be used to measure alignment of other documents (e.g., curriculum materials, survey reports of teachers' instruction) with standards and assessments.
5. The Webb approach offers thresholds for determining the adequacy of alignment on each of its dimensions, while the SEC does not, but instead offers techniques for hypothesis testing of alignment indices.

Forte (2017) concluded that the choice of alignment method “should depend most on what information the state would find most helpful in improving the quality of its systems of standards and assessments in support of instruction” (p. 11).

How Well Aligned Are State Tests With State Standards?³

The main role of alignment methods is to investigate the alignment of tests with standards. Under NCLB and ESSA, states must submit evidence for peer review that their assessments are meaningfully aligned with their state standards. States have typically used the Webb procedure or a variant to conduct these studies (Martone & Sireci, 2009). Evidently, peer reviewers have been satisfied with the alignment evidence that has been produced, because these assessments continued to be developed and administered for accountability. Early Webb alignment studies (e.g., Webb, 2002) identified some common alignment issues that assessments had: failing to cover the full breadth of the standards, failing to cover the objectives under a standard, and failing to reach the adequate depth of knowledge of the standards. In that study, only one of the eight tests studied met all four alignment criteria. More recent studies (e.g., Webb, 2005, 2010) have generally found more acceptable levels of alignment of state tests with state standards and weaker alignment of other tests (e.g., ACT/SAT) with state standards (e.g., NORC, 2015; Roeber et al., 2018).

Test-to-standards alignment studies have also been conducted using the SEC. The most comprehensive of these was a 2011 analysis (Polikoff et al., 2011) that compared 138 pairs of state standards and assessments in mathematics, science, and ELA. That analysis found that assessments (a) routinely overemphasized some content in the standards and underemphasized other content, (b) assessed content at lower levels of cognitive demand than was called for in the standards, and (c) contained sometimes 20%–25% of content that was not in the corresponding grade-level standards. Furthermore, certain content areas of state standards were routinely not tested year after year.

A more recent analysis also investigated the alignment of state assessments, this time in the Common Core era (Doorey & Polikoff, 2016). This study did not consider alignment the way the Webb or SEC approaches do. Rather, it examined alignment in terms of key instructional shifts called for by the Common Core standards. It found that the new generation of assessments—specifically PARCC and Smarter Balanced—did outperform a “best-in-class” state assessment (MCAS) in terms of many of these key shifts. For instance, the new assessments were better at emphasizing close reading, writing to texts, research and inquiry skills, and matching the cognitive complexity of the standards than were MCAS. However, the ACT Aspire—another test intended to align to Common Core standards—scored lower than PARCC and Smarter Balanced (and, indeed, the MCAS) on several dimensions. The PARCC and Smarter Balanced tests did fall short of aligning to standards in several ways. For instance, they failed to assess speaking and listening standards, and they did not match the complexity of the standards in mathematics. Separately, there is also the recent special case of states using college entrance examinations (ACT, SAT) as their summative assessments for high school. These assessments were not constructed for—and are plainly not aligned

to—state high school standards, though they may offer other benefits such as boosting college awareness and enrollment among groups that may be less likely to otherwise enroll in college (Lorié, 2020).

Together, these studies do suggest that state tests have sometimes struggled in certain key areas with regard to alignment to standards. In particular, they have struggled to assess the full cognitive complexity of the standards (falling short of capturing the most cognitively complex content). This is perhaps not surprising because the most cognitively complex content is often difficult to assess unless there is an extended period or some degree of student research and writing. State tests have also sometimes failed to assess key chunks of standards content (for instance, NCLB-era standards overemphasized reading skills and underemphasized writing skills relative to the standards), perhaps undermining the content messages of the standards somewhat. The differences in findings across studies also suggest that different alignment approaches (which are conducted with different groups of raters) may lead to different answers as to how well aligned assessments are with standards. There is no one “best” alignment method, nor is it even clear how one would compare results from different alignment methods to reach broader implications, which makes it difficult to make definitive statements about overall test-to-standards alignment.

KORETZIAN INFLATION THEORY AND THE VALIDATION OF TEST-BASED INFERENCES IN ACCOUNTABILITY SYSTEMS

Alignment also plays a role in the implications and evaluation of test-based inflation, where systematic misalignment creates opportunities for students, teachers, and systems to attend to construct-irrelevant features of tests. We use the term Koretzian inflation theory to credit the empirical and theoretical work of Daniel Koretz and his coauthors toward the validation of test-based inferences under high-stakes conditions (Holcombe et al., 2013; Koretz, 2008, 2015; Koretz & Barron, 1998; Koretz & Hamilton, 2006; Koretz et al., 2001, 2016). Koretzian inflation theory is a corollary of Campbell’s law (Campbell, 1979) as it applies to high-stakes test-based educational inferences. Campbell’s law states, “the more any quantitative social indicator is used for social decision-making, the more subject it will be to corruption pressures and the more apt it will be to distort and corrupt the social processes it is intended to monitor” (p. 49). Koretz and Hamilton (2006) described inflated test-based inferences as follows: “Test scores can become inflated—that is, can be higher than proficiency in the measured domain warrants . . . particularly severe[ly] when the consequences for scores are substantial” (p. 542).

Empirical studies of Koretzian inflation theory ask a counterfactual question of any high-stakes inference drawn from test scores: How would the inference differ had we used a lower stakes test of the intended domain? The theory predicts that the inference drawn from the high-stakes (focal) test is inflated and biased over the inference drawn from a well-aligned low-stakes (audit) test. The canonical case is that of cohort-to-

cohort measures of average progress such as those from the NCLB-era New York State test, which from 2005 to 2009 showed an increase of over half a standard deviation in Grade 8 Mathematics. In contrast, the cohort-to-cohort NAEP progress in New York from 2005 to 2009 was less than 0.1 standard deviations (Koretz, 2017).

Without a clearer specification of the intended inference and measurement, discrepant trends are not necessarily evidence of inflation. Ho (2007) summarized state–NAEP discrepancies from 26 states from 2003 to 2005 and found that state test score trends from 2003 to 2005 were approximately four times the magnitude of NAEP score trends (0.12 to 0.03 standard deviation units over 2 years). Jacob (2007) looked at four states from 1992 to 2003 and found focal test score trends of 0.09 and 0.06 standard deviations per year in math and reading, respectively, compared to 0.05 and 0.02 standard deviations per year on NAEP.

How can we explain discrepant trends? Any differences in differences in sampling, administration conditions, or behaviors may result in a trend discrepancy. For example, this pattern of trend discrepancies might arise if lower proficiency students began to opt out of the high-stakes test but not NAEP. Student motivation may increase disproportionately for the state test over NAEP. Teachers may increase the alignment of the curriculum to tested standards for the state test over NAEP. Teachers may begin to drill tested standards for the state test over NAEP. Or students or teachers may begin to cheat on the state test but not on NAEP. In all of these cases, it is differences in differences, or the interaction effect, not just differences between tests, that account for trend discrepancies.

In the case where trends differ because of what is measured, which one is correct? Koretzian inflation theory (Koretz, 2008; Koretz & Hamilton, 2006; Koretz et al., 2001) is an applied validation framework that emphasizes a sampling principle of testing and, because it is most commonly applied to measures of progress, a distinct temporal dimension. We present a simplified version of the framework in Figure 16.2, where a test and a target of inference are intersecting circles of a Venn diagram full of measurable and inferable elements of performance. This is a common depiction where the tested (but not inferred) section represents construct-irrelevant variance and the inferred (but not tested) section represents construct underrepresentation. If what is tested is a random sample of the population of elements and the construct-irrelevant variance is random, then we appear to be assured of valid inferences.

Koretzian inflation theory adds a temporal dimension to this representation under high-stakes conditions. Applying Campbell's law and a sampling principle of testing, it asserts that even an initially random sample of tested and targeted elements can become the focus of disproportionate weight or outright corruption, if that sample becomes predictable over time. Students and teachers may notice an initially representative subsample and begin to weight it disproportionately over desired inference weights. This may lead to inflation if, for example, such elements of performance are efficient psychometrically and end up being reused or because such elements form the basis of an equating item set that ensures comparability over time.

**FIGURE 16.2**

Illustrating Mechanisms for Inflation When Test Developers Sample Predictably From Content Domains

The theory defines *reallocation* as a process of increasing weights on tested content disproportionately over their inference weights over time. Reallocation also occurs when teachers and students decrease weights on untested elements that are nonetheless part of the target inference. This is commonly called *narrowing the curriculum* or *teaching to the test*, and we discussed evidence of its prevalence in previous sections. Koretzian inflation theory suggests that no test can simply be “worth teaching to.” As long as a test is a predictable sample of desired elements, stakes will lead to invalid interpretations of progress. Reallocation degrades inferences at the right side of Figure 16.2, increasing emphasis on the intersection (what is measured) at the expense of important but underrepresented content.

Similarly, initially ignorable construct-irrelevant variance can also inflate progress over time under high-stakes conditions. The theory defines *coaching* as the disproportionate weighting of tested elements that are not part of the target inference. This may include elements like “process of elimination,” where students are coached to eliminate obviously incorrect options in a multiple-choice item and, if necessary, guess among the remaining possibilities. Coaching works at the left side of Figure 16.2 by increasing emphasis on construct-irrelevant but predictable features. To the extent that eliminating possibly incorrect answers is not part of the target of inference for, say, a reading test score, Koretz (2017) argued that coaching is at best a waste of instructional time and at worst a source of bias and inflation in test scores.

Holcombe et al. (2013) added multiple levels to the simple heuristic figure sketched in Figure 16.2. The opportunities for score inflation are numerous and appear at every stage of the standard development of tests, including selecting the domain, selecting the elements of the domain, selecting standards for testing, and selecting item representations from tested standards. Each stage introduces possible construct underrepresentation and construct-irrelevant variance. The key insight is that this potential for inflation rises

with higher stakes on results, incentivizing educators to employ coaching and gaming and resulting in inflated indicators of progress.

Koretzian inflation theory also motivates a number of tools and solutions. If high stakes on individual measures are necessary, the theory clearly motivates the use of a low-stakes audit test. NAEP has served that *de facto* role for states and urban districts since the reporting of state and district scores in the 1990s. Although state and district leaders are held publicly accountable to NAEP progress via transparent reporting, the stakes are not as high or as direct as they are for school leaders and teachers. Numerous district tests may also serve lower stakes purposes and can serve as audit measures, although they may not be uniform and comparable at the state level.

Koretz and Beguin (2010) proposed self-monitoring assessments that embed two types of audit items into operational tests. A content audit item would assess a desired target of inference that may be underrepresented in operational items. A style audit item would measure existing content in an unpredictable way to protect against possible inflation from coaching. Koretz et al. (2016) concluded that the approach had theoretical promise but faced substantial practical constraints given the already limited space for items on operational tests. There are also potentially disproportionate costs when developing items from underrepresented content domains that may be underrepresented because they are costly to measure.

Neal (2013, 2018) proposed an alternative solution whereby two separate tests or test sections would achieve separate purposes, the first to measure progress and the second to estimate the causal effects of teachers and schools on test scores. The first test would be largely stable to measure change over time but have no direct stakes on teachers and schools. The second test could change substantially from year to year to sample broadly from the domain with no constraints on equating items, balance across content areas, or consistent item formats. Such a test would render reallocation and coaching difficult or impossible and theoretically encourage educators to focus on the curriculum standards rather than construct-irrelevant performance elements. Because models that estimate teacher and school effects regress current-year scores on past-year scores, they do not need to be equated to the same scale.

Koretz (2017) offered additional policy solutions, the most straightforward of which is to reduce stakes or dilute them through the use of a multiple-measure indicator system. Other solutions include setting reasonable and achievable targets and providing supports that are commensurate with stakes in a reciprocal accountability system (Elmore, 2004).

ACCOUNTABILITY TESTING FOR SPECIAL POPULATIONS

The logic of test-based accountability suggests principles of inclusion and comparability for all subpopulations. Following Figure 16.1, if students from special populations

are excluded or not disaggregated, it sends a signal that they are not a priority. If student scores are not comparable or counted, then the incentives to teach them become uncertain or diminished. In this section, we briefly discuss the inclusion of students with disabilities (SWDs) and English learners (ELs, sometimes also called limited English proficient, English language learners, or emergent bilinguals). Our review is necessarily brief and focuses primarily on issues directly related to test-based accountability for students in these groups. For additional consideration of these groups, see Zwick and Rodriguez and Thurlow in this volume.

NCLB's accountability provisions brought substantial focus on the measurement of all SWDs and ELs. From the earliest days of NCLB, scholars called attention to the salient accountability issues for these groups. Issues related to SWDs were prominent under NCLB, with NCLB policy specifically identifying two groups: (a) up to 1% of the tested population—those with the most severe cognitive disabilities—to be measured against alternate achievement standards; and (b) up to 2% of students with less severe disabilities but who would be unlikely to meet grade-level standards to be measured against modified achievement standards (Elledge et al., 2009). And NCLB is credited with bringing about substantial change and standardization in the processes used to assess EL students within and across states.

McLaughlin and Thurlow (2003) described some of the major substantive and technical issues related to educational accountability for students with disabilities. The authors first noted the inherent tensions of standards-based accountability with key provisions of special education law, such as the guarantees of the Individuals with Disabilities Education Act. The heart of federal law for SWDs is the individualized education program, which is not generally standards based and focuses on each child's individualized performance, goals, services, and participation in the general education classroom. In contrast, NCLB's accountability provisions required participation in the state's standards-based assessment for all but a small percentage of students with the most severe disabilities. The very nature of content standards themselves seems to run counter to the individualized nature of special education services, and special education scholars have questioned the appropriateness of standards for some SWDs. For students given alternate assessments based on the nature of their disabilities, McLaughlin and Thurlow discussed the challenges of aggregating these results with the results of the general population, including setting appropriate and attainable goals for these students and issues of confidentiality based on small group sizes. They also discussed test modifications commonly offered to SWDs and the potential for these modifications to affect the validity of inferences made on the basis of student performance. And for SWDs who are excluded for some or all of the general education curriculum, there are concerns about students' opportunity to learn and the validity of the assessment results for inferences about the general education curriculum.

Similarly, Abedi and Dietel (2004) summarized some of the major substantive and technical issues related to educational accountability for ELs. First, EL students are typically among the lowest-performing groups on content-area assessments, so the uniform

accountability targets of NCLB were seen as especially—and perhaps unrealistically—ambitious for this group. Second, EL students are especially sensitive to the language demands of accountability tests, and Abedi and Dietel made clear that these tests measure both students' content knowledge and their language ability. Third, EL students transition out of the category over time as their English language proficiency improves. Because new EL students often have low scores and high-scoring EL students transition out of the category, the average achievement of the EL category can often be low despite academic growth of EL students. If accountability systems incentivize average proficiency for EL students without attention to accurate reclassification, this creates an incentive to retain English learners in the EL category even after they may benefit from these services.

Other issues raised by Abedi and Dietel (2004) include the variation in approaches and assessments used to identify EL students, the diversity among EL subgroups (e.g., Chinese-speaking ELs versus Spanish-speaking ELs), and the tautological relationship between English language proficiency and EL classification (i.e., if all students were proficient in English, as was NCLB's goal, there would be no EL students by definition).

In the prior edition of this volume, Koretz and Hamilton (2006) discussed these and other issues relating to SWDs and ELs in the context of assessment for accountability. For instance, they discussed the heterogeneity of SWD and EL populations and noted the implications for group size (e.g., many EL or SWD groups are too small to be numerically significant for reporting). And they considered specific disability categories and the implications of students' disability types for validity issues related to construct relevance (e.g., a dyslexic student's challenges in reading text in the context of a mathematics assessment). The primary focus of their treatment of SWD and EL issues is their more extensive discussion of accommodations and modifications and their implications for validity. Changes in accommodation and modification policies brought on by NCLB's inclusion mandates had important implications for the kinds of students included in state assessment and accountability systems. While these changes brought needed attention to the academic performance of students with disabilities and raised expectations for many of these students, scholars have questioned the appropriateness of grade-level standards for many students with disabilities.

There are several important innovations pertaining to accountability assessment for ELs and SWDs under ESSA policy. These innovations broadly attempt to deal with some of the unintended consequences and issues that emerged under NCLB-era regulations. For instance, ESSA regulations do away with the 2% group for modified standards, while maintaining the 1% group with the most severe disabilities who can be tested against alternate standards. This addresses concerns that too many students were being excluded from accountability against regular grade-level standards with the 2% cap. Addressing the tension mentioned above between individualized education programs and inclusion, ESSA regulations specifically require states to have guidelines for the inclusion or exclusion of students with disabilities in the alternate assessment

system. In principle, this could again improve the appropriateness of assessments offered to students with disabilities. ESSA law also emphasizes the importance of universal design for learning in the test development process, which it defines as follows:

The term “universal design for learning” means a scientifically valid framework for guiding educational practice that—(A) provides flexibility in the ways information is presented, in the ways students respond or demonstrate knowledge and skills, and in the ways students are engaged; and (B) reduces barriers in instruction, provides appropriate accommodations, supports, and challenges, and maintains high achievement expectations for all students, including students with disabilities and students who are limited English proficient. Every Student Succeeds Act, 20 U.S.C. § 6301 (2015). [congress.gov/114/plaws/publ95/PLAW-114publ95.pdf](https://www.congress.gov/114/plaws/publ95/PLAW-114publ95.pdf)

This is intended to reduce concerns about construct irrelevance, some of which were highlighted by Koretz and Hamilton (2006). For more on the implications of the universal design for learning in the context of accountability assessments, see Rose et al. (2018). For more discussion of alternate assessments and the English Learner population, also see Rodriguez and Thurlow in this volume.

PERSPECTIVES ON EQUITY IN ACCOUNTABILITY TESTING

Educational policies like ESSA have stated aims and mechanisms to provide low-income students with improved educational opportunities. This reflects one definition of equity, the disproportionate allocation of resources to those with greatest need. The intended role of educational tests in these policies is to measure students’ academic needs so that educational systems can similarly provide low-scoring students with disproportionate support. As we have reviewed in earlier sections in this chapter, there are unintended consequences when these systems place unrealistic expectations on teachers and school leaders to raise test scores for low-scoring students. In these cases, attempts to improve equity for low-scoring students may be inequitable for the teachers and leaders who support these students.

Tests may also fail to improve equity when they are disproportionately burdensome to the lowest-scoring students who take these tests. This can occur in the act of testing, when low-scoring students encounter assessment tasks and prompts that are not as engaging or affirming to them as they are to higher scoring students, or when they receive test scores, when low-scoring students may disproportionately interpret their low test scores as evidence of their irredeemable deficits rather than areas for potential growth. This section reviews selected perspectives on equity in accountability testing.

Equity Monitoring Systems

In the 2019 NASEM report, *Monitoring Educational Equity*, the authors argued that relying primarily on test scores to measure school and student performance can

undermine educational equity by neglecting the inputs and context for learning. A more comprehensive system could reveal inequality earlier in the life span, set realistic expectations for student growth, and provide national benchmarks to spur investment and improvement. Such a system would consider factors like school funding levels, curriculum quality, teacher qualifications, class sizes, student health and well-being, extra-curricular opportunities, and other resources that impact learning.

The report recommended that the indicators track inequality in opportunities at the school and district level, as well as for various student demographic subgroups. This would provide insights into how policies differentially impact groups like students of color, low-income students, ELs, and SWDs. Monitoring progress in closing equity gaps could then help target resources and support. Comparisons of progress across the country could inspire learning from proven practices.

The report emphasized that developing a national monitoring system will require considerable input to secure buy-in before full implementation. Using NAEP as an example, the authors proposed a board like NAGB that oversees and reports on a system of comparable equity indicators across states and over time, inspiring improvement through public accountability. They argued that indicators must be selected carefully and with appropriately developed and publicly reported validity evidence. Ongoing evaluation would also be needed to ensure the system meets its goals of revealing inequities and spurring corrective action over time.

Returning to Figure 16.1, adopting an “equity monitoring” approach as proposed by these authors holds promise to both reveal and reduce the unintended negative consequences listed on the right-hand side of the framework. For example, highlighting inputs rather than outputs can help to set realistic expectations for growth. To the extent that there are stakes through public accountability, these stakes would be more distributed across additional indicators beyond test scores, reducing the likelihood of inflation. Unintended consequences of public reporting of indicators, like segregation, would be monitored directly. And systematic attention to disaggregating indicator data by sociodemographic categories, particularly for indicators related to educational inputs, would help to avoid deficit frameworks by highlighting inequality in educational access and opportunities (Quinn & Desruisseaux, 2022).

Culturally Sustaining Assessment and Test-Based Accountability

If the NASEM report is an effort to “measure equity” by documenting disparities in a broader range of school- and student-related indicators, there is also increased effort to “measure equitably.” This effort involves measuring outputs like achievement with particular investment in understanding the learning experiences of historically marginalized students and designing assessments that engage them. This builds on theories of “culturally sustaining pedagogies” (Ladson-Billings, 1995; Paris, 2012), which are educational practices that not only acknowledge but also build on the cultural

knowledge and experiences students bring to the classroom. In classroom contexts, culturally sustaining assessments are activities designed to value, engage, and empower students (Lyons et al., 2021; Randall, 2021). (In this volume, see Ercikan & Flores; Lane & Marion; Rodriguez & Thurlow; and Zwick for discussion of culturally responsive assessments.)

Figure 16.1 distinguishes between direct score-based actions and indirect non-score-based influencing actions. For culturally sustaining assessments to function well in accountability systems, they must have positive direct and indirect actions. Scores from culturally sustaining assessments would need to accurately identify both schools and students who need support. And the practice of culturally sustaining assessment would need to improve agency and engagement among students and educators. An unintended negative consequence would be if accountability pressures on educators led them to customize tests under the banner of “culturally sustaining assessments” that inflated scores for students who needed support, thus decreasing the likelihood that they would receive the support they need.

Dee and Penner (2017) provided evidence that an ethnic studies course designed with principles from culturally sustaining pedagogy has positive effects on student attendance and grade point average in other courses. Using a regression discontinuity approach, they estimated that students near the assignment cutoff (an eighth-grade grade point average of 2.0) would have a 1.4-point higher ninth-grade grade point average had they been assigned to take the course, compared to the counterfactual of not being assigned. Bonilla et al. (2021) showed that there are still detectable causal effects in terms of high school attendance, high school graduation, and postsecondary matriculation. However, the ethnic studies course was not designed with culturally sustaining assessment for accountability as a goal, nor were the properties of scores or grades from this course a target of analysis.

Theoretical foundations for culturally sustaining testing exist in sociocognitive models for learning and assessment (Bennett, 2023; Lyons et al., 2021; Mislevy, 2018; Moss et al., 2008; NASEM, 2018; Shepard, 2021). Sociocognitive models incorporate the past experiences of students and the current context of learning and assessment, including students’ relationships with other students and the teacher in the classroom. These models typically result in inferences that are richer and context referenced and thus are more limited in claims about generalizability. The sociocognitive perspective on conventional large-scale tests is that these are also context referenced to isolated individual completion of a particular subset of decontextualized cognitive tasks. Scores on these tests are then similarly limited in generalizability to other performances on tasks that also require isolated individual completion of decontextualized cognitive tasks.

Thus, although there is optimism around culturally sustaining assessment that serves students and produces low-stakes scores for classroom inferences and scholarly research (Bennett, 2023; Mislevy, 2018; Shepard, 2021), there is skepticism about

the role that scores from culturally sustaining tests might play in accountability systems (Lyons et al., 2021). Stakes would have to remain low to avoid incentives to change assessment tasks to inflate scores. Traditional psychometric frameworks that require strict comparability of score interpretations across contexts would have to evolve. Costs for test development, deployment, evaluation, and scoring would have to be feasible. And building scholarly, political, and community consensus about content standards and test blueprints for culturally sustaining tests would take time and work.

As one example of such a process, the state of Hawaii has allowed Native Hawaiians to design a test and test-based accountability system for students in the Kaiapuni Educational Program, a Hawaiian language immersion program. The Kaiapuni Assessment of Educational Outcomes (KĀ'EO) follows ESSA guidelines, including the requirement for mandatory public reporting in terms of KĀ'EO standards in mathematics, Hawaiian language arts, and science. According to the KĀ'EO technical report (Hawaii State Department of Education, 2018), the development team used the achievement-level descriptors for the English language state test, the Smarter Balanced test, as a foundation for the development of Hawaiian language achievement-level descriptors. These, in turn, guided item writing and standard setting in Hawaiian. Shultz and Englert (2021) described this as “one example of how the test developers and community stakeholders successfully balanced the tension between maintaining the technical requirements of a state assessment and serving the needs of the community as defined by the community” (p. 5).

CONCLUSION

In a first draft of this chapter on test-based accountability, written before the onset of the COVID-19 pandemic, our opening sentence was, “Over the past several decades, the arc of K–12 educational assessments has bent steadily toward accountability.” At the time, although ESSA had granted some flexibility from one-size-fits-all accountability, the statement generally seemed defensible. Years later, the sentence seems laughably dated, a reminder of the pendulum swings that are common between extremes of federal and local control and the imprecision of extrapolating from past trends.

Although predicting future trends in test-based accountability is not our goal, we believe the principles outlined in the beginning of this chapter and revisited throughout should guide future validation of test score use in educational accountability systems. Once educational test scores exist in complex systems, actors use them for a predictable range of purposes that extend well beyond simple descriptions of what individual students know and can do. Validation, and the corresponding anticipation of unintended negative consequences, requires specification of actors, score-based actions, score types, and indirect actions in social and political systems (Figure 16.1).

ACKNOWLEDGMENTS

The authors thank the coeditors, Linda Cook and Mary Pitoniak, the designated reviewers of this chapter, Laura Hamilton and Joan Herman, and the Editorial Advisory Board reviewer, Michael Rodriguez, for their constructive feedback and insights. We also thank Lily An and additional members of the Harvard Graduate School of Education's Educational Measurement Lab for their suggestions.

NOTES

1. Although the statute uses the terminology “valid and reliable academic measure,” the current *Standards* (AERA et al., 2014) and Zwick (this volume) hold that validity is a property of uses of measures and not a property of measures themselves. A valid academic measure is thus one that has sufficient validity evidence to support its intended use in the accountability system.

Assessment for Admission, Placement, and Outcomes in Higher Education

Wayne J. Camara

Law School Admission Council

Ou Lydia Liu

ETS

Krista Mattern

NBME

This chapter focuses on three applications of standardized tests in U.S. higher education—use in admissions, placement, and outcomes assessment. Testing often differs across these three applications, but also within each application across institutions based on institutional need and philosophy. In addition, we address the changes to testing and testing policies that have emerged in the past few years related to the pandemic and other externalities.

Admissions tests serve multiple purposes, some of which are explicitly identified by the testing organization, others that may be proposed by the test sponsors or users (e.g., institution, government agencies), and still others that may be stipulated by policy makers and secondary users of test results. Four purposes or claims have been put forth by ACT concerning the use of admissions test scores: (a) admissions (scholarship), (b) placement (course, program), (c) preparation and academic advising (college readiness, academic planning, application to college), and (d) accountability (school, district, and state). College Board lists five similar purposes for SAT scores: (a) students' college/career readiness, (b) admissions and college course placement, (c) student progress, (d) high school placement, and (e) scholarship decisions (Camara et al., 2019). Graduate and professional admissions tests are much more likely to be used only in admissions and scholarship decisions. Admissions test scores have also been used by policy makers and other stakeholders for purposes that are not intended or sanctioned by test developers, such as for preemployment screening, high school graduation, teacher effectiveness, institutional quality, and ranking. In response, the National Council on Measurement in Education (2019) issued relevant cautionary guidance to dissuade such uses. (See also Ho & Polikoff, this volume, for a discussion of the use of admissions tests for nonintended purposes.)

Placement tests have been described as assessments contributing data to institutional and student decisions about course enrollment, course exemption, and credit by examination for students already admitted to a program or institution (Whitney, 1989). Placement tests are used by many colleges and universities, even those institutions with open admissions policies that do not require testing for admissions, to determine which courses a student should initially complete. They include commercial tests and locally developed tests at individual campuses that are most frequently used for placement in math, reading, and writing/composition. Faculty at many institutions have developed placement tests to determine placement in credit versus developmental courses, as well as the appropriate level in sequential coursework such as foreign languages and mathematics.

Assessments of *student learning outcomes* (SLO) are used by higher education institutions for a variety of purposes, including fulfilling regional and program accreditation needs, internal improvement, faculty/staff interest, equity concerns, and responding to accountability calls (Jankowski et al., 2018). The assessment results are typically examined at the group level without significant direct consequences for individual students. A report by the Commission on the Future of Higher Education released under then-Secretary of Education Margaret Spellings increased the demand and prominence of

SLO assessments. The commission's first report (U.S. Department of Education, 2006) noted a lack of mechanisms for the evaluation of outcomes at U.S. institutions, calling for direct and comparable evidence of learning for improved transparency. The most popular assessments include national student surveys, alumni surveys, locally developed surveys, standardized assessments of general knowledge and skills, rubrics, employer surveys, performance assessments, and portfolios.

CHANGES IN ADMISSIONS AND CURRENT CHALLENGES TO ADMISSIONS TESTING

Admissions tests have been shrouded in controversy since the introduction of the SAT (then known as the Scholastic Aptitude Test) in 1926. The debate about innate intelligence versus achievement, large differences in scores between groups (gender, ethnicity/race), and the influence of coaching on test scores are examples of controversies across the decades (Camara, 2009; Donlon, 1984; Jencks & Phillips, 1998; Lemann, 1999; Willingham & Cole, 1997). However, in 2020, a convergence of externalities emerged, which not only disrupted admissions and admissions testing but also appears to have resulted in profound changes to these processes for the foreseeable future.

COVID-19 and the Social Justice Movement

The coronavirus disease (COVID-19), a severe acute respiratory disease, spread rapidly across much of the globe and was responsible for closing U.S. schools as early as March, 2020. It had a profound impact on admissions and admissions testing for the entering class of fall 2021 and beyond. As of April 3, 2020, all schools in 43 states were closed and most schools in other states were similarly closed (*Education Week*, 2020). Given this closure of schools and colleges, administrations of both the SAT and the ACT were canceled, and initial attempts to administer undergraduate admissions tests resulted in significant reductions in capacity because many test centers remained closed and others introduced social distancing protocols well through 2021. The ACT and SAT tested about 50% of students who registered for testing in the summer and fall of 2020 (Jaschik, 2020). Testing companies sought innovative solutions to bring the admissions tests to students in the fall of 2020; the GRE, Graduate Management Admission Test (GMAT), and Law School Admission Test (LSAT) introduced remote proctored examinations by spring/summer 2020, providing access to thousands of students who tested at home. All three graduate admissions testing programs have continued to employ remote proctored exams for testing at home, while the GRE, GMAT, and, most recently, LSAT have also provided candidates a choice of test center administrations (Camara & Mattern, 2022).

The pandemic coincided with the Black Lives Matter movement (Black Lives Matter: About, 2024), and there was a renewed focus and commitment to equity and social justice by colleges, businesses, and many Americans. A survey of 300 top colleges found that the Black Lives Matter movement influenced changes to admissions processes in

about 30% of institutions (Kaplan, 2021). (See also Cook & Pitoniak, this volume, for a discussion of the impact of the Black Lives Matter movement on assessment.)

Before COVID-19 and the increased spotlight on issues of social justice, about 12% of all 4-year colleges or universities neither recommended nor required admissions tests, which represented about 1% of all freshmen in the United States,¹ with one college test blind (i.e., it did not consider test scores for admissions with any applicants; Camara, 2020). For 2024 admission, over 1,900, four-year colleges (85%) did not require the ACT or SAT for admission and 80 colleges were test blind (FairTest, 2024). Graduate admissions and professional admissions tests were also forced to cancel normal administrations of their tests through spring, resulting in a similar movement to test-optional policies among a number of programs. See the following section for a full discussion of test-optional policies. (See also Ercikan & Flores, this volume, for discussion of the impact of the COVID-19 pandemic on assessment.)

Prior to the pandemic, in early 2019, the University of California's (UC) Academic Senate established an 18-person faculty task force to conduct a study of the university's testing practices, focusing on their role in disproportionate disparities in race, ethnicity, and socioeconomic status (SES) evident in the undergraduate population. This was the third time in less than 20 years that the university system had undertaken a review of its admissions policies and practices to ensure fairness and diversity. The task force was charged with addressing the following questions:

- How well do the UC's current standardized testing practices assess entering high school students for UC readiness?
- How well do the UC's current standardized testing practices predict student success in the context of our holistic, comprehensive review process?
- Should UC's standardized testing practices be improved, changed, or eliminated?
- Do standardized tests fairly promote diversity and opportunity for students applying to UC?
- Does UC's use of standardized tests enhance or detract from UC academic eligibility for high school students?

After conducting meetings, inviting relevant experts in admissions and assessment to make presentations, and completing a comprehensive review of research, the task force released its report with six recommendations (Standardized Testing Task Force, 2020). The recommendations generally encouraged UC to consider additional quantitative factors that could supplement high school grade point average (HSGPA) and tests for eligibility, expand the pool of students eligible for admissions based on class rank, expand academic supports for at-risk students, conduct additional research, and explore the development of a new assessment system.

The task force rejected making admissions tests optional, stating, "With some confidence, we can predict that the following would happen if UC stopped using admissions tests and relied solely on (high school) grade point average (GPA) and other aspects of

the student's transcript for the academic appraisal of applicants" (Standardized Testing Task Force, 2020, p. 85):

- The average student admitted to UC would have a lower first-semester grade point average (FGPA), probability of persistence, probability of graduation, and GPA upon graduation.
- The average financial subsidy by the state would have to rise due to the longer time to graduate per student, and costs per bachelor's graduate would rise.
- Comparisons of in-state and out-of-state applicants would be difficult and unconvincing.
- UC would have less ability to target high-risk students for academic support without tests.

The UC task force similarly dismissed a proposal to adopt the Smarter Balanced Assessment Consortium assessment program in lieu of the ACT/SAT, reasoning that test-taker behavior would change if Smarter Balanced were suddenly used for high-stakes admissions decisions and concluding that diversity-related benefits would not be realized. Camara (2023) compared scores for Smarter Balanced and ACT by ethnicity and race and found that, generally, differences were equivalent, meaning use of Smarter Balanced in place of the ACT would not reduce score gaps for underrepresented minorities. The task force (Standardized Testing Task Force, 2020) found little evidence of instructional validity for achievement tests in general and for Smarter Balanced specifically, noting that since the introduction of Smarter Balanced in California, test performance had been flat, suggesting that additional instruction on the content covered by the assessment shows no increases or effect.

Shortly thereafter, UC president Janet Napolitano made several recommendations to the Regents, which they approved:

1. For fall 2021 and 2022 applicants, campuses will have the option to use ACT/SAT scores in selection consideration if students choose to submit them.
2. Beginning with fall 2023 and ending with fall 2024 applicants, campuses will not consider test scores for admissions selection at all and will practice test-blind admissions selection (California students).
3. During the full period of suspension, from 2021 to 2024, students will have the option to submit an ACT/SAT score for use in scholarship consideration and post enrollment course placement, but not admissions.
4. By 1/21, UC will complete a process to identify or create a new test that aligns with the content UC expects students should have mastered to demonstrate college readiness for California freshmen.
5. If UC is unable to either modify or create a test that meets these criteria and can be available for applicants for fall 2025, UC will eliminate the use of the ACT/SAT for freshman admissions (Office of the President of University of California, 2020).

Napolitano's recommendations were clearly at odds with the task force report, but her recommendations also appeared to consider additional threats imposed by other external factors such as COVID-19, the lawsuit brought against UC,² and the persistent and unrelenting challenges to standardized testing at UC. Generally, the UC task force report (Standardized Testing Task Force, 2020) documented evidence that test scores are the single best predictor of academic success at UC; predict well for all major subgroups; are better predictors for underrepresented minorities, first-generation, and low-income students; and had minimal impact on different acceptance rates experienced by subgroups (Camara, 2023).

After the UC Regents adopted a test-optional policy for 2021–2022 and a test-blind policy for 2023, several subsequent events hastened UC's abandonment of test scores altogether. First, a California superior court issued a preliminary injunction stopping the UC system from considering SAT or ACT scores for admissions or financial aid decisions for the class of 2021. The ruling was issued as part of a lawsuit challenging the use of SAT and ACT scores as culturally biased and a violation of equal protection guarantees (*Smith v. Regents of University of California*, 2020). This injunction stated that the test policy adopted by the Regents in the summer of 2020 denied applicants with disabilities equal access to the tests. The ruling reasoned that applicants submitting scores ("submitters") have an inherent benefit denied to nonsubmitters and cited the difficulties of students, particularly those with disabilities requiring accommodations, in registering and completing the ACT and SAT during the pandemic. Next, on May 14, 2021, UC agreed to a settlement with the plaintiffs that made it the first public university system in the nation to stop any consideration of test scores in admissions, scholarship, and financial aid processes (Rippetoe, 2021).

Test-optional policies were clearly gaining in popularity prior to the impact of COVID-19, social justice movements, and UC's task force report. Additional challenges to admissions testing have been attributed to publicized efforts to cheat on tests and gain advantages in admissions, domestically and internationally, and the continued disparity between the demographics of high school graduates and admitted freshmen at many selective institutions. But taken together, these events formed a near-perfect storm, which further fueled alternative admissions processes without test scores.

Test-Optional Policies

Lucido (2018) documented stated and unstated goals of many test-optional policies, which include genuine concerns about the influence and validity of test scores, the desire to enhance the economic and ethnic diversity of the class, and institutional motivations, which may be less altruistic, such as increasing a college's ranking or selectivity (by raising the reported test scores when lower scoring students are nonsubmitters), increasing applications, and increasing yield (since nonsubmitters are more likely to enroll). FairTest (2024) listed over 1,800 colleges and universities that are test optional or test flexible or de-emphasize tests in admissions. Prior to the pandemic, the vast majority of test-optional institutions were private, liberal arts colleges, including 150

for-profit schools and additional institutions with eligibility requirements (e.g., in state, meeting a minimum HSGPA, and submitting other standardized tests). In fact, between 1987 and 2015, only 15% of selective colleges adopted a test-optional policy (Furuta, 2017).

Some institutions that adopted a test optional policy in 2020 have “permanently” moved to test optional with many selective schools continuing their test-optional policies. However, several highly selective institutions announced they were reinstating test requirements for 2025, including Dartmouth, Yale, Harvard, Brown, Caltech, Massachusetts Institute of Technology, Georgetown, Purdue, and the University of Texas at Austin (Hartocollis & Saul, 2024). These institutions cite a variety of reasons for requiring tests, including their own research which shows test scores are the single best predictor of college success at their institutions and the resulting impact when test scores are missing: (a) overreliance on grades with rampant grade inflation (Sanchez, 2023), (b) reliance on the quality and rigor of high schools, (c) rewarding applicants from high schools that regularly send students to the institution and disadvantaging applicants from relatively unknown high schools, and (d) a heightened importance given to personal statements and letters of recommendation – all of which serve to advantage those applicants who are already advantaged (Camara, 2024). Despite uncertainties regarding whether institutions will realize their goals of increased diversity, whether students admitted without test scores perform similarly to students admitted with test scores, and whether undergraduate admissions testing will partially rebound in a post-COVID-19 world, a large majority of institutions are likely to maintain a test-optional policy for the foreseeable future (Camara & Mattern, 2022; Camara, 2024).

Until recently, test-optional colleges had provided only anecdotal evidence that generally claimed there was little to no difference between submitters and nonsubmitters in terms of grades, graduation, or persistence, but evidence allowing comparisons of the two groups in terms of background, high school grades, and other factors was not included (e.g., Hiss & Franks, 2014).

More recently, a few studies of test-optional colleges have investigated these and other issues across multiple institutions. Prior to the pandemic, research showed that among test-optional institutions, 70%–75% of students submitted scores and nonsubmitters were more likely to include a larger proportion of underrepresented racial/ethnic minority students, first-generation students, and low-income students and attain somewhat lower grades in college (Bennett, 2022). One of the first colleges to adopt a test-optional policy was Bates College in Lewiston, Maine, in 1984. Later, a former admission director and colleagues conducted several studies of test-optional colleges. In their most recent study, Syverson et al. (2018) reported that more than half of the test-optional institutions saw larger increases in applications than matched institutions that required testing. However, many test-optional institutions did not see this gain, and the authors failed to explain their criteria and the process used for matching

institutions. The study claimed that test-optional policies did not impact the academic quality of enrolled students and cited a slight increase in the average test score (about 19 points on the SAT scale) and HSGPA (0.02) after going test-optional, but failed to note that test scores were not available for nonsubmitters, who likely had lower scores. The study did report that nonsubmitters had lower high school grades, earned a lower first-semester grade point average (-0.17 on a 4.0 scale), and were slightly less likely to major in science, technology, engineering, and mathematics (STEM), which appears to undermine claims that test-optional policies do not impact academic quality. In a study of 33 schools with test-optional policies, Hiss and Franks (2014) found only marginal differences favoring students who submitted test scores over nonsubmitters in grades (2.88 vs. 2.83 GPA) and graduation rates (64.5% vs. 63.9%), but submitters were more likely to be STEM majors.

Belasco et al. (2015) studied admissions across 180 selective liberal arts colleges, including 32 that were test optional. They found that nonsubmitters were more likely to be from underrepresented and underserved populations. On average, test-optional institutions saw an increase of 26 SAT score points (on a 1,600-point scale), which enhanced their selectivity, and received about 220 more applications than similar institutions that were not test optional; they did not find a difference in ethnic, racial, or economic diversity of enrolled students. Sweitzer et al. (2018) examined the same issues by calculating propensity scores to match test-optional institutions requiring tests, allowing them to model how a test-optional institution would have differed across various outcomes if they had not adopted this policy. Their findings support those of Belasco et al. (2015), with the biggest benefit of test-optional policies being an increase (about 8 points) in SAT scores from a smaller number of applicants and no significant differences in acceptance rates or the diversity of enrolled students. Bennett (2022) compared nearly 100 private institutions that implemented test-optional policies between 2005–2006 and 2015–2016 (a group of earlier adopters) to more than 100 similar institutions that enacted test-optional policies by December 2019 (a comparison group of later adopters). He found enrollment increases for Pell Grant recipients, underrepresented ethnic minorities, and women at test-optional institutions relative to matched peer institutions, but no evidence of increases in applications or yield. Enrollment increases were modest, favoring test-optional schools by 3.1%–4.2% for Pell Grant recipients, but larger for underrepresented minorities (10.3%–11.9%) and women (6.0%–8.0%). Early adopters of test-optional policies did report moderate increases in applications and admission rates, and these benefits may have dissipated as the number of similar institutions with this policy increased over the years. While research seems to clearly suggest that many of the purported benefits associated with test-optional policies are often not supported with data, these policies do not appear to disadvantage institutions.

Data on applications, admissions, and enrollment between 2018–2019 and 2021–2022 from approximately 60 test-optional colleges, representing more-selective public and private 4-year institutions in the United States, were merged with College Board

assessment data to examine how college-going trends and outcomes were affected by pandemic-related disruptions (Edwards et al., 2023; Howell, 2023). The numbers of applications, offers of admission, and enrolled students increased between 2020 and 2021 for nearly all student groups, but more-selective private institutions enjoyed nearly double the increase (29%) in applications compared to all other types of institutions. The proportional representation of ethnic and racial groups changed marginally, while group differences in applications, admission, and enrollment changed very little between 2018 and 2021 among participating institutions. For example, in 2019, the percentage of Black, Native American, and Hispanic/Latino students was 24.4% compared to 25.4% in 2021. The study also found little difference among ethnic and racial groups in their score-sending behavior; students' test scores relative to the college they applied to was the strongest predictor of the decision to disclose their scores (Howell, 2023). In terms of college outcomes, students who disclosed test scores had stronger first-year outcomes (GPA, credits accumulated, retention) compared to students who had no tests or who withheld test scores.

Similarly, Cruce and Sanchez (2023) examined which students were most likely to withhold their ACT scores from test-optional colleges and the impact on persistence to sophomore year. The research focused on matriculants to 142 colleges that introduced a test-optional policy in 2020 and were located in states with an ACT contract to test all public school juniors. The final sample was 102,745 students who attended one of these colleges and graduated from high school between 2017 and 2021. The two predictors examined were (a) discrepancy between students' ACT score and HSGPA and (b) students' ACT score relative to other students' scores at the college. The authors concluded that students make a strategic decision to submit or withhold their test scores, and to help them make that decision, students evaluate their scores against (a) other academic measures (e.g., HSGPA) and (b) the test scores of their peers. Students whose scores are discrepant or who score lower than their peers are less likely to send scores and more at risk of leaving college. Even after all statistical controls were introduced, students who withheld their scores still had a significantly higher likelihood of leaving college within freshmen year or fall to fall.

Chetty et al. (2023) reported that high school grades do a poor job of predicting success at Ivy Plus colleges. Students with a perfect HSGPA of 4.0 achieve a cumulative GPA in college that is less than 0.1 points higher than a student with a 3.2 HSGPA, and higher test scores are associated with higher college GPAs for students from different socioeconomic backgrounds. In addition, students opting to not submit an SAT/ACT score achieve relatively lower college GPAs when they attend an Ivy Plus college.

High School Grades

One important result of test-optional policies is greater reliance on high school grades and other factors. Camara (2018) compared ACT scores of students with an HSGPA of 4.0 or better in the 30 largest schools in a state ($N > 300$ per school) and

reported large between-school differences in the percentage of such students and their mean ACT scores. Schools ranged from having 2.1% to over 23% of students with a 4.0 HSGPA, and average ACT Composite scores differed by over 7 points on a 1–36 point scale. Research on high school grades has revealed systematic grade inflation since the 1990s, which is increasingly beneficial toward wealthy, White, Asian, and private school students (Camara et al., 2003; Hurwitz & Lee, 2018). Consistent with other studies, the UC Academic Senate Task Force (Standardized Testing Task Force, 2020) reported that grade inflation has reduced the predictive power of HSGPA by a third between 2007 and 2015. Chetty and colleagues (2023) reported high school grades have a much weaker association with college GPA. First-year college GPA of students from less advantaged vs. more advantaged high schools, conditioned on SAT/ACT score, were virtually identical, thus displaying no evidence that students from higher-resourced backgrounds outperform students from lower-resourced backgrounds. In addition, reliance on grades alone often results in greater overprediction of college grades for underrepresented minorities than when grades and test scores are used in combination (Mattern et al., 2008; Zwick, 2013), and substantial subgroup differences advantaging White and Asian American applicants on grades remain.

Varsity Blues

In 2019, federal authorities announced charges against over 50 wealthy and famous parents and college personnel in a criminal conspiracy to influence undergraduate admissions at several highly selective colleges, nicknamed Operation Varsity Blues. Parents allegedly paid an admissions consultant between \$200,000 and \$6.5 million to guarantee their children's admission through a variety of means, including bribing college coaches to place students on lists of recruited athletes regardless of their ability or experience, submitting fraudulent documentation of learning disabilities to secure extra time on admissions tests, and bribing test-site supervisors to correct answers on their child's admissions test after completion (Richer & Binkley, 2019). While the scandal impacted all aspects of competitive admissions, it provided an opportunity for some critics to cite another reason why admissions tests may distort the admissions process (Boost, 2019). However, many saw the incident as an extreme case of distorting admissions in illegal ways, an example of what we have long known about the role of affluence in life and education. Joyce Smith, chief executive officer of the National Association for College Admission Counseling, noted that the scandal reinforces much of what we know:

that wealthy people have always enjoyed many legal advantages in the process, such as the ability to pay for tutoring, test preparation, and application coaching, or for the truly wealthy to make sizable donations, fund scholarships or endow buildings or faculty seats. And we know that economic status affects one's educational choices at every stage of life. (Hawkins, 2019, p. 15)

Undergraduate Admissions Practices, Testing, and Legal Challenges

The goals of the admissions process are rarely specified in a manner that facilitates validation. Many examinations of undergraduate admissions have described the goals and desired outcomes as multidimensional as well as disguised (Gaff & Meachum, 2006; Rigol, 2003; Willingham, 1985). Desired outcomes from admissions processes include both individual student outcomes (academic ability, ability to benefit, appreciation of lifelong learning, leadership skills) and institutional outcomes, which may be referred to as “building a class.” Institutions need to ensure diversity and balance along with many factors, such as financial (ability to pay, need- vs. merit-based aid), talents and interests (to support activities, clubs, and majors), and balance (among other factors, including demographics, geography, and socioeconomic factors).

Admissions processes can generally be classified as mechanistic or holistic. Prior to the 2003 Supreme Court decisions in two affirmative action cases involving the University of Michigan, many large, public universities relied on mechanistic or formulaic components in their admissions processes. In many instances, a minimum test score and/or HSGPA, or a combination of both,³ may have been used to reduce the large number of applications to a more manageable ratio (applications:admission slots). Mechanistic approaches and cut scores were efficient tools for institutions with large applicant pools, limited budgets, and the desire to have objective criteria to defend admission decisions to the public. (See Ferrara et al., this volume, for a discussion of cut scores and standard setting.) Conversely, private colleges were more likely to conduct holistic reviews, also known as comprehensive or individual review. The holistic review may differ in how it is implemented, but normally involves the review of all materials, by at least two readers, for each applicant, including the student’s essay and letters of recommendation (Laird, 2005; Rigol, 2004). Additional components of an applicant’s “whole file” may include student accomplishments, opportunities or context, and experiences (e.g., class rank, test score, extracurricular activities, leadership experience, community service). A study examined the relationships between the content of admission essays, self-reported household income, and SAT scores, quantifying essay content using correlated topic modeling and essay style using linguistic inquiry and word count (Alvero et al., 2021). Based on 240,000 admission essays submitted by 60,000 applicants to the UC, they found that essay content and style had stronger correlations to self-reported household income than did SAT scores and that essays explained much of the variance in SAT scores. Overall, there has been little empirical research examining holistic admissions processes, the consistency of ratings attributed to different factors, or the validity of those factors in predicting academic outcomes.

Moreover, an internal audit of undergraduate admissions practice conducted by UC was harshly critical of improper influences and lack of consistent treatment of applicants, finding that campus staff took advantage of weaknesses in admissions processes to admit 64 students as favors to donors, family, and friends. Several weaknesses were

found with the holistic review process, including inadequately trained and supervised reviewers resulting in sometimes overly harsh or overly lenient ratings. They noted that the Office of the President did not review the campuses' admissions processes to detect and prevent unfair or inconsistent practices. Instead, it has allowed weaknesses to persist for years (University of California, Ethics, Compliance, and Audit Services, 2020). Soon after the Supreme Court decision in *Gratz v. Bollinger* (2003), which ruled that the University of Michigan's system of awarding additional points to underrepresented racial/ethnic minority applicants was unconstitutional, many colleges and universities that had not already done so abandoned highly mechanistic admissions processes, and holistic review processes quickly gained popularity. On the same date, the court supported the University of Michigan's Law School in its narrowly tailored use of race in admissions as part of a compelling interest to promote student diversity (*Grutter v. Bollinger*, 2003). To many, a lesson learned from the dual decisions was that race could be considered as part of a holistic review of applicants, but it should not be applied mechanistically with specified points or weights added for minority status. In addition, race should not be a determinative factor in admissions (Rigol, 2004; Zwick, 2018).

Between 1996 and 2012, eight states banned affirmative action in college admissions, and more colleges and universities abandoned strict mechanistic approaches (e.g., cut scores) to make final admission decisions (Davenport et al., 2018). However, the greatest impact from the University of Michigan admissions cases may be the lack of transparency of admissions processes and a decrease in institutional willingness to share data that could disclose subgroup differences among applicants, enrollees, and graduates.

In 2023, the U.S. Supreme Court reversed decades of precedent, effectively ending race-conscious admission programs at colleges and universities. The court found that admissions systems used by Harvard University and the University of North Carolina at Chapel Hill violate the equal protection clause of the 14th Amendment. Chief Justice John Roberts wrote in the majority opinion that "both programs lack sufficiently focused and measurable objectives warranting the use of race, unavoidably employ race in a negative manner, involve racial stereotyping, and lack meaningful endpoints" (*Students for Fair Admissions v. President and Fellows of Harvard College*, 2023, p. 8). The court did say that the decisions should not prohibit colleges from considering an applicant's discussion of how race affected their life in an essay or other means (*Students for Fair Admissions v. President and Fellows of Harvard College*, 2023, and *Students for Fair Admissions v. University of North Carolina*, 2023). In both cases, Asian American students rejected by Harvard University claimed they had been disadvantaged by vaguely defined "personal" ratings that invited implicit bias and discrimination, despite being better qualified on academic measures (test scores, grades, extracurricular activities). The plaintiffs used Harvard's internal admissions data and emails to argue that despite better grades and test scores than applicants from other races, Asian Americans were held to a higher standard and penalized by subjective ratings in the holistic admissions process. Harvard University admitted consideration of race was one factor in their holistic admissions process.

A few days after the court's decision was released, civil rights groups filed a complaint against Harvard University's preferences for legacy applicants with the U.S. Department of Education. The complaint noted that nearly 70% of applicants with family ties to donors or alumni are White and are six times more likely to be admitted than non-legacy applicants. About 28% of Harvard's class of 2019 were legacies, meaning fewer admissions slots were available for non-White applicants, who are far less likely to have family ties to the school (*Lawyers for Civil Rights v. President and Fellows of Harvard College*, 2023).

Prior to these decisions, in 2016, *Fisher v. University of Texas et al.*, the Supreme Court ruled that admissions officials may continue to consider race as one factor among many to ensure a diverse student body.⁴ In writing for the majority, Justice Anthony Kennedy quoted from another landmark decision: "Considerable deference is owed to a university in defining those intangible characteristics, like student body diversity, that are central to its identity and educational mission," adding that the courts must provide universities substantial but not total deference in designing admissions policy (*Fisher v. University of Texas et al.*, 2016, p. 19).

One important element of holistic admissions processes that has generally escaped scrutiny is the reliability and consistency of ratings. If admissions decisions are to be considered predictive of future success, higher education institutions should provide evidence that ratings of each factor (e.g., leadership), element (e.g., admission essay, letter of recommendation), and student record have high interrater agreement. In addition, validity evidence should be presented that demonstrates the admission processes are accurately identifying students who achieve the desired outcomes of the institution. Legal challenges have largely been directed toward the admissions process and decision, rather than the admission tests. However, the impact of these challenges to affirmative action and the increased demand for diversity of admitted students has had a significant impact on admissions tests, which are addressed later in this chapter.

UNDERGRADUATE ADMISSIONS TESTS AND PRACTICES

The SAT

The inception of the College Entrance Examination Board can be traced to a meeting of the Association of Colleges and Preparatory Schools of the Middle States and Maryland held in Trenton, New Jersey, on December 2, 1899. At that time, there was little agreement among colleges about the subject matter content and preparations that should be required of applicants; College Board was founded to bring order to the chaos of different entrance requirements across established Eastern colleges (Donlon, 1984; see also Clauser et al., this volume). The goal for the fledgling organization was to bring standardization and uniformity to entrance requirements for colleges, but it also had the effect of forcing secondary schools to move from a system built on local autonomy to more common curricula. College Board, formally approved on November 17,

1900, was primarily established to serve as a conduit between colleges and preparatory schools to establish uniformity in admissions standards and preparation/curriculum in secondary schools. It achieved these goals in 1901 by establishing requirements for nine subject matter examinations in English, French, German, Latin, Greek, history, mathematics, chemistry, and physics and administering exams to 973 students, which were read by 39 readers with prominence in their field.

Initially, only 3 colleges replaced their own local exams with the new subject tests, but subsequently, an additional 35 institutions agreed to accept the examinations as substitutes for their own requirements. A decade after their inception, in 1911, the number of students separately examined by Harvard, Yale, Princeton, Penn, Bryn Mawr, Stevens Institute, and the Massachusetts Institute of Technology still exceeded the number of students taking the board exams. College Board examinations continued to consist of a series of essay tests requiring readers to grade each exam; but influenced by the efficiencies and success of intelligence tests during World War I and beyond, the College Board added a comprehensive test of general aptitude to its program in 1926—the Scholastic Aptitude Test (Donlon, 1984; Schudson, 1972). The original College Board achievement tests were transitioned to a fully multiple-choice format in 1937 and placed on the same 200–800 SAT scale; they were rebranded as the SAT II Subject Tests in 2005 and then discontinued in 2021.

The 1926 version of the SAT bears little resemblance to the current test, but it marked the transition from essays to multiple-choice-type items on admissions tests. It contained nine subtests, seven with verbal content and two with mathematical content; and time limits were more stringent, with 315 questions administered in 97 minutes. In 1930, the SAT was split into verbal aptitude and mathematical aptitude, a structure that has remained largely in place over time, including the 2024 design (College Board, 2017a; Lawrence et al., 2002). Other major developments that shaped admissions testing occurring in the 1940s included the transition to machine scoring of the SAT, which replaced the monumental task of human scoring of test questions and eliminated the many hours of training clerical workers, as well as the equating of scores on every SAT form to ensure comparability for admissions decisions. ETS (formerly Educational Testing Service) was founded in 1947 by three nonprofit organizations: the American Council on Education, the Carnegie Foundation for the Advancement of Teaching, and College Board. ETS was established to assume responsibility for test development, administration, scoring, and research, allowing College Board to continue its role as an association and convener of higher education and secondary schools (Fuess, 1950; Zwick, 2006). The use of the SAT increased dramatically during its first 30 years, with over a half-million students testing annually by the late 1950s and over a million students in 1986.

Changes to the SAT were intermittently introduced in content and question type during its history, but the first major revision of the post–World War II SAT did not come until 1994, when antonyms were dropped from the test, reading passages became longer, calculators were allowed, grid-in items were added in math, and the score scale

was recentered in the summer of 1995 based on a full year of operational scores. During this period, the Scholastic Aptitude Test was renamed the Scholastic Assessment Test and then quickly changed to just the SAT I Reasoning Test. Two additional major revisions of the SAT were introduced in 2005 and 2016, and a digital, multistage, adaptive SAT replaced paper-and-pencil version of the SAT in the United States in 2024.

The major change to the SAT in 2005 largely resulted from 2 years of discussions with the UC and was initiated after a speech by Richard C. Atkinson, then UC president, where he recommended elimination of the test as a UC admissions criterion (Schemo, 2001). The most significant change was the addition of a mandatory writing section composed of multiple-choice items and a single 30-minute essay, resulting in now three separate scores (critical reading, mathematics, and writing), each scored on the 200–800 point scale and resulting in a total score of 600–2400. In addition, analogies were removed as an item type in critical reading, quantitative comparison items were removed in the math section, and additional content was added in advanced math topics to better reflect the curriculum.

The 2016 version of the SAT was introduced in March of that year and represented a major redesign of the previous test in terms of content, design, and the interpretation of scores. The redesign was driven by the adoption of the Common Core State Standards by 43 states and a desire to increase market share through statewide adoption (Dudley, 2016; Felton, 2015). In 2013, just 3 states had adopted the SAT for statewide testing, as opposed to 11 states that were using the ACT. The 2016 version of the SAT returned to issuing two scores—evidence-based reading and writing (ERW; which includes a reading test and a writing and language test) and a math score. The essay, which had been required on the SAT since 2005, became optional. Test takers had 3 hours (plus an additional 50 minutes for the optional essay) to complete the test. The two sections—ERW and math—were reported on the 200–800 SAT scale but required a concordance to compare scores with the prior SAT. Other major changes of the 2016 SAT redesign included the elimination of formula scoring, which imposed a penalty for students' incorrect answers, to rights-only scoring, a simple count of correct items, and the inclusion of items in the math section that prohibit calculator use⁵ (College Board, 2017a). In 2021, College Board discontinued the optional essay, except for school-based administration with state specific contracts (College Board, 2024c).

Three stand-alone field trials were conducted to develop new score scales, equate initial forms to future forms, and build a concordance between the 2005 version of the SAT and the 2016 redesigned SAT; each is described in the technical manual (College Board, 2017a). A single group design was used to establish a concordance by selecting students who completed the 2005 version of the SAT in the fall of 2015 and having them complete the 2016 redesigned SAT in December 2015. The concordance demonstrated that scores on the 2016 redesigned SAT were substantially higher, with the difference favoring the 2016 SAT between 70 and 100 points on the total score scale (400–1600 scale) (College Board, 2016). College and Career Readiness Benchmarks were revised in 2016. Using historical data from the 2005 SAT linked to college outcomes, the SAT

scores associated with a 75% probability of earning a C or higher were derived. Those scores were then transformed to the 2016 SAT score scale based on a 2005–2016 SAT concordance table to set the updated SAT benchmarks at 530 and 480 for math and ERW, respectively (College Board, 2017b).

The SAT was primarily a paper-based test but began offering a digital administration to states and districts in 2017 to assist with comparability studies. The SAT fully transitioned to a digital format in March 2024, which was partially motivated from persistent security challenges encountered by maintaining a large volume paper program internationally. The multistage test design organized content into two stages, each composed of a module of test items comprising half of the section's items. After answering an initial (routing) module of items representing a broad mix of easy, medium-difficulty, and hard items, students are routed to either a lower- or higher-difficulty second-stage module based on their performance on items in the initial module. Additional changes to the test design included a reduced overall testing time from 3 hours to 2 hours, significant shortening of reading passages with one question per passage, and more time per test item. The reading section is composed entirely of discrete items and shorter passages instead of item sets and extended-length passages, while the mathematics section retains multiple-choice items and student produced-response items. PSAT assessments transitioned to digital tests in the fall of 2023 (College Board, 2024c).

In 2022, 18,513 students were recruited to take both a digital SAT and the previous paper-based SAT within a month. Data from the SAT straight-line concordance study of the digital SAT and paper SAT were used to establish a link between the paper-based version of the SAT and the digital SAT's item response theory (IRT) metric for the Reading and Writing section score, Math section score, and performance categories in eight content domains. Scores were linked using the equipercentile method of linking digital IRT maximum likelihood theta values to the paper-based scale scores (College Board, 2024c; see Moses, this volume, for a discussion of scaling, equating, and linking methods).

The ACT

The ACT (then known as the American College Testing) was first introduced in November 1959 in the Midwest region of the United States and was designed with three purposes in mind—admissions, advisement, and placement. The ACT was designed to compete with the SAT, whose primary mission was selection of the few for highly selective institutions (Lemann, 1999). Lindquist (1959) argued that the primary need was “one of finding a type of test that will not just serve a single well-defined purpose, but . . . one of building a multiple purpose rather than a single purpose test” (p. 105). He further argued that such a test should be used more broadly by public institutions and expanded to serve “as the basis for advisement and placement, not just admissions” (ACT, 2009, p. 9). At the time, the SAT remained a tool of primarily selective private institutions. A number of states operated their own statewide assessment system, and there was an absence of a national admissions test, which could be used for students applying to out-of-state institutions. Lindquist argued for the expansion of admissions

testing across the country to a greater number of colleges and well beyond the purview of just elite colleges on the East Coast and to address the needs currently met by a series of tests sponsored by individual states and institutions. Finally, he argued that an admissions test should be based on achievement in curriculum found most often in secondary schools rather than aptitude or innate ability (ACT, 2009; Lindquist, 1959).

The creation of the ACT resulted from both the transformation across higher education in the 1950s, which saw a 433% increase in college enrollment and dramatic increases in educational expenditures, and frustration in attempts to bring significant changes to the SAT (ACT, 2009). Designed by Lindquist and Ralph Tyler to address these purposes, ACT scores were reported to students as well as to colleges; SAT scores continued to be reported only to colleges (Jacobsen, 2017).

The ACT was originally composed of four sections, mirroring the format and content of the Iowa Tests of Educational Development and standard college curriculum: English, mathematics, social studies, and natural sciences. In its first testing year, 132,963 students took the ACT, and that number jumped to nearly 1 million by 1967–1968. At that time, strong regional differences emerged, with 85% of institutions in the Mountain West and Plains states participating in the ACT program compared to 10% for the SAT; conversely, about 17% and 53% of institutions in the northeast and middle states were affiliated with the ACT and SAT, respectively.

Aided by concordance tables first produced in the early 1990s, which allowed admissions officers and high school counselors to compare and convert to a single scale, most colleges accepted scores from either test (Marco et al., 1992). Concordance tables have been produced jointly by ACT and College Board after major redesigns of the SAT in 1994, 2005, and 2016.⁶ Similarity of content and strong statistical relationships are required to support the use of concordances to satisfy different goals, such as determining comparable scores, aligning scales, and predicting a student's unavailable ACT or SAT score from their SAT or ACT score (Dorans et al., 1997). The 2018 ACT–SAT concordance tables represent the last time both tests used matched data to establish score comparisons and includes cautions and guidance to assist users in interpreting scores across tests, although recent changes to both the ACT and SAT seem to require a new concordance. In addition, both testing programs have developed assessments for earlier grades (Grades 8–10), which closely mirror the content and statistical blueprints of the ACT and SAT and are vertically scaled to allow interpretation of growth. In particular, the SAT Suite of Assessments includes the SAT, PSAT/NMSQT, PSAT 10, and PSAT 8/9; ACT assessments include the ACT, PreACT (10th grade), and PreACT 8/9.

In 1989, the natural sciences section was transitioned to the science reasoning section and social studies was changed to a reading section (ACT, 2009). In 2005, ACT was also caught up in the debate initiated by Atkinson and the UC and added an optional 30-minute essay. For the 2005 version, ACT consisted of four sections—English, mathematics, reading, and science, with an optional essay. Section scores, a composite score, and a STEM score are reported on the same 1–36 scale used since its inception. The composite score was the average of English, mathematics, reading, and science;

the STEM score is the average of the mathematics and science scores. In 2005, and later updated in 2013 to reflect a more current reference group, ACT established college-readiness benchmarks by empirically deriving the ACT section score associated with a 50% probability of attaining a B or higher in first-year courses in related subject areas (Allen, 2013; Allen & Sconing, 2005), as well as a more rigorous benchmark for readiness in STEM (Radunzel et al., 2015).

For each ACT section test, the construct that is assessed is considered unidimensional—English, mathematics, reading, and science proficiency. In support of this claim, confirmatory factor analyses based on operational data suggest that a one-factor solution has a good model fit for each of the four subject tests (e.g., Li et al., 2017). In 2021, ACT began to also provide an ACT Superscore, which is calculated by averaging students' best section scores across all test attempts to create a new composite score (Radunzel & Mattern, 2020b). The ACT began offering the test digitally, as well as on paper, for school-based administrations (contracts with states, districts, or schools for census testing during a school-day) in spring 2015 and transitioned all international administrations to digital delivery in fall 2018.

In April 2024, ACT announced it was partnering with Nexus Capital Management LP, a Los Angeles–based private equity firm, and transitioning to a for-profit company. The partnership will fund a nonprofit organization conducting services for education and work success and should provide needed capital to stabilize current offerings and grow new products (Arundel, 2024). In February 2024, ACT began offering a digital administration alongside the paper-administration at selected locations⁸ and introduced other changes for online test takers in April, 2025, which included making the science section optional (as is the writing section), fewer items, more time per item, reduced total testing time, and a reduction in the number of answer choices in the math section from 5 to 4. The ACT Composite score is now comprised of only English, math, and reading (requiring only 125 minutes of testing as compared to 195 minutes based on the prior version), while science scores will be reported separately for those who take it.

These changes, which are collectively labelled ACT Enhancements, were introduced for the online national administrations in April 2025 and will be extended to the paper mode in national administrations and all international administrations in September 2025, and finally school-based administrations (under state and district contracts) in spring 2026 (see Table 17.1). ACT notes that the new format is shorter and allows students more flexibility (ACT, 2024b). It has also been noted that students might have been intimidated by the inclusion of science (Knox, 2024).

A linking study was conducted in June 2024 between the Enhanced ACT design and the tradition design with randomly equivalent groups ($N = 7,600$), confirming the factor structure, showing small differences in the score distributions and lower reliabilities for section scores. The ACT Composite score, now comprised of three section scores (English, reading, math), is not strictly comparable with the ACT Composite score prior to 2025 (English, reading, math, and science) due to both the impact of removing science items from the construct, differences in student performance in science relative

Table 17.1 ACT and SAT Content, Testing Time, and Item Counts

Testing Element	ACT (Enhanced Format)	SAT
Reading section	Reading: 40 minutes, 27 scored items, 9 pre-test items	Reading and Writing: 64 minutes (two 32 minute modules). 50 scored items, 4 pretest items (25 scored items, 2 pretest items per module)
Language section	English: 35 minutes, 40 scored items, 10 pre-test items	
Math section	Math: 50 minutes, 41 scored items, 4 pre-test items	Math: 70 minutes (two 35-minute modules), 40 scored items, 4 pretest items (20 scored items, 2 pretest items per module)
Calculator	Permitted	Permitted
Science section	Optional Science: 40 minutes, 34 scored items, 6 pre-test items	Science: NA
Writing	Optional: 40 minutes essay	NA
Score scale	Composite: 1–36 Section: Reading, English, and Math Optional Sections: Science 1–36; Essay 4 domains and Total 2–12	Total: 400–1600 Section: Reading + Writing 200–800, Math 200–800. Four subscores reported for skills under each section. Reading & Writing = Information and ideas, Craft and structure, Expression of ideas, and Standard English Conventions. Math = Algebra, Advanced math, Problem-Solving and Data Analysis, and Geometry and Trigonometry.
Total testing time	2 hours, 5 minutes	2 hours, 14 minutes
With optional essay and Science	3 hours, 25 minutes	NA
Mode and Digital Format	Paper and Digital available for national and school-based administrations. Digital only for international administrations. Linear format.	Digital delivery. Multistage adaptive (1:2 design).
Pretesting	Embedded within section	Embedded within section

Note. For the ACT, the composite score on the 1–36 scale represents a superscore that is based on English, reading, and math scores. Enhancements to the test are taking place on the following schedule: April 2025 (digital national administrations); September 2025 (paper national administrations); and Spring 2026 (school-based administrations). Information for the ACT is from *ACT Assessment Technical Manual*, 2024a; and *ACT Test Enhancements and Changes*, 2024b; ACT. For the SAT, the digital version was introduced internationally in March 2023 and domestically in March 2024, replacing the current SAT with a revised framework. Information for the SAT is from *Assessment Framework for the Digital SAT Suite* (Version 3.01), 2024a, College Board; and *Digital SAT Launches Across the Country, Completing the Transition to Digital and Providing a Simpler Testing Experience for Students and Educators*, 2024b, College Board.

to other sections, and differences in rounding to derive the Composite score. ACT notes that most students will have a new Composite score that is within the standard error of measurement for the Composite score reported prior to 2025 (Allen & Cruce, 2025, p. 25).

Undergraduate Institutions and College-Going

In 2019–2020, there were 3,982 degree-granting postsecondary institutions with first-year undergraduates. Sixty-seven percent of institutions were 4-year institutions and 33% were 2-year institutions. Among 4-year institutions, 29% were publicly controlled, 58% were privately controlled not-for-profits, and 13% were privately controlled for-profits—a segment that decreased by over 50% between 2013 and 2020. About 25.7 million students are enrolled in U.S. colleges, with roughly 33% enrolled in 2-year institutions and 67% enrolled in 4-year institutions (U.S. Department of Education, 2020). In 2019–2020, there were about 300 public and private not-for-profit 4-year institutions with open admissions in the United States,⁹ which indicates that the vast majority of 4-year colleges have some competitive admissions process that considers prior achievement and experience. However, only 75 of these 1,997 institutions examined admit 25% or fewer applicants. Figure 17.1 illustrates that nearly all (86.2%) four-year colleges admitted at least half of all applicants and over half (57.2%) admitted at least three quarters of all applicants (Center for Education Statistics, 2020).

FIGURE 17.1
Percentage of 4-Year Institutions by Undergraduate Admission Rates

Note. The figure does not include the “no application criteria” category, which represents 24.6% of 4-year colleges. Data are from *Digest of Education Statistics, 2020* (NCES 2022-009; Table 219.10), by C. de Brey, A. Zhang, and S. Duffy, 2022, National Center for Education Statistics, Institute of Education Sciences, U.S. Department of Education.

Of the 2.9 million high school completers¹⁰ in 2017, about 67% enrolled in college within 12 months of graduation. Since 1985, 4-year college enrollment has remained fairly stable, at 44% of graduates, while 2-year college enrollments increased by a third, to 23% of high school graduates. Immediate college enrollment rates for students from low-income families was 58%, a rate 50% lower than the enrollment of students from high-income families (Camara & Westrick, 2017). Females continue to outnumber males in immediate college enrollment from high school (72% vs. 61%); and while gaps among racial/ethnic groups have been closing in recent years, discrepancies still existed in enrollment in 2017: 87% of Asian students, 69% of White students, 67% of Hispanic students, and 58% of African American students (U.S. Department of Education, 2019).

An annual survey of admissions trends indicated that applications rose through 2015, with over 80% of students applying to three or more institutions and 35% of students applying to seven or more institutions (Clinedinst, 2019). Despite the media's focus on admissions at the most prestigious universities, only 14% of 4-year institutions accepted less than 50% of applicants in one survey (U.S. Department of Education, 2019), with another survey reporting that figure to be 19% of institutions. While such selective institutions accounted for 37% of all applications, they represented 21% of first-year students (Clinedinst, 2019). Table 17.2 illustrates the prepandemic share of U.S. 4-year institutions, applications, and enrolled students by selectivity.

College admission has remained controversial fodder for the media (Bowen & Bok, 1998; Camara, 2009; Shelton, 1997; Soares, 2012; Zwick, 2002, 2017). Though concerns about the employability of college graduates and their student loan debt have long existed (*The Economist*, 2014), the value of a degree, from both a financial and an individual standpoint, has been well established. Higher levels of educational attainment are associated with reduced unemployment and higher wealth accumulation (Boshara et al., 2015). College degree recipients also engage in more prosocial behaviors, such as volunteering, voting, and participating in political activities (Bowen & Bok, 1998; Goldberg & Smith, 2008).

Table 17.2 Percentage of U.S. Applications and Enrollment by Selectivity at 4-Year Institutions for 2017–2018

Institutional Selectivity	Share of Institutions	Mean Number of Applications per Institution	Share of Applications	Share of Full-Time, First-Time Undergraduates
Accept <50%	19.2	12,492	36.5	21.3
50%–70%	33.4	6,108	31.0	32.3
71%–85%	28.8	5,625	24.6	33.4
More than 85%	18.6	2,771	7.9	13.0

Note. N = 1,599. Adapted from *State of College Admission* (p. 8, Table 2), by M. Clinedinst, 2019, National Association for College Admission Counseling.

The numbers are even more dramatic when recipients of advanced degrees are examined. T. Julian (2012) estimated full-time employees with a bachelor's degree would earn approximately \$2.4 million (in 1999 dollars) throughout their adult life compared to \$2.8 million for employees holding a master's degree, while those with a doctorate (\$3.5 million) and professional degrees (\$4.2 million) were estimated to earn significantly more. Given these benefits, it is not surprising that more students choose to attend higher education institutions after high school and that many aspire to earn graduate and professional degrees. Among students completing an admissions test in 2019, approximately 33% aspired to earn a bachelor's degree, and over 43% planned to earn a graduate or professional degree (ACT, 2019a; College Board, 2019a).¹¹

Use of the ACT and SAT in Undergraduate Admissions

A wide variety of measures are considered in undergraduate admissions decisions. Grades and strength of curriculum were of considerable or moderate importance for nearly 90% of institutions, followed by admissions test scores at 83% of institutions prior to the pandemic (Clinedinst, 2019). Additional factors such as writing samples, a student's demonstrated interest, letters of recommendation, and extracurricular activities were less important to most institutions. Scores on state assessments were of no importance to over 70% of institutions. As a result of the pandemic and other external factors impacting admissions, as discussed earlier, national data concerning trends in admissions and the importance of various factors have not been updated recently.

Admission test scores provide normative- and criterion-referenced score interpretations, both of which are used in admissions. At institutions where the number of applicants exceeds openings, applicants' performance on admissions factors, including test scores where required or when submitted, are used to sort between students in a typical norm-referenced fashion. Today, test-optional policies reduce reliance on scores to rank order students or establish a minimum score for entry. Previously, students with higher test scores, higher grades, and more rigorous high school coursework were relatively advantaged in the admissions process over students with lower scores, grades, or course rigor (Standardized Testing Task Force, 2020). The issue is not whether a student will go to college, but whether the student will gain admission to more competitive colleges (Beatty et al., 1999). Colleges with higher ratios of applicants to openings may focus more on selecting students into their institutions, but even less-competitive institutions apply normative admissions processes when they must determine which small percentage of applicants is not admitted. Admissions tests may be used in a more criterion-referenced manner if institutions segment applicants into categories such as admit, deny, and further review or if used along with high school grades in a compensatory manner or a sliding scale such as that employed previously for National Collegiate Athletics Association eligibility in Division I sports.¹²

Test Scores and College Search

ACT and SAT scores may be used to advise students, families, and educators prior to and during the transition from high school to college and by colleges to recruit and build their entering class. Test scores can help students and families reduce the number of colleges and universities under consideration from the nearly 4,000 possibilities to a manageable few by identifying potential institutions where they may have a strong academic match (in addition to satisfying other college preferences). One frequent admissions strategy is to identify potential institutions of interest that fit into three categories in terms of probability of admissions (safe, match, and reach colleges; Hoxby & Avery, 2013).

Accountability

Admission test administrations are increasingly funded by states with a variety of goals, such as identifying students who meet empirical benchmarks for college readiness, increasing participation in postsecondary education, and accountability purposes (Camara et al., 2019). In 2018, 26 states funded the administration of the ACT and/or the SAT for all public school 11th graders (i.e., census testing), and half of those states proposed to use scores for federal accountability under the Every Student Succeeds Act (U.S. Department of Education, 2015), which is not without controversy (Marion & Domaleski, 2019; refer to Ho & Polikoff, this volume, for a more detailed discussion). Many states fund either the ACT or the SAT for all juniors, but a few states allow each district to select among admissions tests. State funding of admissions testing began in 2001 with Illinois and Colorado administering the ACT to all juniors. In 2019, about 43% of admissions testing volumes resulted from state funding of admissions testing (Camara et al., 2019; College Board, 2019a). By 2022, 22 states were using an admissions test for high school accountability (Education Commission of the States, 2022).

States view census testing with the ACT or SAT as an opportunity to get their students on the radar of colleges and to get colleges on the radar of all students, especially among underrepresented groups (Anderson, 2014). Benefits associated with using the ACT and/or SAT as compared to a customized state assessments include increased motivation or effort by test takers (Finn, 2015), providing all students with scores accepted for college admissions, increased college enrollment and access (Hyman, 2017; Klasik, 2013), greater security, and reduced testing time (Camara et al., 2019). Several studies have been published that show statewide testing increases overall or 4-year college enrollment in a state, increases access for underrepresented groups, and is a cost-effective intervention (Allen, 2006; Hyman, 2017; Klasik, 2013).

Participation in Admissions Testing

ACT testing volumes increased significantly since the mid 1990's and surpassed the SAT in total U.S. test takers from 2012 until 2017 (Adams, 2017), when the 2016 redesigned SAT regained several state contracts. In 2019, the last year prior

to COVID-19, approximately 1.8 million and 2.2 million high school seniors had taken the ACT and SAT, respectively. Overall, undergraduate admission testing volumes declined by 14% and 22% for the SAT and ACT, respectively, between 2019 and 2023, hitting a low mark for both programs in 2021 and rebounding slightly thereafter. Camara (2024) documented the increase in applicants withholding test scores from 2019–2020 (22.6%) to 2023–2024 (53.2%). Between 2017–2018, over 50% of high school graduates completed the ACT; and between 2018–2020, more than 50% of graduates completed the SAT. Note that totaling percentages from the ACT and SAT may exceed 100% as some students take both tests. In 2021–2022, participation rates fell precipitously with a larger recovery in SAT test takers by 2023.

It is difficult to estimate the number of U.S. high school graduates who took either admission test, both tests, or neither test because test-taker data, understandably, are strictly held by each testing organization. However, the last official concordance between ACT and SAT in 2018 provides some insight. Table 17.3 uses the projected number of U.S. high school graduates and national data reported by ACT and College Board to estimate the percentage of students completing both, only one, or neither test in 2017. Results from the ACT and College Board concordance were based on 589,753 students graduating in 2017 who were matched across both testing programs (College Board & ACT, 2018). For the current analysis, students who took both tests but did not meet the inclusion criteria for the concordance study were retained, resulting in a slightly larger sample size of 593,500, as reported in Table 17.3. In 2017, about 16.5% of graduates took both tests and about 12.5% of graduates took neither test. More recently, both

Table 17.3 Estimated Number and Percentage of U.S. High School Graduates Taking College Admissions Tests in 2017

Admissions Test	Number of High School Graduates	Percentage
SAT only	1,121,981	31.2
ACT only	1,436,538	39.9
Both tests	593,500	16.5
Neither test	450,928	12.5
Total	3,596,650	100

Note. The total number of U.S. high school graduates projected by the National Center for Educational Statistics for 2016–17, and national data reported by ACT and College Board were used to estimate the percentage of students completing both, only one, or neither test in 2017. The estimate of 593,500 students for the “both tests” value is based on a total of 599,274 students matched across both tests, minus 6,253 international students. The final concordance sample is based on 589,753 students, which excludes students for reasons not relevant to the issue of multiple versus single test participation. In addition, the estimates of students taking both tests are slightly underreported using the concordance samples because they included students who only took the SAT prior to March of their junior year, when a revised SAT was released. Students who took both tests, but one of them was prior to March of their junior year, are counted as taking only one of the tests. Data for projected number of high school graduates are from *Digest of Education Statistics 2017* (NCES 2018-070; p. 193, Table 219.10) by T. D. Snyder, C. de Brey, and S. A. Dillow, 2019, National Center for Education Statistics, Institute of Education Sciences, U.S. Department of Education. Data for students taking both tests is from *Guide to the 2018 ACT/SAT Concordance*, 2018 (p. 1, para. 3), College Board & ACT.

testing programs have witnessed significant decreases in the number of tested students, coinciding with disruptions in testing due to the pandemic along with a sharp uptake in test-optional admission policies. In particular, the 2021 ACT-tested high school graduating class was comprised of 1.3 million students—which is 375,000 fewer students than the 2020 class (Camara & Mattern, 2022). Similarly, there were nearly 700,000 fewer students in the 2021 SAT-tested high school graduating class, which included 1.5 million students as compared to 2.2 million in 2020. Furthermore, the percentage of college applicants submitting test scores has decreased strikingly from 78% in 2019–2020 to 48% in 2021–2022 (Magouirk et al., 2023).

GRADUATE AND PROFESSIONAL ADMISSIONS TESTS AND PRACTICES

Graduate school and professional degree admissions encompass many academic and professional disciplines (e.g., psychology, economics, English literature, medical school, law school) and a range of degrees (e.g., masters, PhD, MD, JD), housed in large public universities, smaller private and public colleges, and public, private, and not-for-profit stand-alone institutions. This chapter will focus on the admissions processes and tests most widely recognized across competitive academic programs and the largest professional schools—the GRE, GMAT, LSAT, and MCAT. Many additional admissions tests are used for entry to specialty programs in medical fields (e.g., dentistry, optometry, pharmacy, veterinary medicine) but fall outside the scope of the current chapter.

The GRE and GMAT have been administered online and in a computer-adaptive fashion since the 1990s (Graduate Management Admission Council, 2020; Wendler et al., 2014). The MCAT and LSAT transitioned to linear computer-based administrations in 2007 and 2016, respectively (Bingham et al., 2012; Margolis, 2018). In addition to providing an opportunity for improved test security and measurement precision, online testing also allows for the inclusion of more innovative item types and more flexibility in test administration models (e.g., remote proctoring).

Institutions responding to an annual survey of graduate school enrollment and degrees reported approximately 2.1 million applications for admission in fall 2020, with about 68% of applications to master's degree and other (e.g., graduate certificate) programs (Zhou & Gao, 2021). Acceptance rates were 22.3% of doctoral applicants and 55.7% of master's/other applicants, with the largest numbers of doctoral applications in social and behavioral sciences, engineering, and biological and agricultural sciences and those of master's applications in business, mathematics, and computer sciences. Approximately 509,999 first-time graduate students enrolled in fall 2020, with 60.8% female students. Unsurprisingly, given the COVID-19 situation, international graduate first-time enrollment was down by 37.4% between fall 2019 and fall 2020, and a large decline was observed in fields such as engineering, mathematics, computer sciences, and physical and earth sciences (Zhou & Gao, 2021).

Undergraduate admissions processes and tests have received their share of scrutiny in both scholarly research publications and popular media. By comparison, graduate school admissions and tests have been subject to much less examination. A report by the Council of Graduate Schools (Kent & McCarthy, 2016) found that graduate admissions processes are primarily decentralized, with over 75% of academic programs responsible for their own admissions program, in contrast to undergraduate admissions, which are generally centralized within an institution and coordinated by admissions professionals. Graduate admissions decisions are often made by small departments or program-level committees and may include an individual faculty member accepting specific students for doctoral-level programs (Michel et al., 2019). Admissions policies and selection rates differ across disciplines and programs.

In recent years, graduate programs have shown a growing interest in applying holistic review to admission decisions, which suggests that the admissions process includes a broad range of factors (Posselt, 2016). Holistic admissions practices hold great potential in helping programs achieve a targeted balance among admitted student cohorts, particularly in terms of student diversity. Relatedly, there has been a good deal of research suggesting that noncognitive measures provide additional predictive value above cognitive assessments while at the same time increasing the diversity of admitted students (see Shultz & Zedeck, 2011, for research in the law school context). Holistic review is considered a useful, effective, and defensible solution for improving diversity following *Grutter v. Bollinger* (2003); however, decentralized admissions processes present unique challenges with implementation, given limited staff and faculty time. The dominant role played by faculty, the large number of applications, the amount of time required for holistic review, and the long-standing culture have all been cited as reasons that holistic review in graduate admissions often relied heavily on test scores (Kent & McCarthy, 2016).

Admission to medical schools and many law schools remains highly competitive, with the most selective schools exceeding a rate of 20 applications per opening. Test scores and undergraduate grades are typically heavily weighted, among all factors considered in admissions. Many programs compute an index of test scores and grades to aid in ranking candidates, but other factors are also considered in final admissions decisions, including grades in college major, personal statement, letters of recommendation, and, in some instances, personal interviews (Zwick, 2006). Note that personal interviews are common in admissions to medical school but are often optional or not employed in admission to other programs.

Admissions Tests for Graduate and Professional Schools

A persistent criticism of graduate admissions is overreliance on test scores and the use of minimum cut scores to advance in the applicant review process. In a review of admissions processes across 10 highly ranked programs, Posselt (2016) disclosed that the influence of test scores extends far beyond what most departments would

admit or what the testing organizations advise. The Council of Graduate Schools found that minimum test scores are widely used “to eliminate a group of applicants before an initial application review . . . a practice largely rumored but sparsely documented” (p. 8).

A few major trends have occurred in graduate school admissions testing since 2010 that are worthy of mention. First, there is an increased call for holistic reviews, which include cognitive and noncognitive factors in admissions, coupled with a desire to increase the diversity of admitted students (Michel et al., 2019). Second, an increasing number of graduate programs have adopted a test-optional policy. Finally, ETS has actively promoted the use of the GRE as an alternative to the GMAT and LSAT in admissions to business programs and law schools, respectively (ETS, 2017, 2020a). Many business schools and some law schools have moved to accept GRE scores in lieu of GMAT and LSAT scores in an effort to attract more nontraditional applicants (Jaschik, 2018; Olson, 2017). Over 55 U.S. law schools accept the GRE in addition to the LSAT for admission, and more than 90% of business schools are estimated to accept either the GRE or the GMAT for admission. Despite the willingness to accept both scores, there is an absence of research examining institutional preferences and use of scores, score comparability, and comparisons of admission rates and success across testing programs. ETS has produced comparison tools to convert GRE scores to both GMAT and LSAT scores; information on sample size and methodology used in each comparison tool was described by ETS (2017, 2020a; as well as by Klieger et al., 2018). However, the Graduate Management Admission Council (GMAC) and the Law School Admission Council (LSAC) have argued that such score conversion tools are flawed (Han, 2022).

Medical and law school applications represent much smaller cohorts, with approximately 55,000 applicants and 23,000 matriculants to U.S. medical schools in 2023–2024 (AAMC, 2023a, 2023b). First-year enrollment across the 203 American Bar Association–approved schools in 2022 was about 38,000, reflecting a decrease from a peak of more than 50,000 students in 2010. There were 62,545 applicants to law school in 2022, which reflects a decrease of about 25,400 applicants from 2010 (LSAC, 2024).

Tests used for admission to graduate and professional schools have a singular purpose—to predict academic success (grades, graduation). Test scores are also used for selection in fellowship programs, for merit scholarships, and by applicants as a guide in selecting among competitive programs. ETS states that scores from the GRE can be used to identify which applicants are academically prepared for graduate-level study and to measure skills required in graduate and professional schools, including business and law. Inappropriate uses of test scores are generally identified by each testing program and include credit by examination, degree conferral, employment decisions, and use as an outcome measure (ETS, 2022). Recently, a number of law schools have withdrawn from the U.S. News rankings. Table 17.4 provides a comparison of the content, sections, scores, score scale, timing, and number of items across graduate and professional admissions tests.

The GRE

The GRE General Test (hereafter referred to as the GRE) is a cognitive test used for admission to graduate schools in the United States and some other countries (ETS, 2023b). It consists of three measures: verbal reasoning, quantitative reasoning, and analytical writing. Verbal reasoning measures the ability to

- analyze and draw conclusions from discourse; reason from incomplete data; identify author's assumptions and/or perspective; understand multiple levels of meaning, such as literal, figurative and author's intent
- select important points; distinguish major from minor or irrelevant points; summarize text; understand the structure of a text
- understand the meaning of individual words, sentences and entire texts; understand relationships among words and among concepts

(ETS, 2023b, Verbal Reasoning section)

with an emphasis on complex verbal reasoning skills. Quantitative reasoning measures the ability to “understand, interpret and analyze quantitative information, solve problems using mathematical models, and apply the basic concepts of arithmetic, algebra, geometry and data analysis,” with an emphasis on quantitative reasoning skills. Analytical writing measures “critical thinking and analytical writing skills, including the ability to articulate and support complex ideas with relevant reasons and examples, and examine claims and accompanying evidence,” with an emphasis on analytical writing skills.

Table 17.4 Graduate and Professional Admissions Tests

Test	Sponsor	Test Sections and Scores (Score Scale)	Description of Test Sections	Notes
Graduate Management Admission Test (GMAT) Focus Edition (Total Score =205–805 ^a)	Graduate Management Admission Council	Data Insights (60–90)	Graphic interpretation, table analysis, multisource reasoning, two-part analysis, integrated reasoning and data sufficiency question types (20 questions, 45 minutes)	The sections are adaptive at the item level. Candidates may select section order. Candidates may bookmark questions in a section for later review; up to 3 answers may be changed. Administered at test centers or at home via remote proctoring.
		Quantitative (60–90)	Problem-solving in applying algebraic and arithmetic knowledge (21 questions, 45 minutes)	
		Verbal (60–90)	This section measures the ability to read and comprehend written material and to reason and evaluate arguments (23 questions, 45 minutes)	

Test	Sponsor	Test Sections and Scores (Score Scale)	Description of Test Sections	Notes
GRE General ^b (Total score = 260–340)	ETS	Analytical Writing (0–6)	A writing assignment to analyze an issue (30 minutes)	Verbal and Quantitative sections are adaptive. Candidates can skip questions or mark them for later review. Administered at test centers or at home via remote proctoring. Candidates can choose which administrations to use in sending scores.
		Verbal Reasoning (130–170)	Ability to analyze and draw conclusions from discourse, reason from incomplete data, understand multiple levels of word meaning, and selecting most distinguishing points, etc. (Section 1: 12 questions, 18 minutes; Section 2: 15 questions, 23 minutes).	
		Quantitative Reasoning (130–170)	Ability to understand, interpret, and analyze quantitative information, problem-solving using math models and basic concepts (Section 1: 12 questions, 21 minutes; Section 2: 15 questions, 26 minutes).	
Law School Admission Test (LSAT) ^c (Total Score = 120–180)	Law School Admission Council	Logical Reasoning (2 Sections)	Ability to examine, analyze, and critically evaluate arguments as they occur in ordinary language (24–26 questions, two 35-minute sections)	Linear digital test. Candidates can skip items and return to them later. The test has been administered at test centers or at home via remote proctoring since August 2023 and will continue through June 2026. A single scale score is reported for the total LSAT.
		Reading Comprehension	Ability to read, with understanding and insight, examples of lengthy and complex materials similar to those commonly encountered in law school (26–28 questions in four sets, 35 minutes)	
		Writing	The test also includes a 50-minute proctored, on-demand writing exam required of all test takers taken remotely and separately from the LSAT. The writing sample is included in the applicant's test record; no score is given.	

(Continued)

Table 17.4 (continued)

Test	Sponsor	Test Sections and Scores (Score Scale)	Description of Test Sections	Notes
Medical School Admission Test (MCAT) (Total score = 472–528)	American Association of Medical Colleges	Biological and Biochemical Foundations of Living Systems (118–132)	Solve problems by combining knowledge of biological and biochemical concepts with scientific inquiry and reasoning skills (59 questions, 95 minutes)	Test is 7 hours and 30 minutes long, with breaks. Linear test administered on computers in test centers. Offered on approximately 30 dates.
		Chemical and Physical Foundations of Biological Systems (118–132)	Integrating chemical and physical foundational concepts with scientific inquiry and reasoning skills (59 questions, 95 minutes)	
		Psychological, Social, and Biological Foundations of Behavior (118–132)	Understanding how psychological, social, and biological factors impact health, research methods, and behavior (59 questions, 95 minutes)	
		Critical Analysis and Reasoning Skills (118–132)	Passages and questions measuring ability to comprehend what is read (53 questions, 90 minutes)	

Note. Information for the GMAT Exam is from *Exam Structure, Content, & Features*, 2023; *Scores*, 2025; and *Understanding Your Score*, 2024b; Graduate Management Admission Council. Information for the GRE General Test is from *The GRE Tests*, 2023c, ETS. Information for the LSAT is from *What to Expect Starting With the August 2024 LSAT*, 2023, Law School Admission Council. Information for the MCAT is from *MCAT Exam Scoring*, 2025a, *What's on the MCAT Exam? Exam Overview*, 2025b; and *What's on the MCAT Exam? PDF Outline*, 2025c, American Association of Medical Colleges.

^a The previous GMAT score scale, prior to the introduction of the *GMAT Focus Edition* in late 2023, was 200–800 (Graduate Management Admission Council, 2024b).

^b The GRE design was shortened in September 2023 from 3 hours and 45 minutes to under 2 hours (ETS, 2023c).

^c The LSAT design changed in August 2024 to eliminate Analogical Reasoning and add a second Logical Reasoning section (Law School Admission Council, 2023b).

In the fall of 2023, the GRE shortened its total testing time to under 2 hours from the 3 hours and 45 minutes it had required. One of the salient features of the GRE has been that for the verbal and quantitative measures, it is adaptive by section with an initial section primarily comprised of questions of medium difficulty; performance on the initial section is used to route test takers into one of three sections of low-, medium-, or high-difficulty questions on the subsequent section. This design allows the GRE to be adaptive at the section level, not at the item level.

The Verbal and Quantitative Reasoning scores are each comprised of two separate sections with a total of 27 items each with total testing time at 41 minutes and 47 minutes, respectively. Previously, the GRE had a total of 80 scored items compared to 54 scored items today. Additional testing time was reduced by removing the unscored

or experimental section used to pretest items and eliminating one of two essay task. Today, an Analytical Writing score is reported from a single 30-minute essay task on analyzing an issue, which requires test takers to evaluate the issue and its complexities and develop an argument with evidence and reasons to support their views (Wendler et al., 2014). GRE test details are also summarized in Table 17.4.

The GRE, then known as the Graduate Record Examinations, were first developed in 1936 as a joint effort in higher education by the graduate school deans of Harvard University, Yale University, Princeton University, and Columbia University and the Carnegie Foundation for the Advancement of Teaching. It was used by the University of Wisconsin in 1938, the first public institution to adopt the GRE. By 1948, over 45,000 students applying to 500 institutions had taken the GRE. The GRE remained a project of the Carnegie Foundation until shortly after the establishment of ETS (then known as Educational Testing Service) in 1947. The GRE was changed from a linear test to an item-level adaptive test in 1993, aiming to improve testing efficiency and the accuracy of estimation of test takers' abilities (Wendler et al., 2014). In 2011, the GRE underwent significant changes (Lewin, 2009), including a new 130–170 scoring scale, the elimination of item types such as antonyms and analogies, the addition of an online calculator for the quantitative section, and the replacement of item-level computer-adaptive testing with section-level adaptive testing (ETS, 2020b). These changes were intended to provide a better test-taking experience and enhance test security. Additionally, the new types of questions in the revised format are intended to test the skills needed in graduate, business, and law school programs (ETS, 2020a). Another feature of the GRE is that it allows test takers to skip questions within a section and change answers within a section. Research suggests that, on average, over 95% of test takers made at least one change to their answers in the verbal reasoning and quantitative reasoning sections; and among those who did change their response(s), 83% were able to improve their verbal reasoning scores and 68% were able to improve their quantitative reasoning scores (Liu et al., 2015).

In addition to its use in general graduate admissions, the GRE was used in admission to more than 1,300 business schools around the world and 91 law schools in the United States as of February 4, 2022. On November 19, 2021, the American Bar Association Council voted to “permit law schools to accept GRE tests scores from applicants in lieu of an LSAT score under Standard 503” (American Bar Association, 2021). Research based on 480 students from 12 institutions shows that both the GRE verbal reasoning and the quantitative reasoning measures were statistically significant predictors of first-year GPA and cumulative GPA for masters of business administration programs (Young et al., 2014). Similarly, research based on 1,587 current and graduated law students from 21 law schools suggests that GRE scores predicted first-year law school GPA when used alone, as well as over and above undergraduate GPA (Klieger et al., 2018). As mentioned earlier, the GRE is administered in Prometric test centers or at home via remote proctoring, which is offered both domestically and internationally with only a few exceptions.

Graduate Management Admission Test

The GMAT is a cognitive test used for admissions into business master and management programs, globally. An updated version of the test labeled the GMAT Focus Edition was released in late 2023¹² (GMAC, 2023). It consists of three 45-minute sections: Quantitative Reasoning, Verbal Reasoning, and Data Insights. The Integrated Reasoning and Analytical Writing sections were removed from the test.

The GMAC, owners of the GMAT, began as an association of 9 business schools in collaboration with ETS in 1953 to develop a standardized test to identify and admit qualified applicants into graduate management programs (GMAC, 2020). The following year, the first GMAT (originally named the Admissions Test for Graduate Business Study) was administered with a testing volume of nearly 3,000 test takers. In 2005, GMAC dissolved its partnership with ETS and selected Pearson and ACT as its new test vendors. In 2018, the number of students taking the GMAT annually peaked at over 200,000, with over 7,000 programs and 2,300 business schools using the GMAT for admission decisions (GMAC, 2018), dropping significantly with the onset of COVID.

The GMAT has gone through various revisions over the years (GMAC, 2020). Notably, the Analytical Writing section was added in 1994. A computer-adaptive version of the GMAT was first introduced to the market in 1997. In 2012, the Integrated Reasoning section was added in response to survey results of nearly 750 management faculty stressing the importance of these skills for management professionals (GMAC, 2011).

In response to COVID-19-related test closures, GMAC began offering an at-home administration option of the GMAT in April 2020. Initially offered as a temporary response, GMAC made this a permanent option and reintroduced test center-based administrations.

GMAC introduced the GMAT Focus Edition in late 2023, composed of three 45-minute multiple-choice sections: Verbal Reasoning, Quantitative Reasoning, and a new section, Data Insights, which replaces the Integrated Reasoning and Analytical Writing Assessment (essay) sections and shortens the test by nearly 1 hour (GMAC, 2023). The Data Insights section presents text, numeric, and graphical information in business scenarios and asks test takers to analyze, interpret, and apply the data. Similar to the GRE, the Quantitative Reasoning and Verbal Reasoning sections of the GMAT exam are computer adaptive; however, for this assessment, the adaptive algorithm works at the item level, selecting items based on the test taker's performance after each item. Three section scores are reported on a 60- to 90-point scale and a GMAT total score is reported on a 205–805 score scale in 10-point increments. Table 17.4 provides additional details on section content and scales. Unlike the previous item-level GMAT CAT, the GMAT Focus Edition allows test takers to mark specific questions within a section and return to them later with the option to change up to three question responses per section (GMAC, 2023).

Law School Admission Test

The LSAT was first administered in 1948 to supplement undergraduate GPA in assisting law schools' admissions professionals (Reese & Cotter, 1994). The

test is owned and operated by the LSAC, a nonprofit corporation in Newtown, Pennsylvania, with more than 200 law schools in the United States and Canada as members. ETS was charged with test development, administration, and scoring through 1979 when LSAC brought these activities in-house. The test's content has been largely unchanged for about 30 years, but two major changes were introduced in July 2019. First, the LSAT transformed to exclusive digital administration utilizing Microsoft Surface Go tablets (Margolis, 2018), with nine national administrations annually. Tablets are stored centrally and distributed to university-based test centers prior to the administration. Second, students taking the LSAT were able to complete the required unscored writing sample in a separate and remote administration. The Digital LSAT consists of four 35-minute sections: two logical reasoning sections, one reading comprehension section, and a variable section used to pretest items that are not operationally scored. Each section is composed solely of multiple-choice items, but students now select the correct option by tapping the screen. A 50-minute required and unscored writing sample is administered digitally and remotely, separate from the test administration.

Law school admissions have fluctuated greatly and the number of LSAC test administrations has also varied over the past 30 years, ranging from 101,000 to over 171,000. Between 1987 and 2019, testing volumes changed an average of nearly 7% annually. Volumes decreased significantly in the late 1990s, increasing in 2002–2011 to a high of over 170,000 and decreasing again to just over 100,000 students in 2014–2017 before rebounding in 2018–2019 (LSAC, 2020). Finally test administrations reached a near-record 169,781 in 2020–21 rebounding from Covid which created barriers to accessing all admissions testing (Kelly & Morgan, 2024). LSAC maintains college transcripts, letters of recommendations, resumes, and personal statements and processes academic credentials for an average of 60,000 law school applicants annually (Anthony et al., 2016). LSAC periodically surveys law school faculty to determine what skills are most essential for success in law school classes; the most recent survey found that higher order critical reading and reasoning skills assessed by the test were ranked highest (LSAC, 2019). Questions used on the LSAT emphasize logic and reasoning skills. Unlike many admissions tests, there is a single scale score on the LSAC (120–180 point scale) computed across 75–76 operational items.

During the pandemic, the LSAT eliminated the variable section and transitioned exclusively to home testing, rebranding the test LSAT-Flex and noting that strict score equivalence with scores from the prior LSAT was not established. In August 2021, the test reintroduced the variable section, retained at-home administration, returned to its original name without the Flex designation, and established score equivalence across versions (Camara & Mattern, 2022). Similar to the GMAC and GRE, in 2023, LSAC introduced dual delivery at home with remote proctoring and test centers during seven 1- or 2-day testing windows. In 2023, the Analogical Reasoning Section was replaced with a second section measuring Logical Reasoning as a result of a settlement to a 2019 lawsuit charging the item type disadvantaged a legally blind test taker (Knox 2023);

and in 2024, a new writing sample was introduced but remained unscored. Table 17.4 provides additional information on the LSAT.

Medical College Admission Test (MCAT)

Introduced in 1928 as the Scholastic Aptitude Test for Medical Students, the admissions test for medical colleges was designed to mitigate attrition rates as high as 50% at some medical schools and included eight separate sections, which were combined into a single score (McGaghie, 2002). Renamed the Medical College Admission Test in 1948, the test had four sections (verbal, quantitative, science, and understanding modern society), each reported on a 200–800 scale. Several other revisions to MCAT occurred subsequently, with the latest major changes introduced in 2015. There was a shift in the focus of constructs from what students know to how well they could apply their knowledge, as well as the introduction of new concepts in biochemistry. In addition, a new behavioral and social science section was added to existing sections, and a new section score scale was introduced (118 to 132) to prevent comparisons to the previous version of the test (Association of American Medical Colleges, 2015). Table 17.4 provides additional information on the four sections, section scale, and total score scale. The MCAT requires more than 6 hours to complete in a single sitting at commercial test centers (Bingham et al., 2012).

A survey of medical school admissions officers found that MCAT total score and undergraduate GPA (total and science/math) were the most important and valued predictors for admission, along with personal interviews at the last stage in the admission process; however, admissions in professional schools now consider many nonacademic factors, suggesting a move to a more holistic approach (Monroe et al., 2013). In 2022, the Association of American Medical Colleges introduced a situational judgment test (named the PREview professional readiness exam) for use by several medical schools in the 2022–2023 admissions cycle. PREview is a standardized exam that presents a series of hypothetical scenarios students may encounter in medical school and asks test takers to evaluate the effectiveness of a series of behavioral responses to each scenario associated with eight competencies (e.g., resilience and adaptability, capacity for improvement, service orientation). It is a remote-proctored, online exam, administered separate from the MCAT (Association of American Medical Colleges, 2022).

RELIABILITY, VALIDITY, AND FAIRNESS OF UNDERGRADUATE AND GRADUATE ADMISSION TESTS

Given the high-stakes nature of admission tests, it is essential that the design and development of these assessments are in adherence with professional standards, producing scores that are highly reliable and have strong validity evidence supporting intended uses (American Educational Research Association [AERA] et al., 2014; see also Huff et al., this volume, for discussion of best practices in test development). Undergraduate and graduate programs use admission test scores to understand applicants' preparedness to succeed in their programs, helping to inform which applicants are admitted.

Given this use, evidence based on relations to other variables is a critical component of the validity argument for admission tests. As such, there is a significant body of literature demonstrating the validity of admissions test scores to predict future educational performance, overall and for student subgroups. This section summarizes the psychometric properties of undergraduate and graduate admissions tests as they pertain to reliability, validity, and fairness.

Reliability

Reliability estimates for undergraduate and graduate admission tests are summarized in Table 17.5. As discussed elsewhere, the ACT, SAT, GRE, and GMAT all underwent significant redesigns between 2023 and 2025, which entailed reducing testing time and the number of items, overall and per sections. In many instances, section score reliabilities were reduced from earlier designs in exchange for other benefits (e.g., less testing time, reduced speededness). Both at the undergraduate and at the graduate level, standardized tests used for admissions are highly reliable, with estimates for the total or composite score typically reaching values of .90 or higher, exceeding the minimum reliability thresholds proposed for high-stakes applications in the past (Nunnally, 1978).

Table 17.5 Reliability of Undergraduate and Graduate Admissions Tests

Test	Test Sections	Reliability
ACT	English	.88
	Math	.88
	Reading	.84
	Science	.85
	Composite	.96
SAT	Evidenced-Based Reading and Writing	.94*
	Math	.90*
	Total	.96*
Graduate Management Admission Test (GMAT)	Quantitative	.90
	Verbal	.89
	Data Insights	.86
	Total	.94
GRE	Analytical Writing	.76
	Verbal Reasoning	.87
	Quantitative Reasoning	.93
Law School Admission Test (LSAT)	Total Test Score	.90

(continued)

Table 17.5 (continued)

Test	Test Sections	Reliability
Medical College Admission Test (MCAT)	Biology and Biochemical Foundations of Living Systems	.82–.86
	Chemical and Physical Foundations of Biological Systems	.82–.86
	Psychological, Social, and Biological Foundations of Behavior	.82–.86
	Critical Analysis and Reading Skills	.82–.86
	Total Score	.95

Note. Data for the ACT Test are from *Initial Evidence Supporting Interpretations of Scores From the Enhanced ACT Test* (ACT Research Report, p. 12), by J. Allen and T. Cruce, 2025, ACT. Data for the SAT are based on the version that existed prior to the introduction of the digital SAT in March 2023 internationally and in March 2024 domestically, and are in the *SAT Suite of Assessments Technical Manual Appendixes* (p. 70, Table A-6.2), by College Board, 2017b. Reliability coefficient estimates are not reported in the technical manual for the new digital SAT, but the reliability of linear digital scores is comparable to that those for its multistage tests per the *Digital SAT Suite of Assessments: Technical Manual* (p. 48), by College Board, 2024c. Data for the GMAT are from *GMAT Focus Psychometric Updates* [Seminar presentation], by K. T. Han, 2025, October 17, GMAT Test Preparation Summit, Reston, VA, United States. Data for the GRE are an average of the reliability estimates for all multi-stage tests administered between September 2023 and May 2024 to reflect the reliability of the shortened GRE, and are in the *GRE Guide to the Use of Scores* (p. 34, Table 4A), by ETS, 2024. Data for the LSAT are from *2021–22 Interpretive Guide for LSAT Score Users*, by Law School Admission Council, 2022. Data for the MCAT are from *The MCAT Exam: Year at a Glance*, by Association of American Medical Colleges, 2015.

Reliabilities exceeding .90 maybe unrealistic and unnecessary for section scores since total scores are primarily used in admissions decisions. For more detailed information, consult the references listed in the notes section of Table 17.5. (See also Lee & Harris, this volume, for a discussion of reliability.)

Validity

For each of these testing programs, a substantial collection of research evidence exists demonstrating the relationship between admission test scores and subsequent higher education success. This section summarizes this body of literature, with common themes emerging. First, test scores are predictive of future performance across multiple indicators of success (e.g., first-year grades, cumulative GPA, retention, graduation), though the majority of research tends to focus on first-year GPA. This is largely due to the expediency with which first-year grades can be collected as compared to more distal outcomes, coupled with more standardization in course taking in the first year as compared to later years. That said, it is still critical and common practice to investigate the validity of test scores for predicting additional metrics of student success. Second, the research points to the incremental validity of test scores for predicting success, above and beyond other admission criteria, most notably prior grades. In particular, studies have examined the degree to which test scores add to the prediction of first-year GPA above HSGPA in the context of undergraduate admissions and above undergraduate GPA (UGPA) in the context of graduate admissions. Results highlight the unique information provided by test scores, underscoring the value of taking a multiple-measures approach in the admission decision

process. Third and finally, for graduate programs, the research evidence suggests that test scores are more predictive of graduate performance as compared to UGPA, whereas HSGPA tends to be slightly more predictive of college success as compared to test scores in the undergraduate context. Refer to Table 17.6 for a summary of validity evidence across the testing program for a focal outcome of interest: first-year GPA; a deeper review of existing validity evidence for each testing program is provided next. (See also Lane & Marion, this volume, for discussion of validity and validation.) Most of the evidence described is based on older test designs prior to changes introduced after 2023. Similar data on the shortened ACT, GRE, and GMAT will be forthcoming.

ACT

Numerous large-scale, national studies have been conducted linking ACT scores to success in college, including performance in the first year, credit-bearing courses, first-year GPA, retention, progress toward a degree, cumulative GPA, and degree completion (e.g., Allen, 2013; Radunzel & Noble, 2012; Sawyer, 2010, 2013; Westrick et al.,

Table 17.6 Validity of Undergraduate and Graduate Admissions Tests for Predicting First-Year Grade Point Average (GPA)

Test	Test Correlation	Prior GPA Correlation	Multiple Correlation
ACT	.51	.61	.64
SAT	.57	.54	.66
Graduate Management Admission Test (GMAT)	.48	.30	.53
GRE	.34–.38	.33	n/r
Law School Admission Test (LSAT)	.60	.42	.66
Medical College Admission Test (MCAT)	.57	.52	.65

Note. For ACT and SAT, first-year GPA is freshman year in undergraduate programs. For other tests, GPA reflects first year of graduate or professional school study. ACT correlations are for paper-based version of the test, prior to the 2024–2025 enhancements, and are corrected for indirect range restriction and criterion unreliability values. Data are from “The Road to Retention Passes Through First-Year Academic Performance: A Meta-Analytic Path Analysis of Academic Performance and Persistence,” by P. A. Westrick, F. L. Schmidt, H. Le, S. B. Robbins, and J. M. Radunzel, 2021, *Educational Assessment*, 26(1), p. 43, Tables 2 and 3. SAT correlations are corrected for restriction of range. Data are from *Digital SAT Suite of Assessments: Technical Manual* (p. 172, Table 8.12), 2024c, College Board. GMAT correlations are for the version prior to the Focused Edition, for which data are not available at this time. Data for the prior version are from *GMAT Exam User Guide for Institutions* (p. 9, para. 5), by Graduate Management Admission Council, 2018. GRE correlations are for the prior design, and are corrected for range restriction and criterion unreliability. Only bivariate correlations between individual GRE sections and first-year graduate GPA are reported. Multiple correlations were not reported (n/r). For predicting the unit-weighted composite of cumulative graduate GPA and faculty ratings, the multiple correlation for three GRE scores was .45; adding undergraduate GPA increased the multiple correlation to .50. Data are from “A Comprehensive Meta-Analysis of the Predictive Validity of the Graduate Record Examinations: Implications for Graduate Student Selection and Performance,” by N. R. Kuncel, S. A. Hezlett, and D. S. Ones, 2001, *Psychological Bulletin*, 127(1), p. 169, Table 2, and p. 175, Table 9. LSAT correlations are corrected for multivariate range restriction. Data are from *Summary of 2017, 2018, and 2019 LSAT Correlation Study Results* (2nd ed., p. 24, Table 3.2b), 2023a, Law School Admission Council. MCAT correlations are corrected for range restriction. Data are from “The Validity of Scores From the New MCAT Exam in Predicting Student Performance: Results From a Multisite Study,” 2020, by K. Busche, M. L. Elks, J. T. Hanson, L. Jackson-Williams, R. S. Manuel, W. L. Parsons, D. Wofsy, and K. Yuan, in *Academic Medicine*, 95(3), p. 394, Figure 3.

2015, 2021). For example, Allen (2013) showed that students who earn higher ACT scores are more likely to earn a B or higher in first-year, credit-bearing courses in related content areas. In addition to specific course grades, students with higher ACT scores are more likely to earn higher GPAs in the first year of college (Sawyer, 2010, 2013; Westrick et al., 2015, 2021). In particular, based on nearly 170,000 students attending one of 50 higher education institutions, Westrick et al. (2015) estimated a mean correlation of .51 for ACT Composite score with first-year GPA, after correcting for multivariate restriction of range. In a follow-up study based on the same data set, Westrick and colleagues (2021) demonstrated the unique contribution of ACT scores above and beyond HSGPA in terms of predicting first-year GPA. In particular, they estimated correlations of .51 for ACT, .61 for HSGPA, and .64 for the combination of the two measures for predicting first-year GPA; all reported correlations were corrected for indirect range restriction and criterion unreliability.

A good deal of evidence also exists demonstrating the relationships between ACT scores and more long-term college outcomes, even after controlling for HSGPA (Mattern & Allen, 2016). For example, Radunzel and Noble (2012) showed that students with higher ACT scores were more likely to achieve a higher cumulative GPA (i.e., 3.00, 3.50, and 3.75) and were more likely to earn a college degree within 6 years. Finally, accompanying ACT's announcement that it is exploring additional test features such as superscoring, section retesting, and online testing on national test dates (ACT, 2019b), a handful of validity studies supporting the new test options have been published (Mattern et al., 2018; Mattern & Steedle, 2020; Radunzel & Mattern, 2020a, 2020b). Validity evidence for the ACT Enhancements were not yet available at the time this volume was published.

SAT

Similar to the ACT, countless studies have been conducted evaluating the predictive validity of SAT scores, alone and in combination with HSGPA, in terms of college success (e.g., Berry & Sackett, 2009; Bridgeman et al., 2000; Kobrin et al., 2008; Mattern & Patterson, 2014; Westrick et al., 2019). These studies demonstrate that SAT scores are predictive of both short- and long-term college success, including course grades, first-year GPA, retention, and degree completion, alone and in combination with HSGPA.

With the redesign of the SAT in 2016, College Board has been conducting numerous studies to document the predictive validity of the revised assessment (Marini et al., 2019; Shaw et al., 2016; Westrick et al., 2019, 2020). Based on over 223,000 students attending one of 171 postsecondary institutions, results from the first national validity study of the redesigned SAT found a correlation of .51 for SAT total and .53 for HSGPA for predicting first-year GPA (Westrick et al., 2019). When the two measures were used in combination, the multiple correlation increased to .61, demonstrating the unique predictive power of each measure; reported correlations were corrected for multivariate range restriction. In preparation for the domestic launch of the digital SAT in

March 2024, College Board conducted a concurrent validity study with 11 undergraduate institutions representing nearly 2,000 first-year, first-time students (College Board, 2024c; Marini et al., 2023). Corrected correlations for restriction of range (and uncorrected correlations) between the Digital SAT with first-year GPA were:

- .57 (.39) SAT Total Score with FGPA
- .53 (.32) SAT Reading and Writing Section Score with FGPA
- .55 (.35) SAT Mathematics Section Score with FGPA
- .66 (.46) SAT and HSGPA with FGPA
- .54 (.27) HSGPA with FGPA
- .12 (.19) SAT incremental validity beyond HSGPA with FGPA.

The study indicated that the relationship between the digital SAT and first-semester GPA was comparable to that of the paper-and-pencil version and that the digital SAT adds incrementally to the prediction of college performance above and beyond HSGPA, providing initial validity evidence for the use of the digital SAT for college admissions. Digital SAT Total scores and HSGPA individually have moderately strong, positive relationships with the number of first-year credits earned, with correlations of .45 and .39, respectively, and a multiple correlation of .50 when employed together (College Board, 2024c).

GMAT

Hundreds of studies have been conducted demonstrating the utility of GMAT scores for predicting success in graduate business programs (Kuncel et al., 2007; Oh et al., 2008; Talento-Miller, 2017). For example, based on meta-analytic results including over 400 independent samples and nearly 65,000 students, Kuncel et al. (2007) found that both GMAT scores and UGPA were predictive of graduate school outcomes including first-year graduate GPA, cumulative graduate GPA, and persistence. For the first-year graduate GPA results, they reported correlations of .47 for GMAT Total and 0.35 for UGPA, after applying corrections for direct range restriction and criterion unreliability. They concluded that the combination of GMAT scores and UGPA would likely result in superior predictive power. Based on the same data set, a follow-up study by Oh and colleagues (2008) suggested that the predictive power of the GMAT is even higher, estimating a correlation of .51 between GMAT Total and first-year graduate GPA when applying different restrictions of range assumptions. GMAC (2018) reported similar findings, with a correlation of .48 for GMAT Total and .30 for UGPA, as well as a multiple correlation of .53 when the two measures are used in combination to predict first-year graduate GPA.

More recently, a national validity study including 28 graduate business programs was conducted, and the results aligned with previous findings (Talento-Miller, 2017). In particular, GMAT Total is a strong predictor of graduate GPA (.38) and shows a stronger relationship with graduate performance as compared to UGPA (.32). Moreover, this study provided validity evidence in support of the Integrated Reasoning and

Analytical Writing sections, reporting median correlations with graduate GPA of .27 and .13, respectively. Finally, the combination of the four GMAT section scores and UGPA resulted in the strongest prediction of graduate GPA, with a multiple correlation of .51. Predictive validity for the newly introduced GMAT Focus Edition was not available at this time.

GRE

Many studies have investigated the GRE scores' prediction of important academic outcomes in graduate programs, such as first-semester GPA, first-year GPA, cumulative GPA, progress in the program, comprehensive examination performance, advisor and instructor ratings, research productivity, degree attainment, and time to degree (e.g., Klieger et al., 2014; Kuncel et al., 2001, 2010; Powers, 2004; Powers & Fowles, 2000). For instance, a meta-analysis consisting of 1,753 independent samples of over 80,000 students showed that both GRE verbal reasoning and quantitative reasoning were strong predictors of first-year and cumulative graduate GPA and that the predictive validity of GRE scores was as strong as that of UGPA (Kuncel et al., 2001). Additionally, the study demonstrated the incremental validity of GRE scores above and beyond UGPA in the prediction of cumulative graduate GPA.

Another predictive validity study of the GRE analyzed data from 10 public universities in Florida based on 21,127 master's students and 4,229 doctoral students from 28 disciplinary domains (Klieger et al., 2014). The results showed that GRE analytical writing was as strong a predictor of graduate GPA as verbal reasoning and quantitative reasoning scores. It is unclear how graduate programs use analytical writing scores in admissions, yet research shows that the analytical writing score is a strong predictor of graduate GPA and is also a good indicator of students, likelihood to be in academic peril, defined as having an average C+ or lower GPA (Bridgeman, 2016; Klieger et al., 2014). Several meta-analyses of GRE's predictive validity have reported small to moderate, positive correlations between scores and graduate first-year and cumulative GPA ($.20 \leq r \leq .36$). A more recent meta-analysis concluded that GRE validities have declined slightly over time, with an average correlation between GRE and student outcomes of .22 in 1957 compared to .15 in 2022. Similarly, the average correlation between GRE and GPA decreased from .25 in 1957 to .16 in 2022 (Feldon et al., 2023).

Researchers have also investigated the GRE's use in graduate admission in international contexts. Results based on a leading research university in Singapore revealed that both GRE verbal reasoning and quantitative reasoning scores predicted first-semester and first-year graduate GPA (Liu, Klieger, et al., 2016). They also predicted program standing (students in good standing are those who never received an academic warning, academic probation, or dismissal). For example, the difference in GRE quantitative reasoning score between students in good standing and those not in good standing was as large as .86 standard deviations for master's programs. Another study analyzed a multinational sample of students at

a university in the Netherlands, and the results indicated that the GRE analytical writing score predicts graduate GPA and master's thesis grades above and beyond UGPA (Schwager et al., 2015; Zimmermann et al., 2017). Furthermore, such prediction is independent of students' SES as indicated by the highest parental degree. Additional empirical validation studies on the shortened GRE should be available in the future.

LSAT

Routinely, the LSAC conducts national validity studies examining the relationship between LSAT scores and first-year performance in law school, alone and in combination with UGPA (Anthony et al., 2013, 2016; LSAC, 2023a; Stilwell et al., 2007, 2009, 2011). Based on the data from the most recent national validity study, which included 163 schools that participated in LSAT Correlation Studies in the 2019 cycle, LSAC reported a correlation of .40 for LSAT and .26 for UGPA in terms of predicting first-year law school GPA (2023a, p. 24, Table 3.2a). When combined, the multiple correlation of LSAT scores and UGPA with law school GPA increased to .49. After correcting for restriction of range, the correlation between LSAT and first-year law school GPA increased to .60; a similar jump was seen for UGPA (.42). A corrected multiple correlation between LSAT and UGPA with first-year law school GPA of .66 was reported (p. 24, Table 3.2b). Consistent with previous LSAC validity studies, the results highlight the superior predictive power of LSAT scores as compared to UGPA and indicate that the combination of the two measures results in the best prediction of law school performance.

MCAT

A good deal of research has been conducted demonstrating the value of MCAT scores for predicting important outcomes for medical students, including grades earned in medical school, performance on the United States Medical Licensing Examination, and unimpeded progress toward graduation (Donnon et al., 2007; Dunleavy et al., 2013; E. R. Julian, 2005). Across these various operational definitions of medical school success, results of these studies have consistently found that MCAT Total scores are predictive of medical school performance and that they have larger validity coefficients as compared to the results based on UGPA. Moreover, MCAT Total scores provide incremental validity above and beyond UGPA, with the combination of the two resulting in the best prediction of medical school performance.

Similar to several of the other testing programs, the MCAT went through a major revision, requiring the collection of new validity evidence to support the use of the revised assessment for medical school admissions. In 2013, a concurrent pilot study was conducted with 11 participating institutions, providing initial evidence of the predictive validity of the new Psychological, Social, and Biological Foundations of Behavior section (Association of American Medical Colleges, 2015). The results

indicated that the new section correlated more highly with medical school grades (.41) as compared to scores from the old exam (ranging from .12 to .30). Busche et al. (2020) conducted an initial validity study of the new 2015 MCAT assessment, examining the validity of MCAT scores, alone and in combination with UGPA, in terms of predicting first-year medical school performance and on-time progression to the second year. The study included roughly 1,000 students who took the new MCAT and entered medical school in 2016 at one of the 16 participating institutions. The results found MCAT Total scores to be predictive of first-year medical school GPA, with a median correlation coefficient of .57 as compared to .52 for UGPA. Based on the combination of both measures, the multiple correlation was .65, highlighting the unique predictive power of both measures. Reported correlations were corrected for range restriction.

Fairness

The fairness of standardized tests is often heatedly debated in the popular press and is the focus of much research of admission tests (refer to Zwick and Rodriguez & Thurlow, this volume, for a more in-depth discussion of fairness in educational measurement and score interpretation). The belief that standardized tests are biased tends to revolve around the finding that there are large performance differences by demographic characteristics (e.g., race/ethnicity, SES). This is true for all testing programs (Association of American Medical Colleges, 2015; ACT, 2024; Busche et al., 2020; College Board, 2017a; Dalessandro et al., 2014; ETS, 2020b; Talento-Miller, 2017), as well as for other measures of educational achievement, such as grades and educational attainment level. That said, subgroup differences, in and of themselves, do not establish test bias (AERA et al., 2014). However, when such findings are observed, follow-up analyses should be conducted to determine what may be contributing to these differences. Subgroup differences by ethnicity/race or SES “do not originate with college admissions tests but are instead reflective of long-standing, systemic variation in educational resources and opportunities that also manifest themselves in achievement disparities on standardized tests at the K–12 level” (Bennett, 2022, p. 183).

More globally, admission testing programs tend to follow a similar protocol to ensure the fairness of their tests (e.g., ACT, 2024; College Board, 2017a; GMAC, 2018; Wendler et al., 2014). This includes providing candidates with appropriate testing accommodations for special populations, conducting extensive item and form reviews by independent fairness experts, analyzing items for differential item functioning, and examining test data for subgroup differences, differential validity, and differential prediction. More detailed research on the fairness of admission tests with a focus on differential validity and prediction results is described below for each testing program. Most data are based on older test designs prior to changes introduced after 2023.

ACT

Differential validity and prediction by student subgroups have been the focus of much research on the ACT (e.g., Allen, 2016; Radunzel & Noble, 2013; Sanchez, 2013). For example, Sanchez (2013) examined the degree to which the ACT exhibited differential prediction of first-year GPA by race/ethnicity, gender, and income level. Results showed that the strength of the relationship was similar across subgroups, with slight overprediction for underrepresented racial/ethnic minority students, males, and low-income students. Based on the same student subgroups, Radunzel and Noble (2013) reported similar results when examining the differential prediction of more distal college outcomes, including cumulative GPA and degree completion. A subsequent study by Mattern et al. (2017) found that the underprediction of female performance was reduced roughly by half after controlling for conscientiousness. Contrary to the belief that test scores are biased against underserved students given lower average scores, research consistently shows that underserved students tend to perform worse in college than predicted based on their ACT scores.

SAT

Differential validity and prediction results for the SAT mirror the ACT findings. In particular, the strength of SAT scores for predicting important college outcomes, including first-year GPA, cumulative GPA, and graduation, is similar across student subgroups (Marini et al., 2019; Mattern et al., 2008; Mattern & Patterson, 2014; Young, 2004). SAT scores tend to slightly overpredict college performance for underrepresented racial/ethnic minority students, students from lower SES backgrounds, and males; the extent of overprediction associated with HSGPA exceeds that of SAT scores for underrepresented racial/ethnic minority students. Various explanations for differential prediction have been offered, such as differences in course-taking behavior and noncognitive factors (Keiser et al., 2016).

GMAT

The degree to which the relationship between GMAT scores and graduate school performance varies for relevant student subgroups has been the focus of numerous research studies. For example, in their 2007 meta-analysis, Kuncel et al. tested whether the relationship between GMAT scores and first-year graduate GPA was moderated by gender, native language, full-time status, and undergraduate major. The results indicated that the predictive strength of GMAT scores did not vary by student subgroups except for a slightly stronger relationship for part-time students.

More recently, Talento-Miller (2017) examined the differential validity and differential prediction of GMAT scores in terms of graduate GPA by gender, race/ethnicity, citizenship, native language, and age. Based on data from 28 business programs, the results indicated that the predictive strength of GMAT Total scores is similar across subgroups, with slightly higher correlations for older students (≥ 31) and slightly lower

correlations for non-native English speakers and students who were citizens of East or Southeast Asia. In general, the results support the predictive validity of GMAT scores, overall and for student subgroups.

GRE

Prior research has also examined GRE's prediction by common subgroups such as gender and ethnicity. For example, Burton and Wang (2014) examined GRE's prediction of first-year GPA and faculty ratings in the mastery of the discipline, professional productivity, and communication skills across five disciplinary areas (biology, chemistry, education, psychology, and English). Results did not show consistent over- or underprediction for gender groups. Also, after course taking was controlled within a discipline, the gender prediction differences largely disappeared. The findings showed sizable overprediction for African Americans. However, the authors speculated that the sample size for this group may have had an impact on such conclusions. Kuncel and Hezlett (2007) reported that underprediction for females was observed at the undergraduate level but not at the graduate level and cited differential disciplinary choice and course selection as possible reasons accounting for the differential gender prediction.

LSAT

In addition to examining the overall validity of LSAT scores for predicting first-year GPA among law students, the LSAC also regularly investigates the degree to which LSAT scores exhibit differential prediction of first-year law school GPA by relevant subgroups, alone and in combination with UGPA. Two reports were recently published investigating this issue by gender and racial/ethnic subgroups using data from schools participating in the LSAT Correlation Studies from 2012 to 2015 (Rahman & Trierweiler, 2017; Trierweiler & Rahman, 2017). Encompassing data from 148 law schools with sufficient racial/ethnic sample sizes, the results indicated the LSAT first-year GPA validity coefficients were similar across racial/ethnic subgroups (Trierweiler & Rahman, 2017). Both LSAT scores and UGPA overpredicted first-year GPA for underrepresented racial/ethnic minority students, with the combination of the two measures resulting in the least amount of differential prediction.

As for the analyses by gender (Rahman & Trierweiler, 2017), the results were based on data from 158 law schools. Similar to the racial/ethnic findings, the results indicated the LSAT first-year GPA validity coefficients were similar for males and females. In terms of differential prediction, LSAT scores, alone and in combination with UGPA, exhibited minimal prediction error by gender, supporting the validity and fairness of LSAT scores for use in law school admission decisions.

MCAT

Prior studies have examined the degree to which MCAT scores exhibit differential validity, with results indicating comparable validity across racial/ethnic subgroups (Busche

et al., 2020). However, with the introduction of the new MCAT in 2015, the collection of evidence supporting the validity and fairness of new MCAT scores is essential. In response to that research gap, Busche and colleagues (2020) not only investigated the overall predictive validity of the new MCAT scores but also examined whether new MCAT scores exhibited differential prediction of first-year medical GPA and on-time progression to Year 2 by demographic characteristics (gender, race/ethnicity, and highest parental education level). Based on an analysis of mean residuals, there was no evidence of differential prediction by the subgroups examined; none of the mean residuals were significantly different from zero.

PLACEMENT TESTS

Placement Decisions: Remediation Versus Credit-Bearing Courses

According to the *Standards* (AERA et al., 2014), placement tests are designed to be efficient and usually cover only a subset of prerequisite content taught in high school. Postsecondary institutions may use scores to determine student eligibility to enter credit-bearing courses rather than remedial developmental courses or to determine the appropriate initial course in a sequenced area of study (e.g., English, foreign language, mathematics).

Historically, placement in remedial or college-level courses has been based on a single placement test score, often locally determined through a study or faculty judgment. Remedial courses may be helpful to some students, but they also require students to make a substantial investment of time and money that could otherwise be applied to college-level coursework. Studies have suggested that the effects of remedial courses on student outcomes are at best mixed for those who are thought to be on the cusp of needing additional academic support. Students who enroll in one or more remedial courses must still pay tuition without earning credits toward graduation and remedial coursework may exhaust students' financial aid before they graduate, reducing their graduation rates (Attewell et al., 2006). Colleges also incur a large financial burden from developmental programs, estimated at more than \$4 billion in 2015 (Rodriguez et al., 2015).

The high cost in dollars and opportunity associated with remedial courses spurred legislation and policies that sought to limit remediation by eliminating remedial courses at some institutions (e.g., 4-year colleges), require evidence of readiness for college admissions (e.g., ACT/SAT or placement test scores), or require the use of multiple measures for placement decisions. While the number and percentage of students placed into remediation show a moderate decrease since 2010, nearly 70% of new students entering a 2-year college each fall are assigned to such programs (Chen & Simone, 2016; Rodriguez et al., 2015).

Bailey et al. (2010) examined the enrollment patterns of 257,672 first-time credential-seeking students who began their enrollment in fall 2003 to fall 2004 in 57 colleges that participated in a developmental program entitled "Achieving the

Dream.” Student enrollments and course completions were tracked for 3 years. The researchers found that about 30% of students referred to developmental education did not enroll in any remedial course, and only about 60% of referred students enrolled in the remedial course to which they were referred. The results also show that more students exit their developmental sequences because they did not enroll in the first or a subsequent course than because they failed or withdrew from a course in which they were enrolled. Bailey et al. (2010) also found that students who enrolled in a college-level class despite a recommended placement in remedial courses were slightly less likely to pass the course than students who were placed directly into the college-level course by virtue of passing the placement test but were much more successful in the course than students who complied with their remedial placement, because relatively few students who entered remediation ever attempted the college-level course. Despite the prevalence of remedial programs in colleges, studies of program effectiveness and the validity of placement tests assigning students to such programs have produced at best mixed results, with most studies suffering from small samples and a lack of rigor (Scott-Clayton, 2012). A more comprehensive study of remediation explored the interaction of remediation and academic preparation, finding that students who exhibited poor precollege academic preparation (as measured by high school grades, the highest math course taken in high school, and college admission test scores) and completed remedial programs fared better on a range of college outcomes than similarly prepared students who did not complete remediation programs; however, these findings did not hold for students who had moderate or strong precollege academic preparation and were assigned to remedial courses (Chen & Simone, 2016).

In 2012, the National Assessment Governing Board commissioned a college survey to determine which placement tests and cut scores were most prevalent. The study documents differences across 2-year and 4-year institutions (Fields & Parsad, 2012). Table 17.7 illustrates that 80% of 2-year institutions use a placement test in math compared to 65% of 4-year institutions. ACT math was used at about a quarter of institutions (2-year and 4-year), whereas the SAT was being used at 20% of 4-year institutions but only 12% of 2-year institutions. Seventy-three percent of 2-year institutions reported using a placement test in reading as compared to less than 40% of 4-year institutions. ACT’s Compass and Asset and College Board’s ACCUPLACER placement tests were the most popular instruments at 2-year colleges, but both ACT tests were discontinued because ACT cited research showing placement tests, in general, are not as effective at determining readiness as previously thought (Fein, 2015). Of course, these data are now over 10 years old, and patterns in usage may have changed.

Given that test scores tend to be only moderately predictive of course success, concerns about the degree to which test scores lead to incorrect placement decisions have surfaced, especially in light of the poor educational outcomes for students placed in remedial college courses (Barnett & Reddy, 2017). Placement tests have been found

Table 17.7 Estimated Percentage of U.S. Postsecondary Institutions Using Selected Math and Reading Tests for Placement in Fall 2011

Institutional Level	Est. Number of Institutions	% Using Any Math Test	ACT Math	SAT Math	ACCUPLACER Elementary Algebra	ACCUPLACER College Math	Compass Algebra	Compass College Algebra	Other Math
All institutions	3,650	71	23	17	16	5	20	4	22
2-year	1,470	80	23	12	24	7	34	8	16
4-year	2,180	65	24	20	11	3	10	2	26
Institutional level	Estimated Number of Institutions	% Using Any Reading Test	ACT Reading	SAT Critical Reading	ACCUPLACER Reading Comprehension	ASSET Reading Skills	Compass Reading	Other Reading	
All institutions	3,650	53	16	11	19	9	22	10	
2-year	1,470	73	21	10	29	19	43	12	
4-year	2,180	39	13	12	12	2	9	8	

Note: The number of institutions may not sum to totals because of rounding or suppressed data. Adapted from *Tests and Cut Scores Used for Student Placement in Postsecondary Education: Fall 2011* (p. 11, Table 1, and p. 17, Table 6), by R. Fields and B. Parsad, 2012, National Assessment Governing Board, U.S. Department of Education.

to underplace students, in comparison to coursework completed and grades, having an adverse impact on underrepresented minorities. In response, an emerging trend in college placement is for institutions to take a more holistic approach (Rutschow & Mayer, 2018), using additional measures such as high school grades, high school courses completed, and performance in dual enrollment or Advanced Placement grades. Moreover, legislative and policy eliminating the use of placement tests have been associated with large increases in retention, transfer credits, and graduation rates at 2-year colleges (Zamundio-Suarez, 2022). About 13% and 21% of all institutions report using one of these measures along with test scores for placement decisions in reading and math, respectively (Fields & Parsad, 2012).

ACCUPLACER

College Board's ACCUPLACER placement testing program is the only remaining major large-scale placement test after ACT discontinued both Compass and Asset placement tests in 2016. For over 30 years, ACCUPLACER (originally branded as Computer Placement Tests) has been used to assess student readiness for college-level courses. The ACCUPLACER battery of placement tests, labeled Next Generation ACCUPLACER, was redesigned in 2016 based on data from a survey of higher education users. New items were written based on new specifications and field tested and calibrated to a new reporting scale, 200–300, with increments of 1. The battery includes tests of English Literacy (EL) and tests of computer skills, but this chapter will focus only on the Next-Generation placement tests: Reading (20 questions), Writing (25 questions), Arithmetic (20 questions), Quantitative Reasoning, Algebra, and Statistics (20 questions), and Advanced Algebra and Functions (20 questions).

ACCUPLACER has also been used with high school students to identify students prepared to enter college credit-bearing courses or in need of further developmental instruction prior to graduation. The technical manual states that scores can be used to identify high school students “eligible” to enroll in dual enrollment courses but provides no evidence or guidance on such uses (College Board, 2019b). All ACCUPLACER assessments are computer adaptive, fixed length, and tailored to each test taker using an item-selection algorithm based on a weighted deviations model.¹³ A number of constraints are built into the assessments, including content constraints. In 2016, 11 million ACCUPLACER tests were administered, but that number counts each assessment completed; the same student will often be routed through multiple tests in a single subject (e.g., all three math or EL tests) to receive a single placement score (College Board, 2017c, 2019b); additionally, volume counts are based on the larger set of assessments used, including Next-Generation, traditional, EL, computer skills, write placer, and diagnostic tests.

The program handbook states, “Multiple factors should be used when making high-stakes decisions like college placement” (College Board, 2018, p. 4) and encourages colleges to conduct a local validity study if establishing cut scores. The Next-Generation

ACCUPLACER redesign incorporated changes in content, item types, and other elements, but publicly available statistical specifications are based on the prior design (College Board, 2017c).

Technical Characteristics

Reliability estimates range from .80 to .92, and standard errors of measurement range from about 7 to 12 points on the 200–300 point scale (L. Bay, personal communication, April 27, 2020). The ACCUPLACER Battery relies on content validity to support claims and provides a detailed description of content and skills measured. Although criterion-related (e.g., predictive) studies have not been reported for ACCUPLACER Next-Generation, the previous battery had moderately strong evidence supported by a meta-analysis of 47 placement validity studies across 17 institutions between 2001 and 2006 (Mattern & Packman, 2009). The mean operational validity coefficient for individual ACCUPLACER tests in the previous battery (before 2016) ranged from .16 to .36 ($M = .24$) when success was defined as obtaining a “B or higher” and from .10 to .32 ($M = .19$) when success was defined as obtaining a “C or higher,” suggesting a weak to moderate relationship between ACCUPLACER scores and course success. However, mean validity coefficients increased to .42 and .34 after correcting for restriction of range. Validity of placement tests is also evidenced by examining the percentage of students recommended for placement in a course who eventually pass that course. Such studies have shown moderate to strong relationships for the previous tests.

STUDENT LEARNING OUTCOMES

Definition of SLO Assessment

SLO have received heightened attention from many higher education institutions for reasons such as accreditation, accountability, and internal improvement (Liu, 2023). The National Institute for Learning Outcomes Assessment (NILOA; 2019), a pioneer in the promotion of valid use and effective practices of SLO assessment, defines learning outcomes as “the expected knowledge, skills, attitudes, competencies, and habits of mind that students are expected to acquire from an educational experience (para. 1).” It is important to note that learning outcomes encompass both domain-specific knowledge and skills and generic, transferable competencies.

In the acquisition of domain-specific knowledge and skills (e.g., journalism or economics), students typically follow a structured progression of a curriculum, designed purposefully to build and reinforce their knowledge and skills in these domains. In this regard, students’ increased understanding and proficiency can be largely attributed to their experience in that defined sequence of courses.

Students’ development of generic, transferable competencies such as critical thinking and intercultural competency is more complicated and can hardly be attributed to a single college experience. For example, institutions may not offer critical thinking

courses but still include critical thinking as a measured outcome, since students could gain critical thinking skills from exposure to a broad range of courses, programs, and institutional activities. Students may hone critical thinking skills, for example, from a philosophy course that discusses inductive and deductive reasoning and from a statistics course that introduces correlation and causation. Students could also gain critical thinking skills from participating in an undergraduate research program or being part of a debate club. Furthermore, they could take a Massive Open Online Course (MOOC) on critical thinking. All these activities can contribute to a student's critical thinking skills without the student's enrollment in a course dedicated to critical thinking. In this sense, students' critical thinking skills reflect the overall learning experience they have at an institution.

In addition to the important distinction between domain-specific and generic learning outcomes, it is also critical to note that the focus of college learning outcomes by higher education institutions is on a spectrum of cognitive abilities, personality and behavioral traits, and social and emotional skills (Pellegrino & Hilton, 2012). The focus is closely aligned with the "whole student" notion and also reflects the demands for both technical and nontechnical skills in the modern workplace. A notable example is the three clusters of competencies identified: cognitive (e.g., critical thinking, creativity), intrapersonal (e.g., intellectual openness, work ethics), and interpersonal (e.g., collaboration, leadership). Moreover, the value placed on nontechnical skills by employers has increased over time. The 2018 IBM Institute for Business Value Global Country Survey revealed that adaptability, time management and prioritization, teamwork, and communication overtook technical skills in becoming the most valued skills by employers (LaPrade et al., 2019).

Notable International SLO Efforts

In parallel to the attention SLO assessment has received in the United States, there are also a number of notable international initiatives about the promotion of college-level learning outcomes. For example, the Assessment of Higher Education Learning Outcomes (Tremblay et al., 2012) project, sponsored by the Organisation for Economic Co-operation and Development (2013), attracted 17 countries to participate in its pilot examining college students' performance in critical thinking, quantitative reasoning, and economics, reflecting a focus on both generic and domain-specific skills.

Another notable example is the Modeling and Measuring Competencies in Higher Education—Validation and Methodological Innovations (KoKoHs) project, funded by the German Federal Ministry of Education and Research over two phases, totaling 9 years (2011–2015; 2015–2019). KoKoHs was focused on the assessment of competencies in both general and disciplinary-specific domains and built a consortium of institutions and programs in Germany and with its international partners in addressing students' learning outcomes (Zlatkin-Troitschanskais et al., 2018).

The European Union also funded a two-phase project titled Measuring and Comparing Achievements of Learning Outcomes in Higher Education in Europe to identify

a common assessment framework for five broad areas of disciplinary domains: engineering/civil engineering, social sciences/education, humanities/history, health care/nursing, and natural sciences/physics. On the basis of collaborations between faculty members and with input from ETS, a series of assessment frameworks were published articulating the knowledge, skills, and competencies students are expected to master and demonstrate at both the bachelor and the master levels (Wagenaar, 2018).

Different Types of SLO Assessments

The majority of U.S. higher education institutions specify their own learning objectives and student learning outcomes. According to a survey of 811 regionally accredited, undergraduate degree-granting institutions, Jankowski et al. (2018) reported that 82% of institutions have specified learning outcomes. The institutions surveyed reported using multiple assessment approaches to measure learning outcomes using four different types of tools on average. The most popular assessment tools include national student surveys, alumni surveys, locally developed surveys, standardized assessments of general knowledge and skills, rubrics that define competencies (e.g., VALUE Rubrics by Association of American Colleges & Universities), employer surveys, external performance assessments, and portfolios. Notable examples of standardized SLO measures include the HEIghten suite of assessments (Liu et al., 2014), the Collegiate Learning Assessment (Kaniuka & Wynne, 2019), and the California Critical Thinking Assessment (Davies, 2011). The HEIghten assessment suite includes five independent modules in critical thinking, written communication, quantitative literacy, civic competency, and intercultural competency (Griffith et al., 2016; Liu et al., 2014; Roohr et al., 2014; Sparks et al., 2014; Torney-Purta et al., 2015). Rubrics are also a popular tool used by faculty members to evaluate learning outcomes. Each assessment tool has its own advantages and limitations. For example, national student surveys are easy to implement and can be an efficient way of gathering information on student experience and engagement on campus, yet they typically do not provide direct evidence of student learning. Rubrics offer great flexibility for adaptation but could fall short of consistency in implementation if users are not adequately trained. As Liu (2017) pointed out, there is no one-size-fits-all solution when it comes to assessing student learning outcomes. Depending on their assessment goals, priorities, and resources, institutions should select the tools that best fit their needs.

How SLO Assessments Have Been Used and Current State

SLO assessments serve many purposes, such as a program or regional accreditation, internal institutional improvement, faculty/staff interest, equity concerns, and responding to accountability calls (Jankowski et al., 2018). The assessment results are typically reported at an aggregate level. As noted earlier, the purpose of the Commission on the Future of Higher Education was to identify prominent issues in American higher education and develop improvement solutions. The commission's first report (U.S. Department of Education, 2006) sparked a series of accountability initiatives that required participating institutions to provide more data on key performance metrics

to the public, with particular attention to the assessment of learning outcomes using standardized measures. The Department of Education also provided a grant with a component to examine the comparability of students' performance in critical thinking and analytic writing assessed across three standardized measures (Klein et al., 2009). National accountability efforts include the Voluntary System of Accountability for public 4-year institutions and the Voluntary Framework of Accountability created for community colleges.

As is true for many initiatives and changes in education, the focus on accountability has evolved since 2012 as a result of challenges in implementation and shifting policy guidance. The impact of accountability initiatives on institutions' use of learning outcomes assessment has declined significantly, from 31% in 2007 to 13% in 2017 (Jankowski et al., 2018). Internal improvement has become an increasingly important driver for institutions to examine students' learning. Some of the most significant challenges that institutions face include decreasing student enrollment, rising student debt, competition from nontraditional education providers (e.g., online programs, boot camps), and lack of connection to the workforce. When asked whether most Americans have an accurate view of higher education, only 15% of college and university presidents agreed or strongly agreed (Inside Higher Ed, 2019). For many institutions, the focus on SLOs has been driven by the need to prove value instead of a response to federal calls for accountability.

Prominent Issues in Assessing Learning Outcomes

Test-Taking Motivation

In this section, we discuss a number of issues in the implementation and interpretation of SLO assessments. As previously mentioned, most institutions administer SLO assessment to drive institutional change, rather than to monitor individual learning. The assessment outcomes rarely bear direct consequences for students. As a result, students' motivation for taking SLO assessments has been a long-standing concern. Abundant research suggests that when test stakes are low, test takers may not try their best; and therefore, their performance tends to be an inaccurate reflection of their abilities (e.g., Braun et al., 2011; Gneezy et al., 2019; Liu et al., 2012; Wise & DeMars, 2005). Gneezy et al.'s (2019) study revealed that if U.S. students had used their best effort in the Programme for International Student Assessment (PISA), U.S. ranking on the PISA mathematics test would have been improved from 36th to 19th. Researchers have explored strategies to help improve students' motivation. Offering incentives contingent on performance seems to be an effective way of improving motivation and performance (e.g., Braun et al., 2011; Gneezy et al., 2019).

Measuring Performance Differences

A concept that was frequently explored in the beginning of the accountability initiatives around 2007 was value-added learning of college education, implying that the amount of learning that can be attributed to the effectiveness of higher education could be

accurately measured. Although the concept was appealing in holding education providers accountable for the instruction and experiences they provide, there were many designs as well as methodological and practical constraints that prevented meaningful interpretations. In the analysis of change of learning, longitudinal samples are typically preferred over cross-sectional samples because of the invariance in key background variables for longitudinal samples. However, longitudinal samples are very difficult to obtain in higher education because the first-year to second-year attrition rate is about 17% for 4-year public institutions and 38% for 2-year colleges (National Student Clearinghouse Research Center, 2019). In addition, significant transfer rates also make it difficult to track students. About 37% of students who start at 2-year institutions and about 39% of students who start at 4-year institutions transfer to another institution within 6 years (Shapiro et al., 2018). These are the main reasons that many studies employ cross-sectional samples when examining learning gains in college (Klein et al., 2009; Liu et al., 2012; Roohr et al., 2019). However, students in different cohorts may vary in key background and academic variables, which could potentially influence the comparability of these groups (Liu, Liu, et al., 2016). For example, senior students who manage to remain in college may have possessed higher academic qualifications on average when they were freshmen than the current freshmen in the cross-sectional sample, thus introducing inequality in the two samples to be compared. There is another issue of differential participation from freshmen and seniors in that seniors are less likely to sign up for voluntary institutional testing because of other priorities, which further exacerbates the sample inequality. The confluence of methodological challenges, differential motivation (e.g., freshmen try harder than seniors), and mobility in higher education poses difficulty on any attempt to disentangle the contribution of any individual institution on student learning. Researchers have also provided solutions to address unequal samples when examining cross-sectional learning gain. For example, Liu, Liu, et al. (2016) explored the application of a propensity scoring weighting approach aiming to control for possible differences in key background variables (e.g., gender, ethnicity, college entrance exam scores) between cohorts of freshmen and seniors used in the analysis.

Reimagining Learning Outcomes Assessment: Connecting Assessment, Learning, and Careers

Despite the widespread use of learning outcomes assessments, institutions have varying degrees of success in utilizing the assessment results for driving improvement and innovation. A unique challenge around the interpretation and use of generic SLO assessments is that the results are typically not directly related to any course but instead reflect a culmination of a wide range of experiences in and outside college. Institutions at times struggle with identifying a practical entry point to provide remedies when students show a deficiency in a generic field. According to Jankowski et al. (2018), there are many examples of expansive assessment efforts that lead to limited changes on campus. In the following section, we discuss how the use of SLO assessments can be reimagined to help enhance students' key competencies and increase connection with the workforce.

Employers have long been concerned about skills gaps, and such concerns are exacerbated by industry changes introduced by automation. McKinsey Global Institute (2017) projected that by 2030, about 3%–14% of the global workforce will need to switch occupational categories, and all workers will need to adapt as their jobs evolve with automation. An employer survey from the National Association of Colleges and Employers (2018) suggested significant gaps in key competency areas, including critical thinking/problem-solving, global/multicultural fluency, career management, digital technology, leadership, teamwork and collaboration, oral and written communication, and professionalism and work ethic. These skills are also emphasized in Liu, Kell, Liu, et al. (2023) in which the researchers proposed a new vision for assessment that reflects the continuity of skills development throughout K–12, higher education, and workforce. Although institutional assessment reflects a wide range of educational objectives, having a connection to employer expectations has great potential for increasing students' workforce readiness and engaging students in the assessment process because the results will likely bear more significance for students. Offering a clear definition of what these skills mean and how they manifest in concrete contexts is also important as institutions strive to help students improve on these critical skills, which calls for close collaboration between education providers and employers to contextualize these skills (Liu et al., 2021; Liu, Kell, Williams, et al., 2023). Currently, learning resources for skill improvement are provided from a range of sources, including locally or institutionally developed resources MOOCs, and offerings from education start-ups and non-traditional education programs. Making students aware of these resources and offering more systematic support following the assessment activities has great potential to motivate students to capitalize on the learning opportunities for skill improvement.

CONCLUSION

The use of tests in higher education, especially for admissions, remains one of the most highly contested uses of standardized testing in America. College degrees remain a highly valued commodity in our society. Entrance to selective institutions is valued more than entrance to typical or less selective institutions, and the ratio of applicants to openings is highly restricted in the most selective undergraduate and many graduate and professional degree programs. As long as these conditions exist, there will be heated debate about who gets in and the tools and criteria used to make such decisions. As Zwick (2017) reminded us, there is no universally accepted definition of merit or equity and no completely objective way to evaluate admissions systems or decisions. The outcomes of admissions processes serve as *prima facie* evidence of a lack of fairness for many stakeholders, and accumulated evidence of validity, reliability, and fairness of scores is often unpersuasive.

However, results of the body of research on admissions tests continue to reflect their value and efficacy, as described by a 1999 report from the National Academy of Sciences. This study (Beatty et al., 1999) noted that standardized tests provide an efficient, low-cost, valid, and reliable method to identify talent (college readiness) and minimize

differences that exist between schools, grades, and learning opportunities. A more recent study found that admissions tests result in greater diversity, and policies that would eliminate or reduce their use would reduce diversity and have other negative effects on educational outcomes (University of California, Academic Senate, 2020). Although this finding was not directly rejected, the UC president and Regents did reject the recommendations from the task force. However, admission tests must also be used appropriately, which precludes reliance on test scores as the primary or sole measure used for admissions, placement, or assessment of learning outcomes. The discrepancy between the public's perception of standardized tests and the research that contradicts common beliefs points to the need for the measurement community to do a more effective job in promoting a national dialogue of assessment that is data driven and evidence based.

Another important trend emerging in the use of assessments in higher education includes the increasing influence of technology because all major admissions test are now digital and models of testing such as remote proctoring and increased use of artificial intelligence have emerged. In turn, the marked demands for increased flexibility and customization may challenge the very principles associated with standardized testing and score equivalence (Camara & Davis, 2022). Similar to K–12 state assessments in accountability, four of the major admissions tests discussed have also undertaken substantial design changes to reduce testing time and length. Reducing testing time, stress of anxiety of test takers, and providing free and substantial programs for test preparation have gained importance in this industry segment. We should anticipate continued efforts to improve the test taker experience, given its heightened importance in a test optional environment where learners have much greater autonomy and flexibility in their testing choices.

In the brief period between completion of the first draft of this chapter (late 2019) and the final version (2025), testing in higher education has undergone the most profound changes in its history. These changes, continued challenges, and future uses are still very fluid and unknown as we conclude. In the next few years, we anticipate the release of additional research, which can better help us evaluate the efficacy and utility of admissions testing, and we hope such research will also address the efficacy and consequences of admissions practices and decisions made based on other factors. Placement testing has undergone additional scrutiny and the assessment of learning outcomes is in its infancy. The next decade will present challenges to testing organizations and higher education in both continuing practices of assessing students for admissions and placement and deriving meaning from assessments of student learning.

ACKNOWLEDGMENTS

We would like to thank the editors, Linda Cook and Mary Pitoniak, for their guidance and coordination of this work and especially our reviewers, Jerry Lucido, Emily Shaw, and Rebecca Zwick, for their detailed review, suggestions, and comments over multiple reviews, which only strengthened the manuscript.

NOTES

1. Data were obtained through the National Center for Education Statistics Integrated Postsecondary Education Data System data center at <https://nces.ed.gov/ipeds/datacenter/reportmain.aspx>. Enrollment of all students at test-optional colleges represented about 5% of all freshmen nationally in 2018, but since about 70%–80% of students at such colleges submit test scores, the estimate is that students admitted without scores represent 1%–1.25% of freshmen.
2. See page 1194 in this chapter for a discussion of *Smith v. Regents of University of California*, 2020.
3. See Rigol (2004) for an example of an admissions index chart, which illustrates how admissions decisions could be made in a compensatory fashion allowing higher performance in either test scores or grades to serve a compensatory role for lower test scores or grades.
4. Plaintiffs failed to gain acceptance by automatic admission where the top 10% of students in each Texas high school's graduating class were accepted to the University of Texas at Austin, irrespective of race, and were denied admission during a second review for students not automatically admitted. In 2009, legislation limited automatic admissions to 75% of the university's enrollment capacity, which has lowered the automatic admission to the top 6% at each high school (Jaschik, 2017).
5. Of the 58 items, 38 prohibit calculator use.
6. The last official concordance study sanctioned by both testing programs and tables can be found at ACT (2018).
7. The ACT was administered exclusively on computer for international test takers, and available by computer for some state and district school-based administrations prior to 2024.
8. Open admission is an unselective and noncompetitive college admissions process in the United States, where the only requirement is a high school diploma or a General Educational Development certificate. The number of open-admission institutions was obtained through the National Center for Education Statistics Integrated Postsecondary Education Data System data center at <https://nces.ed.gov/ipeds/datacenter/reportmain.aspx>. Sorting variables for the 2018–2019 year included admissions and test scores, open admission policy (yes); and the following institutional characteristics: level of institution (1 four or more years); sector of institution (1 public, 4 years or above; and 2 private, not-for-profit, 4 years or above); degree-granting status (1 degree granting); and undergraduate offering (1 undergraduate degree or certificate offering). Total enrollment was about 2 million at these open-admission institutions. Some of the institutions were branch campuses of institutions that had selective admissions at their main campus.

9. Includes individuals ages 16–24 who graduated high school or completed a General Educational Development certificate or other equivalency program. See https://nces.ed.gov/programs/coe/indicator_cpa.asp.
10. The ACT and SAT report degree aspirations separately and with slightly different categories. The percentages were calculated by a weighted average from ACT and SAT data, which may result in double counts of students who completed both tests.
11. The National Collegiate Athletics Association suspended and has now eliminated its test score requirement for Division I or II athletics (Bauer-Wolf, 2023).
12. After July, 2024, the name transitioned back to the *GMAT Exam* (Graduate Management Admission Council, 2024a).
13. Two fixed-length paper forms called companion tests had been developed for each of the five adaptive tests.

Assessment for Licensing and Certification

Regulation, credentialing, licensure, certification: These terms refer to aspects of occupational oversight that may occur at the federal level, the state level, the intra-professional level, or a combination of all three. Regardless of the responsible entity or entities, this oversight serves the primary purpose of ensuring that practitioners demonstrate a specific level of competence to protect themselves, the profession, and, most important, the public from harm.

Regulation tends to refer more generally to higher level oversight of different aspects of a profession. In essence, professional regulation can refer to “any activity that is intended to promote and protect the public interest by reducing, suppressing, mitigating or eliminating harms or potential harms stemming from the practice of a profession” (Balthazard, 2017). In some domains, professional regulation is, relatively speaking, straightforward: Professional engineering practice, for example, is governed by individual states that have specified educational, internship, and examination licensure requirements. The work of the state licensing boards is supported by a regulatory body, the National Society of Professional Engineers, which promotes strong licensure laws intended to protect “public health, safety, and welfare” (2023, Our Values section). Other domains, such as medicine, have a multifaceted and complex regulatory process involving numerous required or elected entities that have interconnected levels of oversight throughout a given physician’s professional career (White, 2014).

Credentialing is a term that can refer to the process of verifying eligibility for participating in a profession. Though such verification may occur at multiple points along the continuum of education and training (e.g., verifying completion of the educational requirements for taking a required examination, verifying successful completion of required examinations), the ultimate credentialing activity requires verification of *all* credentials that are necessary for performing the required job. Examples of credentials include licensing and certification, as well as other types of designations such as professional certificates, badges, or microcredentials. For the purposes of this chapter, the examples focus primarily on professional licensing and certification rather than on other types of credentials that have more recently gained traction in the professional arena. When relevant to the discussion, these other designations will be considered.

Licensure and *certification* typically refer to processes that are intended to provide the public with evidence that certain professional standards have been met; through these two processes, members of a profession are granted certain privileges that are associated with that profession (Raymond, 2015). A historic, yet somewhat tenuous, distinction between the two credentials relates to whether obtaining the credential is mandatory or voluntary. With licensing, a governmental agency grants permission to engage in an occupation after the specified requirements have been met; these requirements usually relate to educational activities, experience working in a supervised setting, and one or more examinations that a candidate must complete to demonstrate minimum competence with respect to the knowledge, skills, and abilities that are required for practice. For those occupations that require it, licensing is mandatory; without a license, one is not permitted to engage in the occupation even if all other requirements have been

met. Alternatively, certification typically is *not* a requirement for occupational practice. Instead, it traditionally has been viewed as an activity that is designed to demonstrate competence for entering an advanced level of practice; as such, it is more a reflection of professional oversight rather than the governmental oversight that applies to licensing. To further complicate matters, certification in business and industry may be used to indicate mastery of knowledge and skills associated with products or services, rather than as a gateway into a field (e.g., technology hardware, software, medical devices). Though the historical approach to distinguishing between licensure and certification based on the mandatory versus voluntary nature of the process has been popular and in many cases is accurate, there are exceptions to this general rule. In some professions, such as teaching, certification is mandatory and acts as a *de facto* license (Raymond, 2015).¹ There are professions in which both credentialing practices are relevant, and the distinction between them is clear. In the licensing of allopathic physicians, for example, licensure is governed by the state medical board; candidates must meet the educational, training, and assessment requirements for licensure and then apply to the state for the undifferentiated license to practice medicine. Should a licensed physician desire specialty certification, they must complete additional required training in that discipline and then pass one or more certification examinations administered by the specialty board; passing the examination(s) allows that diplomate to use the associated specialty designation (e.g., a board-certified plastic surgeon). In other professions, the distinction between licensing and certification is less clear. The medical example leads to consideration of an additional distinction that often is used to differentiate the two credentials: Licensing tends to be conceptualized as more of a hurdle to enter a given profession, whereas certification tends to reflect a more advanced level of practice (Kane et al., 1999). There are additional complexities associated with variability in credentialing requirements within a given field. In psychology, for example, health service (clinical, counseling, and school) psychologists typically require a license to practice, whereas the same credential may not be required in other applied psychological domains (DeMers et al., 2014; Elchert, 2016). With few exceptions, because licensing in the United States is a function of individual states/territories, there is variability across jurisdictions regarding which professions require licenses and what is required to maintain them.

Despite differences in terminology or specific requirements, the overarching goal of both credentialing processes is the same: to ensure that the practitioner has attained at least a minimum level of competence in the profession to protect the welfare of the public. As we have mentioned, professional credentialing organizations typically specify at least three types of requirements for receiving the credential: educational, experiential, and examination. This is not universal, however, and many certifications do not have education or experience as eligibility requirements to sit for an examination. The specific educational and experiential requirements for licensure and certification vary greatly across professions and jurisdictions; considering the third requirement—completion of one or more examinations—allows for focusing on the similarities in requirements that exist across these high-stakes contexts.

Each year, hundreds of thousands of test takers complete examinations that are designed to provide information about the extent to which they have met certain professional standards (Raymond, 2015). Because licensing and certification examinations are intended to inform decisions about a candidate's ability to perform effectively at the relevant level of practice (Kane et al., 1999), developing these tests focuses specifically on identifying the necessary requirements for professional practice at the level of interest (e.g., entry level for licensing, a more advanced level for certification); this allows for greater confidence in the link between performance on the assessment and effective job performance. Additional important considerations with respect to these examinations relate to topics such as legal issues associated with using tests to make decisions about the ability to enter practice (or practice using a specific title), the importance of methodological rigor throughout the item and test development process, the extent to which relevant stakeholders are included in the process, elements of standard setting that are unique to or warrant special attention in credentialing contexts, and other factors that are relevant to settings in which results of the assessment process have significant professional implications. By outlining these critical areas, the chapter aims to support the development of more effective, equitable, and evidence-based assessment practices in high-stakes professional contexts.

As should be clear from the preceding pages, we present a broad review of considerations that are applicable to professional licensing and certification contexts. Other chapters in this volume delve into many of these issues in substantial detail, and the interested reader is referred to these chapters for an in-depth discussion of relevant content within a given topic area. We intentionally limit our review to the specific context in which tests are used to make decisions about whether a practitioner has demonstrated competence to practice in a given profession or to use a specific practice-related designation. As such, the content of the chapter is presented with the intent of meeting the following goals:

- providing a clear presentation of the issues that historically have been and currently are most relevant for defining use(s) for developing, scoring, evaluating, and defending scores from licensing and certification tests;
- describing the legal precedents that have continued to shape standards for licensing and certification tests;
- presenting a detailed explanation of the foundational measurement issues that guide development and use of tests for licensing and certification (e.g., considerations of fairness, reliability, validity, establishing performance standards); and
- discussing related factors including policy considerations, stakeholder perceptions, and antitest sentiments.

We conclude our introduction with an overview of the major sections of the chapter: "Rationale and Historical Perspective," "Fairness and Legal Issues," "Test Development," "Reliability," "Validity," "Standard Setting," and "The Future of Assessment for Licensing and Certification."

1. “Rationale and Historical Perspective”: In this section, we begin by describing the historical context for licensing and certification assessments and explore how perspectives on these types of assessments have developed and changed over time. Content represented in this historical background includes a discussion of different types of tests and their uses, with a focus on licensing and certification, an examination of how licensing and certification practices differ in different contexts, and a focus on how assessment for licensing and certification has changed since the publication of the prior *Educational Measurement* volume in 2006.
2. “Fairness and Legal Issues”: This section reviews important considerations with respect to fairness and legal issues in credentialing contexts. The primary focus is on the legal bases that would allow for challenging testing practices and/or outcomes in both licensing and certification contexts (e.g., Title VI and VII of the Civil Rights Act of 1964; Equal Employment Opportunity Commission, 1985). We also consider fairness from the perspectives of mitigating risk for bias during test development, testing accommodation policies, and the implications of the outcomes of accommodated and nonaccommodated test scores.
3. “Test Development”: This section describes test development considerations that are particularly relevant to licensing and certification assessments. These include a discussion of the importance of clearly specifying the purpose of the test and focusing on test development as a data-driven process informed by an understanding of the knowledge and skills that one must demonstrate in the context relevant to the specific credential. Recent research on advanced test development approaches such as automated item generation and automated test assembly are included, as is a discussion of innovative item types and issues surrounding the provision of performance feedback.
4. “Reliability”: This section addresses relevant issues that are unique to or require special emphasis in licensure and certification contexts. Content includes discussion of several key topics, including classification consistency and accuracy, with a particular focus on false-positive and false-negative errors and the impact of these factors on policy decisions, as well as a review of measures of classification accuracy in the contexts of both traditional and cognitive diagnostic assessments. We also discuss the special issues in classification accuracy associated with allowing failing test takers to retake an examination.
5. “Validity”: In this section, we describe validity issues that are unique to or need special emphasis within credentialing contexts. We highlight Kane’s (2006) validity framework to discuss the importance of a multifaceted and thorough approach to collecting validity evidence in professional testing environments, discuss the particular importance of the extrapolation and interpretation components with respect to evidence for performance in practice, reflect on the theoretical underpinnings of why assessment may be important in the professions, and discuss threats to validity such as security-related issues.

6. “Standard Setting”: This section addresses issues that are central to standard setting in assessments used for licensing and certification, including a brief discussion of the content-based methods typically used in credentialing contexts, considerations related to the variety of activities that comprise the overall standard-setting process, and a discussion of the role of judgment in standard setting.
7. “The Future of Assessment for Licensing and Certification”: In the final section, we discuss what is to come in the domain of assessment for licensing and certification. This includes a review of major milestones that have influenced the practice of assessment for licensing and certification, such as the availability of new technology, reconceptualization of how competence is developed and demonstrated, and the rise of antitesting and antiregulation sentiments.

RATIONALE AND HISTORICAL PERSPECTIVE

Licensing and certification are based on a foundation that continues to evolve as professions seek to distinguish themselves through designation processes for both the profession and individuals. This history goes back hundreds of years. Some of the earliest records of licensure requirements are presented by Schmitt (1995), who described when tariffs were imposed on medical practitioners as part of an effort to regulate practice; these early requirements date to approximately 2000 B.C.E. (and are analogous to the requirement that exists in many jurisdictions of registering and paying a fee for a business license). Some of these fees were levied by governmental agencies, but as noted in the following paragraphs, professions also had an interest in controlling access to the profession itself. During this same period, the Chinese civil service began periodic testing to evaluate fitness for remaining in designated positions (see Dubois, 1970, and Clauser et al., this volume). Evidence of these efforts to regulate or monitor professions were related to healthcare, which contributed to the concern for protection of the health and welfare of the public. However, motivations for developing these systems were neither entirely altruistic nor fully driven by governmental or regulatory bodies.

The guild systems that emerged in Europe between the 1200s and the 1400s established rules for membership, expectations for education or training through apprenticeships, and member-determined expectations for entry (Schmitt, 1995). In this regard, these systems may appear analogous to contemporary professional associations that sponsor programs, but the original purpose of these systems was more about control of the profession and commerce than about ensuring minimum competency of individuals entering the profession. From an economic perspective, this control over the profession also would have influenced prices and wages. This initial shift from government-driven oversight to profession-driven monitoring represents an early phase in the movement toward more professional self-regulation. As with other policies that have used testing as part of oversight or accountability, licensing and certification programs have experienced periods of greater or lesser support for their efforts.

One reason for the reduction of oversight of certain professional licensing requirements in the mid-1800s was that there was a perception in some fields—such as medicine and law—that the schools training these practitioners were of a higher quality than had been observed at the outset of the licensing legislation. Not surprisingly, the growing recognition of supply and demand principles led to the opening of more schools to meet the increasing demand for training. However, by the late 1800s, the expectation that candidates from all training programs were equivalent had waned, as did the quality of practitioners (due to the increase in the population; Schmitt, 1995). Since then, the number of professions regulated by states or monitored by professional associations has continued to grow as professions and roles have continued to evolve.

Discussions among professional training or educational programs, credentialing bodies, practitioners, and the public have continued for decades, along with considerations for why some licenses or certifications exist. Administrators and faculty at many professional training programs often take the position that graduation from an accredited training program should be sufficient for candidates to claim that they have achieved minimum competence in the knowledge, skills, and abilities required for the credential. There have been criticisms of this perspective, however, including the fact that training programs may have incentives to retain students that are not based on competence. Instead, they are perceived to be based on factors such as the need to maintain tuition and related revenue, along with program accreditation requirements that might rely on test information to inform outcomes assessment. Concurrently, there are practitioners and policy makers (e.g., legislators, licensing board members, certification board members) who would claim that these conflicts of interest are precisely why an independent demonstration of competence is needed. Criticisms of the practitioner stakeholders often are consistent with those levied against the historic guild system, where there may be perceptions that the licensure or certification process is used as a barrier to entry of a profession and that it limits opportunities for otherwise qualified candidates, particularly those from underserved communities. Because the influence of licensing and certification testing impacts millions if not billions of people, concerns related to these perspectives are important considerations for the measurement community.

Focusing on licensure to illustrate the point, Shimberg (1982) noted that more than 800 professions require licenses; significant expansion in licensing requirements began in the early 1900s with the proliferation of licensing agencies established through jurisdictional legislation. Morath (2015) subsequently estimated that the number of licensed professions had increased to more than 1,100. When applied to the United States workforce, this represents approximately 30% of workers (Kearney et al., 2015). The increase is driven partly by the creation of new professions and roles that did not previously exist. In addition, professions have sought to increase credibility and add a layer of protection through legislative intervention. The public protection goal of professional licensing and certification serves as a powerful reference point for professions seeking both visibility and a modicum of protection from practitioners who do not meet a standard of minimum competence for professional practice.

Considering the now thousands of professions and specializations that are licensed or certified, the meaning of some of these credentials is at risk of being devalued. As an example, the plaintiff in a legal case in Utah challenged the Barber, Cosmetology/Barbering, Esthetics, Electrology and Nail Technology Licensing Board for the right to provide African hair braiding services without a license after being ordered to cease and desist from offering the service (Romboy, 2012). The court in this case noted that the specific hair braiding service was beyond the scope of the public protection interests of the licensing board and supported the plaintiff's right to be able to practice without a license. Similarly, there are instances where licensing and certification programs have been eliminated. For example, in 2019, Texas removed licensing requirements and related laws for plumbers (Ura, 2019). This decision was related to an effort to reduce barriers to entry into a trade, but unintended consequences for the public may result from making such a decision without consideration of the need for additional independent verification of the competence of individuals offering these services. These examples illustrate instances where licensing boards have potentially exceeded the scope of their public protection charge or where support for a licensing requirement has eroded (affirmatively ending a program) or become inactive (allowing a program to sunset through lack of renewal or reauthorization).

Licensure and Certification Processes

Licensing and certification are the two most prevalent examples of formal recognition associated with an occupation, role, or profession. Although we discuss them collectively, the requirements, interpretation, and use for these and other professional credentials are unique to the defined eligibility, demonstration of competence, and expectations for maintaining the credential. A first step in designing and developing a testing program involves beginning with a clear statement of purpose. As will be discussed, terminology associated with licensing and certification testing can quickly expand beyond the historical definitions. For the sake of consistency in this chapter, we will use licensing and certification terminology, but additional types of professional credentials will be discussed when relevant, along with how they connect to these more common forms.

Just as we recognize a range of achievement levels in education and a variety of roles within employment settings, it stands to reason that licensure and certification would reflect a similar diversity. This variation may be seen not only in the reasons for establishing specific licenses or certifications, but also in how scores are used and interpreted in relation to those purposes. For credentialing programs, the primary claim relates to public protection: Candidates who receive the credential meet the minimum standard for entry to the profession or ability to use the designation(s) afforded by the credential. This claim can be distinguished from a claim for uses of certification credentials in a work setting that might be used for employment selection or retention. The concept of public protection stems from the desire—of judiciary, legislative, or regulatory authorities, as well as professional associations—to help members of the public distinguish

between qualified and unqualified practitioners. For licensed professions that are directly associated with potential risk to the public (e.g., architecture, aviation, health-care, law), actions of an incompetent practitioner can produce lasting harm.

In a more historical context, the concept of public protection often is closely associated with professional licensing and certification. However, particularly in certification, the purposes have expanded beyond this core purpose. For example, some certification programs were created to recognize individuals who have demonstrated specialized knowledge, skills, and abilities in a particular domain or subdomain within a profession (e.g., specialty certification, subspecialty certification). Other certifications may function more like educational assessments and are aligned with curriculum, instruction, training, or experience and designed to serve as evidence of knowledge or skills that would be needed or desired by employers (e.g., assessment-based certificates). Even for industry certifications that are based on experience or lack formal education eligibility requirements, the underlying emphasis remains on learning and the acquisition of knowledge and skills needed to demonstrate job-related competencies. Additional certification programs have expanded more into areas such as stackable credentials, microcredentials, and badging. Although these types of designations have become more prevalent and are increasingly visible, there is little consensus on quality standards and how they are to be designed, developed, evaluated/validated, or maintained. Therefore, though we note that this is an emerging area to continue to monitor, the breadth of licensing and certification testing continues to be guided by industry standards for quality.

Distinctions between goals of public perception and market recognition are important to remember when thinking about the value of these processes for stakeholders. From a candidate's perspective, the purpose of seeking a license or certification may be to demonstrate sufficient competence to be eligible to practice in or use a specific designation within a profession. Beyond minimal requirements for a role or profession, there often are market-based incentives for candidates to demonstrate deeper or more specialized competence that help them to distinguish themselves from colleagues. In addition, certain credentials may be used as part of employment eligibility requirements; this has implications for necessary validity evidence as well as legal expectations.

Link to Employment Testing

Because results from credentialing examinations may be required as part of employment eligibility processes, the question of whether these examinations could potentially be interpreted as employment tests that support selection purposes becomes relevant. Phillips (2017) discussed these implications based on the *Gulino v. Board of Education* (2002) case in New York. In that case, the court viewed the licensing requirement for teachers as a *de facto* employment test because teachers who had been employed without certification were either not promoted, not hired for full-time positions, or terminated based on their certification test performance. Although the primary

purpose of a credentialing examination may be to differentiate between candidates who are minimally competent and those who are not, integration with the employment selection process indicates a clear—though perhaps not universal—secondary use. The *Standards for Educational and Psychological Testing* (Standards; American Educational Research Association [AERA] et al., 2014) distinguish between tests used for selection, placement, and promotion in employment contexts and those used for licensing and certification, which are designed to determine whether individuals meet established criteria for professional practice. Selection tests within employment settings may be used to rank order or categorize candidates in the hiring process. This is particularly useful if the number of available positions is limited. To accomplish this goal, the test needs to yield scores that support those types of decisions. This distinction between rank ordering candidates for selection, promotion, or retention purposes versus a broader claim of minimally qualified or not has implications for test design, development, and validation, as well as the evidence needed to support legal defensibility of the resulting scores (see Ercikan & Solano-Flores, this volume).

Because licensing and certification programs often have educational components as part of their eligibility criteria, the intersection of expectations for testing in these areas along with employment considerations requires clear distinctions among purposes and heightens the importance of transparency with respect to associated limitations. Confusion among stakeholders increases when programs' purposes are not clearly delineated. The expansion of purposes can raise challenges for licensing and certification programs in terms of both validation evidence and defensibility. For example, within student achievement testing in the United States, we have observed policies that incorporate results for purposes of both school and educator accountability. In higher education, results from licensing and certification exams often are used as an indicator of outcomes for purposes of program accreditation. Within licensing, provisional or conditional licenses may be granted in emergency situations that then require successful examination performance as a condition of continued employment. Often seen as intuitive by policy makers or sometimes even by programs seeking to provide evidence for or expand credibility of its credential, additional interpretations or use cases should be critically evaluated prior to implementation.

Program Sponsors

Licensure and certification programs have a wide range of sponsors. Agencies, associations, or organizations that grant the credential may assume responsibility for development and validation of the associated tests (e.g., American Board of Internal Medicine, National Commission on Certification of Physician Assistants). At the same time, some professions have formed associations or collaboratives where one or more intermediary agencies assume responsibility for development and validation of the tests (e.g., National Council of Architectural Registration Boards [NCARB], National Board of Medical Examiners, American Board of Dental Examiners, Federation of State Boards of Physical Therapy). In these instances, test users (e.g., state licensing boards,

regulatory agencies) may contribute to the process and then agree to accept or recognize the results of the tests to support consistency and portability.

For some credentialing contexts, membership associations may serve as the sponsor for the program (e.g., American Physical Therapy Association for physical therapy specialties, National Strength and Conditioning Association for strength and personal training). In some professions, this may be a single professional association; in others, there may be multiple membership associations or programs that compete for credibility and market share among members of the eligible population. In addition, some credentialing programs are sponsored by organizations that then seek to certify or confirm qualifications of individuals to perform specific roles within divisions of the parent organization (e.g., Armed Services, Federal Bureau of Investigation, National Security Agency within the U.S. Department of Defense). However, these credentials sometimes begin to have value in the workforce or labor market beyond just the requirements of the sponsoring organization. For example, industry certifications developed by companies in diverse economic sectors such as finance, healthcare, or technology are valued by a range of employers, internally and externally, that use products and services from these companies. Within employment settings, companies and governmental agencies may develop internal credentials that are used to support nonselective promotion or wage decisions.

The distinctions among government-regulated, profession-driven consortia or combinations of these processes are discussed in the next section. As noted previously, the primary differentiator is whether holding the license or certification is mandatory or voluntary for practice, with these differences creating more confusion among stakeholder groups.

Mandatory Professional Credentials

A license likely is the most frequently cited instance of a mandatory professional credential. Well-known professions such as architecture, accounting, law, medicine, nursing, and clinical psychology require practitioners to obtain a license to practice or represent themselves in their profession. What may be less well known, however, is that many jurisdictions also require professionals such as auctioneers, barbers, contractors, cosmetologists, real estate agents, and security guards to obtain a license to practice.

Licensure generally is a jurisdictional legislative responsibility. In the United States, there are some exceptions, including the Federal Aviation Administration's oversight of private pilot licenses and the judiciary's responsibility for admission to the bar for lawyers. As such, there may be jurisdiction-specific requirements for eligibility, demonstration of competence, and maintenance of the license. As described earlier, the focus of licensure is public protection and is based on the rationale that a governmental agency can serve as a dispassionate intermediary between the candidate and the public in evaluating minimum competence. However, even these agencies will necessarily rely on or seek input from members of the profession to help define expectations for entry-level practice.

Although having a license may be necessary to practice in a given field, it does not ensure employment or even employability because of other factors that may go into selection. Further, there are exceptions even to the *mandatory* requirement. For example, some emergency situations (e.g., severe shortages of practitioners, pandemics, natural disasters) may necessitate a temporary relaxation of requirements to grant a provisional or conditional license so that more practitioners can be mobilized. A credentialing examination may serve as an eligibility criterion within the hiring process, similar to the expectation that a valid driver's license is a prerequisite for applicants for a delivery driver position. However, scores from these examinations are not designed to predict successful performance on the job or distinguish among applicants who meet minimum eligibility requirements. In contrast to claims made about scores for employment selection tests, validity evidence for a licensing or certification exam should be sufficient to support the inference that a candidate has met the standard for minimum competence. In addition to this initial demonstration, some credential holders are expected to maintain the credential in good standing; this may involve activities such as continuing education, retesting, or contributions to the profession. The purpose of this practice is to ensure that licensees have a level of continued competence to maintain currency in the profession. This maintenance component often is what distinguishes professional credentials from certificates or industry certifications of products or services that are intended for specific skill sets (e.g., technology certifications, trade certifications, course-based certificates). However, it is important to note that some of these industry certifications do have a maintenance or continuing education requirement.

Voluntary Professional Credentials

In instances where someone can practice in a field without a license, a certification can serve as a point of distinction for the public. Because a voluntary certification may be sponsored by an association, a private organization, or the profession itself, there are fewer barriers to creating a certification; this can be offset by the challenge of building credibility for the value of the credential. Licensed physicians can work as general practitioners, but it is common to seek one of the many specialty/subspecialty certifications offered by American Board of Medical Specialties (ABMS) member boards (e.g., Emergency Medicine, Family Medicine, Internal Medicine, Obstetrics/Gynecology, Pediatrics). Within some jurisdictions, lawyers may seek specialty certifications in criminal law, estates and trusts, family law, or intellectual property. Individuals in the financial services sector may strive to obtain recognition through programs like the Chartered Financial Analyst Institute or as a Certified Financial Planner. These examples illustrate the range of options available to individuals seeking opportunities to voluntarily demonstrate competence within a specific professional domain or subdomain.

In contrast to the jurisdictional oversight of licensure programs, certification programs could be developed by a professional association or a company that offers a product or service on which someone desires to be certified. As a result, there is a wider

range of program designs and methods for implementing them in practice. There may be some level of competition within the certification program space where multiple providers offer credentials (e.g., crane operators, personal trainers, food protection). In these instances, it can be more difficult to ensure independence and mitigate conflicts of interests in governance policies with respect to program development and implementation.

In terms of test development and validation, certification programs are like licensing programs in that the primary claim relates to competence for practice. In addition to eligibility or prerequisite requirements, the demonstration of competence is based on the knowledge, skills, and abilities related to the type of practice implied by the certification. In industry, this may be defined in terms of a level of mastery; in other professions, it may relate to competence in some area of specialization. Earning a voluntary certification does not ensure employment but may be used in the employment process as part of preferred qualifications of applicants. In contrast, if a certification is used as an employment eligibility requirement, it could be interpreted as shifting the certification from voluntary to mandatory.

Although not universal, many professional certification programs have maintenance of competence requirements like those seen in licensure. These requirements will be unique to the program but may include such activities as continuing education, contributions to the profession, or retesting. In a separate section of this chapter, we further explore how some healthcare certification programs offer maintenance of competency assessments that blend learning and assessment. In addition, some certification programs have depended on assessment to inform continuing education recommendations for certified individuals. Related to licensure, there is some debate about whether maintenance of competence requirements should include a demonstration of *continued* or *enhanced* competence. From a measurement perspective, the question is related to the intended interpretation and use of the evidence from the maintenance of licensure process.

Program Stakeholders

Stakeholders for licensing and certification programs are varied, and each has its own perspectives and interests associated with the credentialing process. The public often is noted as the primary stakeholder because public protection tends to be the principal reason for the existence of these types of programs. Clearly, it is important to protect the public from an incompetent physician, teacher, attorney, engineer, or crane operator. In general, when there is a jurisdictional license involved, there has been a decision that incompetent practice could harm the public and that market forces may not offer sufficient protection. This may be particularly true for more technical or specialized domains where members of the public would not be able to differentiate competent from incompetent performance. Beyond initial licensure, another public interest may be served by recognizing individuals who have demonstrated more specialized competence within their field to distinguish themselves from others who have not achieved an additional credential.

Another key stakeholder group comprises the candidates or applicants seeking the credential. These individuals have a personal interest in achieving certification and a legitimate expectation of fair access to professional practice. Their perspective may shift after becoming certified, as the same standards that once posed a barrier now serve to uphold the value and credibility of the credential they hold. In many certification programs, candidates also are connected to professional associations or organizations that define standards for the profession. These groups represent another type of stakeholder with a dual responsibility: to protect the public interest and to serve their members. At the same time, they may have an organizational self-interest in maintaining the perceived value of the credential and sustaining membership, which supports their continued existence.

The training programs that prepare candidates for practice comprise yet another important stakeholder group. The nature of these programs varies across professions. In the case of medicine, the stakeholders in this group are medical schools. For certification, the stakeholders are residency programs. In both cases, access to the credential is important both because individuals are attracted to the program based on their belief that they will succeed in receiving the credential and because accreditation of the training programs may depend on satisfactory performance using this same metric.

Within the healthcare community, insurance providers are another stakeholder group. They may require medical professionals to have certain credentials to provide treatment and may have different pricing or reimbursement tiers for different types of credentials. Possession of the credential also may serve as a form of risk management by having third-party agencies or organizations recognize someone as having a particular skill set. In this instance, it distributes the risk across the insurance company, the provider, and the credential-granting entity.

For employers, credentialing adds a layer of quality control and external attestation of competence that may not be able to be discerned on one's own. Employers in the public and private sectors are stakeholders of credentialing programs and sometimes sponsors of these programs. For example, employers may require a given credential as an expectation for consideration of employment. In these instances, employers are placing trust in the credentialing body and the credential itself as being able to support associated claims about competence. Similarly, labor unions may want to use credentials not only for helping to establish quality standards for their members but also as part of a negotiating strategy to support increased leverage in advocating for the competence of their members.

Additional Evolving Practices

Whereas the fourth edition of *Educational Measurement* highlighted some of the measurement approaches in computerized scoring of performance assessments (e.g., NCARB), challenges associated with staying current with respect to changes in the technologies used in practice have altered the strategy for some of these programs.

For example, NCARB removed performance items (i.e., vignettes) that required candidates to use a generalized but simplified design software to respond to tasks. This decision was driven both by changes in practice regarding the roles responsible for these activities and by the job relatedness of the software that was being used. In response to those concerns, they opted for a more flexible strategy that permitted continued measurement of the important content and cognitive processes associated with being an entry-level architect and provided better alignment of the measurement with the task (see NCARB, 2023a; NCARB, 2023b). This approach to designing an examination—which is less dependent on a specific technology and more responsive to the knowledge and skills required by the profession—is becoming more prevalent in practice.

Similarly, as noted in the fourth edition, a content-neutral demonstration of professional skills has been part of many jurisdiction bar examinations for years. In this approach, candidates (or applicants) are provided with a library of resources and are expected to complete a task that requires them to engage with these materials and respond in a job-relevant manner. The emphasis on skills has taken on new meaning as the number of practice areas has continued to expand. Based on national job analysis research (National Conference of Bar Examiners, 2020), more than 25 different practice areas were noted by survey respondents, suggesting that the scope of practice is diverse. An additional unique feature of the bar examination is that, rather than being overseen by the legislative branch of government as is typical for other professions, it is the only licensure process overseen by the judicial branch of government (within jurisdictions).

As we hope has been demonstrated, there is a long and complex history behind the field of assessment for licensing and certification. Many advances have been made with respect to understanding the complexities of credentialing contexts and how to advance both theory and practice, yet many challenges still exist. The next section reviews topics relating to fairness and other legal considerations that can provide more insight into some of the issues and challenges that have faced this field in recent years.

FAIRNESS AND LEGAL ISSUES

The high-stakes nature of decisions made based on scores from credentialing examinations places additional responsibilities on programs that develop and maintain these examinations. Specifically, in addition to the professional expectations articulated in the *Standards* (AERA et al., 2014), programs and practitioners should be aware of the legal frameworks and case law that may interact with theory and practices within the measurement community. Phillips (2017) organized her comprehensive discussion of legal challenges that have occurred in licensure and certification using the following framework:

1. *Protecting the public*: Conditions under which it is fair to require candidates to demonstrate minimum competence for defined knowledge, skills, and abilities.
2. *Testing accommodations policies*: Defining criteria for disabilities and reasonable accommodations and ensuring that the meaning of the license or certification is not changed through modification of the construct.
3. *Test security policies*: Procedures for maintaining confidentiality of test content, ensuring valid score interpretation through detection and enforcement of test security violations.
4. *Test construction procedures*: Options for licensing and certification programs pressured to adopt item selection criteria that minimize differential performance between majority and minority candidates.

We discuss some of the recent case law associated with the first three of these areas and refer interested readers to Phillips (2017) for discussion of some of the historical background associated with the fourth area as it relates to legal precedent that conflicts with what often are considered professional expectations and best practices within measurement. Though this section largely focuses on case law covering issues related to fairness, the topic of fairness also is explicitly discussed relevant to test accommodation and score interpretation and is included as central to test development, reliability, and validity considerations. For a broader discussion of issues related to fairness, the interested reader is referred to Zwick, and Rodriguez and Thurlow, both this volume.

With a focus on U.S. jurisdictions, federal law forms the basis for most of the challenges described in this section. Most legal challenges to licensing and certification programs point to alleged violations of the 14th Amendment to the U.S. Constitution, Title VII of the Civil Rights Act (1964), Section 504 of the Rehabilitation Act (1973), the Copyright Act (1976), and the Americans With Disabilities Act (1990). The courts have relied on the *Uniform Guidelines on Employment Selection Procedures* (Equal Employment Opportunity Commission, 1985) for interpreting expectations for licensing and certification litigation. These legal expectations generally are intended to guard against discrimination of protected classes that include the demographic characteristics of age, disability, ethnicity, race, or sex. It is important to note that these legal expectations are not universal and some of the case law discussed in this section may not warrant action or be part of legislation in other countries. As such, readers should consider the jurisdiction-specific expectations applied to their licensing, certification, or equivalent program (e.g., qualification, accreditation, registration).

As noted earlier, there are documented examples of licensing boards overreaching in terms of their charge to protect the public (e.g., the plaintiff offering African hair braiding services). Similarly, decisions like the one against the North Carolina Board of Dental Examiners (2015) indicated that the courts recognize that there is a limit to how a licensing board defines its need for oversight and public protection. This case began with a complaint filed with the Federal Trade Commission by owners of teeth-whitening kiosks after the state board of dental examiners claimed exclusive domain under their practice

act and told them to cease and desist. The Federal Trade Commission concluded that the interpretation was an overreach of the practice act and ruled against the board, citing that, even within a dentist's office, nonlicensed staff members administered and monitored teeth-whitening procedures, thereby suggesting that the risk to the public was limited. Within Phillips's (2017) organizing framework, this illustration would fall within challenges related to assertion of public protection. Challenges to licensing and certification examinations may not come through judicial processes such as lawsuits because legislative (e.g., House, Assembly, Senate) and policy bodies (e.g., licensing or certification boards) seeking to sunset (Drew, 2016) or remove (Taylor, 2017) requirements may be as effective as litigation.

Because the treatment of the historical foundation for legal challenges for licensing and certification programs is articulated in greater detail by Phillips (2017), B. E. Clauser et al. (2006), Phillips and Camara (2006), and Ercikan and Solano-Flores, and Zwick (both this volume), we have limited our discussion to key decisions that have occurred within each of these areas since the publication of the fourth edition of *Educational Measurement*. This is not a comprehensive review of all decisions but rather illustrates the types of challenges that have occurred in licensing and certification.

Protecting the Public

Because of the potentially broader implications for licensing and certification testing programs, the *Gulino v. Board of Education of the City School District of the City of New York* (2002) case is of particular interest for the measurement community. In the Gulino case, the court interpreted a teacher certification examination as having properties of an employment test because of how the state permitted provisional or temporary licenses that allowed teachers to teach. This temporary license included an expectation for completion of licensure examination requirements within a specific time frame. Because passing the examination became a condition of continued employment in a given role, the court viewed this as a de facto employment test. When examinations are mandatory for employment eligibility, as is the case for licensing and many certification examinations, the Gulino ruling could be extended to the broader family of licensing and certification examination programs in which passing the examination is a condition of initial or continuing employment. Litigation on the case has been ongoing for more than 2 decades.

The original action was filed in 1996, when a group of African American and Hispanic teacher candidates alleged that the teacher certification test discriminated against racial minority candidates because passing rates for both racial/ethnic groups were below the 80% rule that defined disparate impact under the *Uniform Guidelines*. The 80% rule means that a protected class has an observed passing rate that is less than 80% of the passing rate of the majority group. The lawsuit was certified as a class action in 2001. As it relates to test development and validation, the court's interpretation of necessary evidence to support the test's continued use was important. The court ruled that five sources of evidence were needed to support the job relatedness of an employment test.

Specifically, these sources of evidence were (a) a suitable job analysis, (b) competent test development, (c) test content related to job content, (d) tested content representative of the job, and (e) an appropriate performance standard (i.e., passing score) for selecting competent applicants. The court held that the new test was not properly validated because the vendor did not conduct a rigorous job analysis, did not competently develop the test, tested content unrelated to and unrepresentative of the job of teaching, and applied a passing standard unrelated to teaching competence (Gulino, 2002).

More specifically, the court found that the vendor's test framework—developed by reviewing teacher education materials, consulting with education experts, and surveying teachers and teacher education faculty—was flawed because the vendor: (a) did not start with a task analysis of teaching; (b) had not documented the reference materials or persons interviewed; (c) had pilot tested items on college students rather than on working teachers; (d) had failed to link the tested content to minimum and representative content required for teaching competence; and (e) set the passing standard based on a small subset of items with no definition of minimum competence or data relating test scores to student outcomes. Thus, the court concluded that the board violated Title VII when it required teachers to pass the new test to obtain permanent licenses. The decision was affirmed on appeal.

Several lessons emerged from this case. An important lesson was that even though the *Standards* (AERA et al., 2014) is intended to serve as a primary guide for the testing profession, the court in this case did not recognize it as such. Further, because the court appointed a neutral expert who prioritized the *Principles for the Validation and Use of Personnel Selection Procedures* (Society for Industrial and Organizational Psychology, 2003) along with the *Uniform Guidelines on Employee Selection Procedures* (Equal Employment Opportunity Commission, 1985), the value of the *Standards* in this proceeding was further diluted. Although not intended to be prescriptive, if guidance from the *Standards* does not align with legal expectations, practitioners will be exposed to risk. Although the *Standards* includes a caveat about its utility in legal proceedings that may supersede the profession's expectations, these legal standards often are not widely known, nor are they necessarily consistent. Different jurisdictions may have different expectations, so beyond some core expectations that would be articulated in federal law (e.g., U.S. Constitution) or regulations (e.g., Civil Rights Act of 1964 as amended in 1991), the legal standard may not become fully evident until it is settled by the Supreme Court. The court's rationale for interpreting the state's credentialing exam as an employment test was that it was used as a condition for continued employment following issuance and potential extension of a temporary or provisional license, not just eligibility for employment. Therefore, without passing the examination, an applicant would not have been eligible for a permanent license. The focus of the proceedings then centered on the job analysis evidence and whether there was a clear connection between knowledge, skills, and abilities that an educator would need to know in practice.

Although evidence from the state and most evidence collected by the vendor from practicing educators and faculty who train educators suggested that there was a connection, the court's expert disagreed and offered an opinion that suggested a specific methodological preference for what would constitute an appropriate job analysis study. The perspective offered by the court's expert focused on the incremental validity evidence provided by the test in question and whether all educators should be required to demonstrate this level of minimum competence. During the hearing, the plaintiff's attorneys and the judge questioned whether the range of content represented on the test was job related and important for all educators. The intuitive perspective of the judge was that content areas such as fine arts would not apply to what a science teacher would need to know and be able to do (*Gulino, 2015a*).

Concurrently, the state had been in the process of redesigning and developing the examination with a focus on making changes to the content specifications. The revised examination recharacterized the construct as inclusive of literacy and writing abilities rather than the range of liberal arts skills that were defined in the prior version. This new exam also was challenged as part of the proceedings in the case as having adverse impact and not being properly validated. In this instance, the state's test vendor contracted with an external organization to conduct a practice analysis. The extensive study evaluated the knowledge, skills, and abilities of educators to determine whether the content of the examination was consistent with job-related expectations.

Again, the court's appointed expert concluded that the examination was not properly validated for reasons almost identical to those advanced for the prior iteration of the examination in the broader program. However, in this instance, the court's ruling for *Gulino* (2015b) yielded a different outcome in that the court accepted the content evidence for the program. Although the methodology for evaluating content evidence for these examinations was different, they were both within a common set of validation activities conducted for credentialing examinations. It is possible that the court's acceptance of the evidence of examination content for the new examination was based on an intuitive understanding of content that educators would need to know and be able to use. In other words, it was more difficult to argue that the literacy skills of reading and writing content areas were not important for all educators in practice, as opposed to the diversity of content represented in the prior version. However, the opinion of the court's expert likely leaves room for additional litigation on this issue because the implications for the testing program and its users are substantial. The ongoing litigation costs and questions regarding how to interpret the court's rulings in this case have continued to have ripple effects for other educator certification programs as well as for the licensing and certification community more broadly.

Testing Accommodations Policies

The Americans With Disabilities Act (ADA, 1990) requires that licensing and certification programs make decisions about accommodations for candidates with disabilities (see Rodriguez & Thurlow, this volume, for further discussion of fairness

issues related to test takers with disabilities). To support a violation of the ADA, plaintiffs need to provide evidence that there is a qualifying disability and that a reasonable accommodation was denied (*Cox v. Ala. State Bar*, 2004). The three elements of a qualified disability are (a) an impairment (b) that substantially limits (c) a major life activity. As it directly relates to some of the knowledge and skills measured in licensing and certification tests, it includes many prerequisite abilities such as literacy and communication skills that generalize across professional domains.

Accommodation, Not Modification

It is important to differentiate between what is intended with an accommodation and something that would modify or change the construct that is being measured. In the instance that providing an accommodation would fundamentally change how the job-related knowledge or skills are demonstrated, a candidate does not need to be permitted to receive the accommodation under the ADA. It then becomes important for a licensing or certification program to define the critical knowledge, skills, and abilities that are part of the intended construct. Phillips (2017) suggested that licensing and certification programs that use simulation or more real-world measurement approaches may not be able to offer accommodations as easily as examination programs that focus more on knowledge or application of information without potentially modifying the intended construct.

Although accommodations often are interpreted within the measurement community as facilitating opportunities for candidates with disabilities to demonstrate their skills, there is an important distinction in stakeholder groups' perceptions. Phillips (2012) noted that advocates for disabled candidates may interpret increased access as applying to opportunities within a profession or occupation; this is notably different from attempting to facilitate greater access to the examination. She further makes the point that if the accommodation is construct relevant, the interpretation of the candidate's job-related abilities may be called into question as a result of the shift in the meaning of the score and resulting decision.

The interesting court ruling in *Palmer College of Chiropractic v. Davenport Civil Rights Commission* (2014) raises the question of how job relatedness is interpreted, and it extended the question about what types of accommodations are reasonable. In this case, the court ruled that the college was required to provide a visually impaired student with a sighted assistant for reading and interpreting radiographs (i.e., X-rays). The question of the job relatedness of being able to read, interpret, and diagnose radiographs for the purpose of developing and implementing a treatment plan is an important one. The court's ruling suggests that it is a skill that in practice can be delegated to another role in support of the chiropractor role. If this is the case, then it is a reasonable interpretation. If not, however, then the court in this instance has appeared to define expectations that may run counter to the legislative practice act that defines the scope of practice for the profession in the jurisdiction.

Evaluating Reasonableness

Part of the ADA's expectations for accommodations rests in the interpretation of what constitutes a *reasonable* accommodation, recognizing that there are some limits to the interpretation. In *Kelly v. W. Va. Bd. of Law Exam'rs* (2010), the plaintiff (Kelly) was diagnosed with a reading disability after being accepted to law school and received a time-and-a-half accommodation for exams. He then transferred to a new law school, where he received a double-time accommodation. He did not receive any accommodations during college or for his admission exams.

For the West Virginia bar examination, Kelly requested double time but was granted a time-and-a-half accommodation. Although it was not part of the bar exam, Kelly also passed the required professional responsibility exam within the licensure process for lawyers without an extended time accommodation. A member of the licensing board testified that it was a job-related skill for a lawyer to be able to work under time constraints and that most applicants used the full testing time, with not everyone finishing. The plaintiff failed the West Virginia exam twice with the time-and-a-half accommodation and then successfully appealed to Kentucky's Board of Bar Examiners to provide a double-time accommodation for its bar exam.

In evaluating the differing opinions of expert witnesses for the plaintiff and the board, the court held that the board's position was more credible given the plaintiff's prior education experience and related test score performance that were provided as evidence of the need for the accommodation. The court further held that providing more time than was necessary would shift the impact of the decision from being a disability-based accommodation to being an advantage over other applicants. As part of its deliberation, the court considered the historical pattern of accommodations for the plaintiff: specifically, that there were no accommodations provided until law school. As a result, the court interpreted that the request was unreasonable and not required under the ADA.

Currier v. NBME (2012) was another case that focused on the definition of a reasonable accommodation. The context for this case was Step 2 of the United States Medical Licensing Examination (USMLE); the two-part accommodation request was for (a) extended time for diagnosed learning disabilities and (b) additional break time for the candidate, a nursing mother, to pump breast milk. In response, the National Board of Medical Examiners (NBME) offered to provide a double-time accommodation for the learning disabilities (dyslexia, attention deficit hyperactivity disorder), administering the exam over 2 days, in a separate room. To respond to the candidate's request for the 60 extra minutes each day to pump breast milk, the NBME offered to provide its standard break time of 45 minutes each day, along with a power outlet and the ability to bring food into the separate room that was previously offered for the double-time accommodation.

The plaintiff sued to get the extra break time to be able to pump. NBME's position was that the break times needed to be uniform for all candidates, and the combination of accommodations—double time and extra break time—made

the administration logistics untenable. The trial court sided with NBME, but on appeal, the court then sided with the plaintiff and ruled that the extra-time accommodation should be provided. With that additional court-ordered accommodation, the plaintiff failed the examination; she then passed the examination after retesting without the accommodation. As the legal proceedings continued, the court decided in favor of NBME, with the plaintiff appealing again. The appeals court ruled that nursing mothers were covered under the *state* equal rights act, but not under the ADA, based on sex discrimination. It is important to note the distinction between state and federal jurisdictions and how they may not always overlap with respect to interpretation.

Test Security Policies

Many licensing and certification testing programs have transitioned to computer-based testing. This occurs in testing centers, through in-person events, or with remote proctoring. Although early proponents of computer-based testing argued that it would increase test security because the test material could be encrypted, concerns about security of test content and validity of scores have continued to be a significant problem. Not surprisingly, this has led to litigation related to test security and administration. Here we highlight two instances of these types of cases.

In *ETS v. Hildebrant* (2007), a candidate who was taking a principal certification test had signed a candidate agreement about confidentiality, nondisclosure, and the testing conditions included in the candidate manual for the program. According to the test proctor, the plaintiff twice refused to stop writing when time was called. Following an initial warning, the proctor completed a test irregularity report to document the nonstandard condition and noncompliance of the candidate to the administration timing conditions. The candidate insisted that she had not violated the administration conditions. After an investigation, the vendor concluded that there was a violation and canceled her test score. During litigation, the court held that the candidate's unsworn, general denial was insufficient evidence to create doubt that the vendor acted in good faith. Further, the plaintiff was unable to convince the court that the proctor had a motive to lie about the violation of the administration protocol. The court held that the vendor complied with the terms of its own policies and procedures in relying on the proctor's observations and documentation of the violation. As such, the court agreed with the vendor's position that the misconduct justified score cancellation.

A second example, *NCBE v. Multistate Legal Studies* (2006), deals specifically with the security of test material. In this case, the defendant was the Preliminary Multistate Bar Review, a test preparation provider that offered review courses for the Multistate Bar Exam across multiple sites. Detection of an attempt to steal test content occurred after a proctor caught an applicant—who was an employee of the provider—attempting to remove test content on scratch paper. Following an investigation that uncovered approximately 100 stolen items, the National Conference of Bar Examiners (NCBE) brought a lawsuit against the provider for copyright infringement. In the court's

discussion of their decision in support of a ruling for NCBE, they found substantial overlap between items that were offered by the test preparation provider and the actual items from NCBE's examination.

Discussion of legal considerations that are relevant to licensing and certification tests provides some insight into areas that should be a central focus of test developers and score users because of the associated risk for legal action. In the next sections, we review three main topics that are critical in high-stakes credentialing contexts because of their direct impact on the interpretation and use of test scores: test development, reliability, and validity.

TEST DEVELOPMENT

In most, if not all, credentialing contexts, candidates seeking the credential will be required to complete at least one examination to demonstrate their competence. A passing score on this examination will serve as an indication that the test taker has the requisite knowledge and skills to competently and safely perform the duties of the profession. As described in the *Standards*, a number of specific considerations and recommendations apply to design and development of tests used for educational, psychological, or credentialing purposes (AERA et al., 2014). This section presents test development considerations that warrant particular attention in the context of licensing and certification; for a comprehensive review of test design and development more broadly, we refer the interested reader to Huff et al., this volume.

Specifying the Purpose

The general purpose of credentialing examinations is clear: to identify individuals who have the minimum knowledge and experience to perform required tasks competently and safely (Chinn & Hertz, 2010). As noted previously, the focus in licensure is on the need to demonstrate that an individual is qualified to practice in the profession; in certification, the focus may be on specific specialization within the profession or on a more advanced level of performance.

The importance of developing and publicizing a clear statement about the purpose of the overall test—or, when relevant, the main components comprising a test—cannot be overstated. Doing so serves several functions. First, it guides subsequent test development efforts by specifying what is in and out of scope for the examination. It also informs stakeholders about the nature of the examination. For example, the NCARB has publicized the following purpose statement about the Architect Registration Examination (ARE):

The ARE is designed to assess aspects of architectural practice related to health, safety, and welfare. Specifically, the ARE focuses on areas that affect the integrity, soundness, and health impact of a building, as well as an architect's responsibilities within firms, such as managing projects and coordinating the work of other professionals. (NCARB, 2023b)

Although the specifics of the examination content are not provided, the reason for administering the test and general test content are clear to test developers and other stakeholders, including candidates who will be taking the examination. According to Cizek et al. (2011), “The test development process begins and is guided by clear, explicit statements regarding the purpose of the test and the inferences that are intended to be made from the test scores” (p. 6).

One of the challenges inherent in constructing a purpose statement is developing a clear understanding of (a) what *should be* assessed with respect to the critical knowledge and skills needed by practitioners, as well as a realistic idea of (b) what *can be* assessed given the inherent constraints associated with assessment. Careful consideration should be given to the requirements of practitioners at the specific level at which the examination is targeted. This need highlights the importance of a systematic evaluation of the profession that will yield information to guide decisions about examination content (AERA et al., 2014; Chinn & Hertz, 2010; Cizek et al., 2011; Raymond, 2001, 2002) and, by extension, development of a purpose statement.

Identifying Appropriate Content

As we have mentioned, one of the central requirements for credentialing in professional disciplines is successful completion of an examination or series of examinations that is/are intended to provide insight into whether the test taker has the necessary knowledge and skills to practice in the profession safely and competently. Regardless of the discipline or the type of credentialing, the common thread among these examinations is the need to determine the content that will provide the evidence for minimally acceptable performance. According to the *Standards*, best practice for determining the content of credentialing examinations is surveying members of the profession about the knowledge, skills, and abilities that are required of practitioners to identify the actual tasks that practitioners must be able to perform competently and safely. If done properly, this *job* or *practice analysis* will collect information about what activities are required for practice and thus will inform decisions about the content that is relevant for the examination (A. L. Clauser & Raymond, 2017). It is important to note that the practice analysis does not dictate what will be included on the test, but instead provides test developers with information about the requirements of the profession; it is the responsibility of the test developer to carefully review the results to identify the content that can be assessed within the constraints of the examination format.

A license indicates that the practitioner has the knowledge, skills, and abilities required for competent and safe practice. It is not a prediction that the individual will develop those skills over time and, in most cases, it is not restricted to a set of entry-level tasks.² To use an example from outside the professions, a driver’s license allows an individual to operate a motor vehicle. It may be ill-advised for the newly licensed driver to operate a vehicle in a highly congested area, but the license does not include such a restriction. Similarly, when a state licenses someone to practice medicine, the license does not come with prescribed limitations. There are, however, circumstances where these lines are blurred.

For example, some states require passing the first two steps in the three-step USMLE to enter a residency program and practice under supervision. Similarly, residency programs typically require successful completion of those components of the examination, making those components of the test a *de facto* license for practice under supervision. In many professions, there is a presumption that practitioners will improve their skills after being licensed; advanced certification documents that improvement, but licensing tests typically are a stand-alone evaluation. It is not uncommon for language about “entry level” or “readiness to enter the profession” to be used when discussing licensure. Insofar as this characterization implies a trajectory, we believe that it may be misleading.

It is worth mentioning that practice analyses done for the purposes of occupational licensing and certification may be different than those conducted for other purposes. For credentialing purposes, the focus is on those areas that are observable and are related to “impact on public health, safety, and welfare” (Chinn & Hertz, 2010); consideration of those areas that provide insight into other professional activities, such as those that allow for personal achievement within a profession, for example, would not be relevant. This focus on the safety of the public is a thread that carries through the entire test development process.

Much has been written about practice analysis design and the relationship between the design and the ability to extrapolate data to inform test specifications (and, ultimately, examination content; Chinn & Hertz, 2010; Raymond, 2001, 2002). The following paragraphs provide a brief overview of practice analysis in credentialing as well as recommendations and cautions associated with its use (see Raymond, 2001, 2002; and Raymond & Neustel, 2006, for a more detailed review of relevant considerations).

The decision to conduct a job analysis is only the first step in the process; a series of additional decisions about the specifics of the process must follow. These decisions generally relate to the scope of the project, the overall methodology that will be used, and the rating scales that will allow for collecting the actual practice data. Subsequent decisions about use of the resulting data to inform test specifications also must be made, but careful attention to the initial design considerations will help to ensure a more seamless process of applying the data to the next phase of test development.

Numerous approaches to practice analysis are available to practitioners, and much has been written about the different methodologies and their associated strengths and weaknesses in particular contexts and for particular uses (Raymond, 2001, 2002; Raymond & Neustel, 2006). That being said, of particular focus in credentialing contexts has been the task inventory approach and, subsequently the professional practice model (Raymond, 2002).

With the task inventory approach, a list is created that outlines the tasks or activities that are performed by practitioners in a profession. The list typically would be created by a group of subject matter experts, and the results then would be included in a survey that asks a representative sample of people in the field to respond to rating scales about different aspects of the included tasks (e.g., the importance of the task for

practice or the frequency with which the task is performed). The primary benefit of this approach is efficiency: A lot of information can be collected in a short time. The breadth of information that can be collected is especially important in credentialing contexts (where readiness for performing a variety of tasks needs to be specified across a range of settings), and the data translate well to the test specification phase (Chinn & Hertz, 2010; Raymond, 2002). A disadvantage, however, is that the focus is on individual tasks rather than higher level skills such as critical thinking and problem-solving approaches. Task inventories that emphasize discrete, observable tasks may overlook the cognitive nature of many professions (LaDuca, 1994).

This approach, regarded as an overarching framework within which practice information can be organized rather than a distinct method (Chinn & Hertz, 2010), focuses on including multiple dimensions that are important to the practice. Doing so allows for creating a matrix in which the practice analysis content is included at the intersection of the two dimensions. In medicine, this might be represented as a setting-by-competency design in which the practice settings (such as inpatient wards, emergency department, ambulatory clinic) are crossed with critical competencies such as medical knowledge or communication skills. The tasks that rely on a given competency within a setting then are included in a given cell. This approach is more comprehensive than a strict task inventory and likely is more appropriate for the complex domain of professional credentialing. The framework also is consistent with the model of practice analysis proposed by Kane (1997).

The professional practice model was developed as a way to address these limitations; it focuses on the problems that practitioners will need to solve within the relevant contexts in which they occur (Chinn & Hertz, 2010; LaDuca, 1994; LaDuca et al., 1995; Poniatowski et al., 2019; Raymond, 2002).

Though a variety of acceptable options for data collection exist, research findings indicate that a more comprehensive approach may be preferable to any single identified or named method. A comprehensive practice analysis therefore might include the following elements. First, instead of looking at discrete tasks or specific knowledge, skills, or abilities, it would focus on the types of problems professionals solve and the tools and ideas they work with to solve them. Second, it would be model driven. The model could be used for specifying a preliminary domain of practice, developing questionnaires, and establishing content weights. The goal of the practice analysis would be to confirm, modify, and refine the model. Third, the information would be obtained from multiple qualified sources, depending on the type of information being sought (e.g., a large sample of practitioners for some types of information, panels of subject matter experts [SMEs] for others). For example, the study of dietetic practice conducted by D'Costa (1986) contained elements of functional job analysis (Fine, 1986), emphasized the social and environmental context of dietetic practice, and described practice in terms of a multifaceted model. It also specified critical scenarios, which provided the basis for test items. Other examples of integrating multiple methods into a comprehensive practice analysis questionnaire include studies of nurse anesthetists (Zaglaniczny, 1993) and psychologists (Rosenfeld et al.,

1983). Future projects might follow suit by going beyond the traditional task inventory as the basis for describing occupations and professions.

Specifically designing the data collection approach to answer the question(s) of interest is extremely important. If task importance is the most critical determinant of examination content, contributors should respond to questions about task importance. Similarly, if knowing the frequency with which a particular activity or competency is required, questions about frequency should be asked explicitly. It also is critical to design the practice analysis so that the results can readily inform the development of test specifications (Raymond, 2015). See Huff et al., this volume, for more information about designing test specifications that are used to guide examination development.

It is important for the entire process of conducting a practice analysis to be viewed as an empirical activity that must be performed carefully and systematically. Done correctly, a practice analysis is likely to be resource intensive. It also is a process that should be repeated on a regular basis (e.g., every 7–10 years) so that any changes in professional practice can be identified and examination content coverage can be revised. Though potentially daunting, the effort is critical to the credibility of the examination program. As was described earlier, the legal implications are potentially significant for a credentialing program that has not done its due diligence in aligning examination content with practice requirements.

Adapting the Assessment to Changes in the Profession's Practice

In professions such as medicine and law, the potential for frequent changes in practice necessitates ongoing attention to evaluating practice data and making necessary adjustments to test content. New science changes medicine and new judicial decisions change law. This means that in addition to periodically updating the practice analysis, item pools must be reviewed and updated frequently. In some cases, specific events may trigger such a review; for example, the change in guidelines for the use of hormone replacement therapy that occurred in the early 2000s led to a review of related items in the USMLE item pools.

In addition to changes in practice specific to test content, technology has created more pervasive changes in how professions work. An important example of one of these technological changes is the availability of electronic resources that provide easy access to a wealth of information. For example, Myers and Bashkov (2020) reported that, on average, physicians consult resources for approximately 30% of the patients they see. A central role of credentialing organizations is to steer away from questions that assess factual recall of test content and instead assess performance related to constructs that are needed for practice (e.g., judgment on case law). This has led to several professions deciding to include online resources as part of their assessments. Aligning the assessment conditions with practice activities has the potential to support the validity of the resulting inferences that are made based on the test scores. At the same time, such changes lead to a question of whether access to electronic external resources during an assessment may unintentionally change the construct that is being assessed from actual professional knowledge, skills, or abilities in a particular area to the ability to retrieve pertinent information. Lipner et al.

(2017) provided an example of research designed to answer this question. They conducted a randomized experiment using case scenarios and multiple-choice questions to assess physicians' clinical judgment skills under timed testing conditions. They found that the inclusion of an electronic resource did not adversely affect assessment performance and did not change the construct targeted by the assessment. Due to testing time limitations, the external resource functioned as a tool much like a calculator used on the SAT exams. If, however, there were no time limit, they posit that the construct might change significantly such that what was being measured was the test taker's ability to find the correct answer through information retrieval skills. This change could make it possible for a non-physician to pass the assessment, which clearly undermines test validity.

Automated Item Generation

Recent advances in testing and technology have allowed researchers to explore the use of model-based approaches to content development that will improve efficiency in the production of test material and support the design of assessments to enhance both the quality of the resulting questions (Gorin & Embretson, 2012; Leighton, 2012) and the validity of associated score interpretations. Mislevy and Haertel (2006) stated that "evidence-centered assessment design (ECD) provides language, concepts, and knowledge representations for designing and delivering educational assessments, all organized around the evidentiary argument an assessment is meant to embody (p. 6)"; this conceptualization meshes well with Kane's popular validity framework (2006, 2013).

Automated item generation (AIG) is an advanced test development approach that attempts to address the need for fast, efficient production of domain-specific test items by employing a generative process that uses models and computer technology to create new test items. Where traditional item development is a resource- and labor-intensive process requiring subject matter experts (SMEs) to develop individual items one at a time, AIG automates and streamlines the process by using technology to rapidly generate hundreds of test item iterations. Gierl and Lai (2015) described a model-based approach to content development using cognitive task analysis (Clark, 2014). At present, relatively little is known either about the cognitive processes used by test takers in responding to test items or about the characteristics of those items that impact their psychometric performance, although one study indicates that AIG items perform similarly to other test items (Gierl et al., 2016). Although AIG continues to be studied, the technology is not currently in widespread operational use. More research is needed to evaluate whether the anticipated benefits of AIG will be realized for the approach to be adopted more broadly.

Innovative Item Types

Since the 1960s, multiple-choice items have been the most commonly used item format in credentialing contexts (M. McDonald, 2014).³ This format was introduced in 1915 as a way to (all but) eliminate the scoring errors that were rampant in educational assessments, and it has additional benefits in that it both supports broad sampling of test content in a fixed amount of testing time and reduces the effort required for scoring.

The primary disadvantage, particularly in credentialing contexts, is that test takers select a response from a predetermined list rather than constructing a response based entirely on their own knowledge and skills. At more advanced levels of credentialing, the concern is that this does not necessarily provide clear evidence that test performance will generalize to performance in the real-world practice environment. In some contexts, this disadvantage may be trivial. If, for example, it is important for Certified Public Accounts to know/be able to identify the fraudulent activities that could be perpetrated because of a lack of effective internal controls in the revenue cycle, (a) that knowledge can be readily assessed using multiple-choice questions and (b) doing so is completely relevant to what is necessary for performance in practice. In other contexts, competent practice necessitates not only content knowledge but also demonstration of how that foundational knowledge is to be applied; in some of these situations, multiple-choice items may be less appropriate. It is these situations in which there has been a focus on developing and administering *innovative* or *alternative* item types.

Innovative (or alternative) items are those presented in a format other than the traditional multiple-choice format (Association of Test Publishers & Institute for Credentialing Excellence, 2017; Parshall et al., 2002; Wendt & Harmes, 2009). Many varieties of innovative items exist, and we provide a brief overview here both to provide insight into why these item types increasingly have been used for credentialing purposes and to explain why this trend is important and relevant in credentialing contexts. (See Huff et al. and Bennett et al., both in this volume, for further information about item types.)

The hallmark of alternative item types is that at least one of the following aspects of the items is different from traditional multiple-choice items: item presentation, the test-taker task, the response method, or item scoring (Association of Test Publishers & Institute for Credentialing Excellence, 2017). Though many types of innovative items exist, several categories tend to be used most commonly: items that include audio or video as stimulus material, multiple choice multiple response (two or more keys, often more than four options), hot spot (answer in the form of clicking on part of graphic), drag and drop/place (clicking and dragging text or graphics to match, sort, or rank), written response (an open response to a prompt such as an essay or short-answer question), and audio/video prompt (an audio or video clip is part of the item stem; Cadle & Parshall, 2015; International Test Commission & Association of Test Publishers, 2022; Parshall & Harmes, 2008).

The decision to include innovative item types should be motivated by a need and/or desire to create assessment tasks that capture important construct-relevant information about test takers, rather than simply because it is possible and exciting to develop something new and different. In credentialing contexts, where the assessment is intended to provide some level of insight about a candidate's ability to practice competently and safely, the focus may be on including more realistic assessment tasks that provide a clearer link between test performance and performance in the profession. The reason for developing these items also may be the need and/or desire to present

tasks that require the same types of cognitive processes that are necessary in practice. The typical guiding principle behind including these items in the assessment is greater fidelity; unfortunately, greater fidelity does not guarantee validity (Parshall & Harmes, 2008). When developing these novel assessment tasks, it is important to be sure that the constructs of interest are the focus of the assessment and that the item type is selected because it adds something important to the measurement of the construct. If, for example, it is important for a medical student to be able to interpret heart sounds, one complex assessment option might be a performance-based examination in which students examine standardized patients using an electronic stethoscope that presents simulated heart sounds. An alternative approach would be to incorporate audio into a text-based multiple-choice item. The latter option is a more efficient approach that likely allows for equal, if not better, measurement of the construct of interest.

Increasingly sophisticated technology permeates most aspects of daily life, and the domain of testing is no exception. A desire for increased authenticity has continued to influence the trend toward technologically innovative assessment solutions in which test takers engage with and demonstrate competence through activities that more closely approximate real-world practice. Computer simulations have gained in popularity, though the complexity, fidelity, and interactivity of these approaches can vary significantly (Association of Test Publishers & Institute for Credentialing Excellence, 2017; Margolis et al., 2002). A low-fidelity example might present four pictures of dermatologic conditions and have the test taker click on the one that is appropriately treated with cryotherapy (Association of Test Publishers & Institute for Credentialing Excellence, 2017). A high-fidelity example might be using a patient mannequin and simulated catheterization laboratory to assess interventional cardiologists' procedural skills. This type of simulation could yield information supporting the claim that candidates know how to do the procedure instead of just knowing the right thing to do without actually performing the task under pressure (Lipner et al., 2010). As noted previously, the evolving nature of professional practice has prompted innovations in assessment design. A notable example—aimed at more closely mirroring real-world conditions by allowing access to key resources during testing—is the American Board of Internal Medicine's decision to incorporate commonly used point-of-care tools into its certification exams (Lipner et al., 2017). Similarly, the Uniform Certified Public Accountant examination uses task-based simulations that typically require test takers to use authoritative literature provided in the examination (<https://www.aicpa.org/becomeacpa/cpaexam/downloadabledocuments/cpa-exam-digital-brochure.pdf>). Other examples of new innovations include drag and drop/place as well as hot spot items in the ARE exam (<https://www.ncarb.org/blog/a-deep-dive-are-5-item-types>), drag and drop/place items used by the National Council of Examiners for Engineering and Surveying (<https://ncees.org/exams/cbt/>), and the computer-based patient management simulations used in Step 3 of the USMLE (<https://www.usmle.org/step-3-test-question-formats/computer-based-case-simulations>).

Feedback

Test takers have increasingly demanded that testing organizations enhance the educational value of assessment by providing feedback about strengths and weaknesses. This is especially true for continuing certification programs where a new focus on learning and improvement is intertwined with the assessment (American Board of Medical Specialties, 2019). Metacognition has been shown to be important in self-regulated lifelong learning, from having the ability to adjust one's learning to becoming a better professional (e.g., a better clinician who makes fewer medical errors; Medina et al., 2017). Metacognition includes planning, monitoring, and evaluating one's own learning process, and the idea is to make this process more automatic so that errors are not repeated. For example, in the Doctor of Pharmacy program, a key goal of ensuring the reliability and validity of examination scores is to enhance student learning and achievement of the program goals; this is done by providing meaningful feedback for metacognitive learning after an examination (Ray et al., 2018). To enhance metacognition, the authors suggest an exercise after the test where cohort performance data by topic are shared with students and they engage in a three-step process of describing their understanding of concepts when they took the test, reviewing faculty feedback and identifying essential concepts, and reflecting on their knowledge gaps. Despite the clear value of feedback from the perspective of the test taker, testing organizations must contend with the natural tension between the risks and benefits of providing such information. Ideally, once the assessment is complete, individuals would benefit from receiving feedback in the form of the question, the correct answer, and an explanation of why the correct answer is right and the incorrect answers are wrong. From the perspective of the test taker, the benefits of receiving this information are clear. For the testing company, however, the associated risks of exposing examination content may not be acceptable.⁴

Much has been written about score reporting guidelines and feedback (Zenisky & Hambleton, 2015) and the influence of the context of the testing experience on what makes a report useful and understandable (see also Zenisky et al., this volume). Klesch (2010) complemented this literature with detailed work on score reporting for teacher certification, specifically identifying ways to use technology to provide better and more engaging feedback to teachers on their performance. She also noted that raw scores, percentage scores, or even narrative performance descriptions were more desired than scaled scores and that use of statistical terms or abbreviations was not recommended. Likewise, information about confidence intervals (i.e., measurement error) was not useful for those preparing to take the test again. Klesch found that providing information in many different ways (e.g., contextual, statistical, visual) was important for different learning styles.

Short of giving the full question/answer/rationale, some medical testing organizations have provided feedback in the form of subscores (performance scores for subdomains of an exam) to provide more diagnostic performance information (e.g., areas of relative strength and areas in need of improvement). An example of this type of feedback can be seen in the Internal Medicine Certification exam in which

subdomain scores are presented to test takers following the examination (American Board of Internal Medicine, 2023). Presenting subscores introduces an array of measurement concerns because assessments are designed to measure the overall construct of the discipline such that the total score is the most appropriate measure of the test taker's knowledge in the field (e.g., Feinberg & Jurich, 2017; Feinberg & von Davier, 2020; Feinberg & Wainer, 2014a, 2014b; Sinharay, 2010; Zapata-Rivera, 2018). Despite this caution, test takers desire performance information because it helps them to understand their areas of strength as well as areas that are in need of improvement. Particularly in credentialing contexts, test takers who are not successful often request additional information specifically to aid them in understanding where they fell short so that they can address those weaknesses in a focused way. Subscore use has increased over the years, and this makes it even more important for testing organizations to ensure that reported subscores are reliable and valid. Augmentation of subscores with information obtained from other parts of the assessment sometimes is done to achieve this goal, especially when the subscores are correlated (de la Torre & Patz, 2005; de la Torre et al., 2011; Edwards & Vevea, 2006; Sinharay et al., 2011; Wainer et al., 2001). Puhan et al. (2010) showed that reporting subscores may be most beneficial (or at least not harmful) at an institutional level (e.g., programs where 30 or more students were trained) but that they typically do not add much value over the total score. However, augmenting subscores using information from the total score did result in increased subscore reliability. Similarly, augmenting subscores using even just one prior testing occasion can improve subscore reliability, especially when the number of domains is limited and the overall test length is relatively short (Smiley, 2019). Feinberg and von Davier (2020) described a method for identifying unexpectedly high or low subscores that could stand out for test takers and be more actionable. This may help to limit misinterpretation of subscore reporting.

Another approach to enhancing the educational value of an assessment is to provide feedback at the topic and task level such that the intended measurement objectives of the incorrectly answered questions are revealed without exposing the exact item content. This enables test takers to understand their knowledge gaps at a more detailed level than does providing simple subdomain scores. The development of this approach is described in detail elsewhere (Brossman, 2018), and an example of the final presentation of the score report feedback is presented by Lipner et al. (2019). The obvious concern about this approach is low subscore reliability; there are few questions in any single subdomain because the assessment is a sampling of the entire domain. Focusing on areas with low reliability may give test takers a wrong signal of where their weaknesses lie. When there is significant variability in the number of questions represented by a subscore, there also may be instances in which studying the topic area with more questions is a better strategy than studying the topic area in which the test taker had relatively poorer performance. That said, providing more specificity does help test takers better understand what they got wrong on the test

and, as long as they are aware of the limitations, it helps them focus on the topics where test questions were missed.

A slightly different perspective on the provision of feedback relates to contexts that employ a hybrid assessment approach intended to satisfy both formative and summative assessment needs. Formative feedback is provided with the goal of helping learners identify areas of strength and areas in need of improvement so that they can focus their efforts on those areas for the summative component. This practice can lead to challenges in interpreting test results and in evaluating the overall validity of the inferences made from those scores. This topic is further discussed in the “Validity” section, specifically from the perspective of consideration of threats to test validity. In the next section, we address aspects of reliability that either are unique to or warrant special consideration in credentialing contexts.

RELIABILITY

Reliability relates to the estimation of error in measurement that might arise from different sources. The measurement community has developed several formulas and indices to estimate the error of scores, scorers, decisions, and classifications (Haertel, 2006; Lee & Harris, this volume) and, more specifically, has provided practical insight into the applications of these measures in credentialing contexts (B. E. Clauser et al., 2006). The expected reliability for licensing and certification examinations will depend on multiple factors. For example, the types of items, scoring methods, decisions, and decision rules that are used for the examination will influence the selection of methods to estimate reliability. Practitioners are encouraged to use methods that focus on the greatest potential sources of error. To illustrate this point, for a human-scored performance task that has subjective features of a rubric, one important source of error likely is in inconsistent application of scoring criteria to the performance; when the assessment is based on relatively few tasks, the sampling of tasks (the person-by-task interaction in generalizability theory terms) also may make a substantial contribution to error.

Kane (1996) discussed another concept that is particularly important to credentialing tests: error tolerance. The high-stakes nature of any test used for classification and decision-making increases the need for precision around the passing (cut) score. The conditional standard error of measurement (CSEM) around the cut score provides users with an estimate of the uncertainty of the decision: The larger the CSEM, the greater the uncertainty. The location of the cut score in the score distribution also influences the confidence and connects with Kane’s recommendation to consider the error tolerance in describing it. As users think about Type I (false-positive/pass) and Type II (false-negative/fail) errors in terms of decisions, the tolerance for these types of errors will be dependent on the risk of making each one. In the instance of a Type I error, policy makers will need to evaluate the risk to stakeholders and the public of someone entering a profession whose true score may not meet the minimum standard for competence (assuming all other eligibility and licensure or certification requirements are

met). This is where the interpretation and use of the credential is important to consider. One can make a reasoned argument that for members of the healthcare community, the risk of an unqualified candidate can have devastating, if not deadly, consequences. The risks of false-positive outcomes in other professions (e.g., architects, lawyers, educators) can be similarly costly.

Conversely, the risk of a Type II error has additional consequences, such as potentially limiting the pool of qualified practitioners available to the public. The challenge is that programs are unable to accurately determine which candidates are the results of Type I or Type II errors; it is only possible to know that there are some candidates within that range of uncertainty that may be misclassified. Because of these risks and the associated limitations, it is important for testing programs to review information about classification and discuss the levels of risk tolerance associated with different decision points. It is in these instances where the combination of validity, reliability, fairness, legal risk, and testing policy intersect.

Methods

To reduce redundancy with the discussion of methods provided by Lee and Harris (this volume), we have focused our discussion on measures of classification consistency and accuracy. The *Standards* (AERA et al., 2014) noted that licensing and certification tests should prioritize these sources of reliability evidence. It is important to note that methods for estimating reliability of scores also are applicable for credentialing testing. However, per Standard 11.14, estimates of decision consistency also should be provided, and “the consistency of decisions on whether to certify is of primary importance” (AERA et al., 2014, p. 182). As applied to licensing and certification tests, Popham and Husek (1969) discussed the issue of calculating reliability for criterion-referenced tests in an educational context when there was an expectation of limited score variability and scores well above the passing score. This led to the subsequent development of methods that could respond to estimates of classification or decision consistency (see Brennan & Kane, 1977; Brennan & Prediger, 1981; Huynh, 1976; Livingston, 1972; Subkoviak, 1976). These initial efforts represented an expansion of the concept of reliability and, by extension, an expansion of some of the evidence that would be valuable for licensing and certification programs.

An additional wave of methods emerged in the late 1980s and 1990s, driven by efforts to clarify the interpretation of these indices (S. A. Livingston, personal communication, January 18, 2002) and by advances in computing power that made it easier to implement more sophisticated techniques. Approaches described by Hanson and Brennan (1990), Breyer and Lewis (1994), and Livingston and Lewis (1995) sought to respond to these questions. Further research by Brennan and Wan (2004) described the application of bootstrap techniques. More recently, work by Cui et al. (2012) using cognitive diagnostic models provided additional value to this still growing line of research. The application of cognitive diagnostic models along with application of measurement decision theory methods (see Rudner & Gao, 2011) has seen greater utilization in licensing and certification, particularly in maintenance of certification and the use of longitudinal

assessments where test/assessment items may be used more as assessment for learning to evaluate and promote continued competence. These longitudinal approaches are currently being used (e.g., American Board of Anesthesiology, American Board of Pediatrics, American Board of Internal Medicine) and explored (e.g., National Commission for Certification of Physician Assistants) as new forms of assessment for maintenance of certification that are not event-based test-delivery experiences. In these longitudinal assessments, programs often will administer a smaller number of questions (e.g., from 1–5 to 20–30) every month or two as a strategy to facilitate ongoing engagement in professional literature and to maintain currency in the profession.

Implications for Practice

Although there is no single approach that is appropriate for all situations, it is important to understand the assumptions and limitations of available methods in order to make informed decisions about which approach to use in a given context. As it relates to the passing score, a CSEM can be interpreted, but with CSEMs often yielding relatively standard values, the use of a classification consistency index that is reported on a metric between 0 and 1 may be easier to communicate to more diverse stakeholder audiences. This means that when communicating with policy bodies or lay stakeholders, stating that a program has 90% or 95% confidence in the accuracy of its pass/fail decisions is often more interpretable than sharing a CSEM value. When these statistics are reported, it also is appropriate to note limitations or cautions with respect to the stability of the estimate. The practicality of using classification consistency estimates illustrates the interrelated nature of dependent characteristics of scores that are produced by licensing and certification exams; these include sample sizes, first-time takers versus retest candidates, location of the passing score, and related risk management considerations.

Something unique to credentialing contexts that is not frequently discussed in methods of reliability relates to smaller volume programs. The data dependency of most methods (bootstrapping or simulation being exceptions) means that estimating reliability or classification accuracy for smaller volume programs remains a meaningful challenge for which neither historical nor modern methods offer satisfactory solutions. As with the initial nudge from mastery testing within educational assessment to explore single administration estimates of decision consistency, there may be an opportunity to again look to K–12 education for consideration of additional methods or concepts that could be applicable solutions for credentialing programs.

Statistical estimates of reliability are often unstable with small sample sizes. Similarly, estimates of the conditional standard error of measurement at the passing score also may be imprecise, though they can still offer some empirical insight. However, in response to the challenge of providing evidence of reliability for the many smaller volume credentialing programs, it seems necessary to move beyond statistical calculations/estimates only. If we conceptually define reliability as the replicability of observations of samples of candidates' abilities that are judged to align with a given construct, then extending

the interpretation of reliability may be appropriate. To that point, the ideas suggested by J. K. Smith (2003) in a reconceptualization of reliability for classroom assessments may be worth exploring in greater detail. Classroom assessments often suffer from some of the same challenges as smaller volume credentialing programs: There is a small sample of test takers and the expected range of abilities for those test takers may be limited. The combination of these factors often yields unstable and potentially suppressed estimates of score reliability. Corrections for attenuation may not be enough to provide a reasonable estimate.

In rethinking the characterization of reliability, J. K. Smith (2003) suggested using a criterion of sufficiency as a proxy for traditional measures of reliability. In other words, psychometricians often recommend having a minimum number of measurement opportunities (e.g., items, questions, score points) for each important concept or domain of interest. Using that approach, and absent robust data sets to conduct traditional analyses, we may be able to make an argument that the object of measurement is being sufficiently represented by multiple observations in alignment with other sources of recommended best practices. For licensing and certification programs, the concept of sufficiency could be applied as an interim step until data can be collected to apply more traditional methods. This approach also may provide a solution for an important source of evidence for credentialing programs where the current practice may be to simply ignore consideration “due to low sample sizes.” Professional standards suggest we can do better, yet currently there is a dearth of evidence-centered approaches to guide such improvement. In 2017, the Institute for Credentialing Excellence published a revised version of the National Commission for Certifying Agencies’ Standards for the Accreditation of Certification Programs. In this document, Standard 20 addresses reliability concerns and provides specific commentary associated with estimating reliability for small-volume programs:

When candidate volumes are so small or there are other factors which lead to reliability estimates that are not meaningful, programs should describe the procedures used to demonstrate that the decisions made on the basis of scores are reasonable and fair. (Institute for Credentialing Excellence, 2014)

This comment clearly acknowledges limitations associated with providing meaningful reliability estimates in certain contexts, but limiting solutions for small-volume credentialing programs to provision of a thoughtful narrative about their procedures provides some insight into the fact that there still is a long way to go. Newer approaches, such as bootstrapping techniques, may hold some promise in advancing the assessment of reliability with small samples (Amalnerkar et al., 2020), but more work is needed to evaluate the application of these procedures to credentialing contexts.

Another unique aspect of licensing and certification tests is the opportunity for failing candidates to retest with different policy conditions governing these opportunities. One of the outcomes of this approach is that it results in inflated false-positive/passers (Type I) error rates. B. E. Clauser et al. (2006) illustrated that administration conditions with only repeat candidates lead to inflated Type I error rates. Attempts to

control this characteristic were discussed by B. E. Clauser and Nungester (2001) and included such decision rules as using average scores, most recent scores, or best scores within a defined period. Another strategy would be to potentially increase the passing score for subsequent attempts. However, this may lead to equal protection concerns if the passing expectation is differentially applied to candidates, raising questions about the extent to which any given administration is an independent observation of the candidate's ability that is not dependent on prior information or test-taking performance.

Similarly, there is an important relationship between estimates of classification consistency and the location of the passing score. This relationship extends in multiple directions. First, depending on the choice of classification consistency method, the location of the passing score relative to the distribution of candidate scores can potentially inflate or suppress the estimate. For example, this risk is highlighted if a method is chosen that is more influenced by the location of the passing score relative to the mean of the distribution. Second, as discussed in the section on legal challenges to licensing and certification tests, the location of the passing score also may be influenced by the impact on different demographic groups if there is a goal to reduce the potential effects of adverse or disparate impact.

In this section, we discussed the unique aspects of reliability as they relate to licensing and certification tests. As noted, concepts and methods are generally applicable across a range of testing applications. The interpretations and uses of scores from licensing and certification tests suggest additional and integrated considerations that are noted here as they relate to the larger validity framework articulated in the next section.

VALIDITY

Validity is a fundamental concept in educational measurement that is relevant to all aspects of the testing process, spanning test development and delivery, the analysis of testing data, and the interpretation and use of resulting scores. Lane and Marion (this volume) provide a comprehensive review of validity and validation; as such, the focus of this section will be on the aspects of validity that are most applicable to licensing and certification assessment programs. We use Kane's validity and interpretative argument as our guiding framework for this discussion.

Kane's Validity Framework/Interpretative Argument

In credentialing contexts, Kane's framework espouses employing a multifaceted approach to collecting validity evidence to maintain a program of high integrity that is fair to test takers and defensible to stakeholders. It calls for "a clear statement of the proposed interpretations and uses and a critical evaluation of the interpretations and uses" (Kane, 2013, p. 1). Four types of inferences, or claims, are important within Kane's approach: scoring, generalization, extrapolation, and interpretation/use. For assessments with scorable item types, the assigned score becomes a reflection of performance in a test setting where the assessment is taken under standardized conditions and test takers have no prior

knowledge of the specific content that is included on the test. The *scoring* component includes considerations of adherence to the defined administration procedures as well as appropriate use of raw scores (if used), item response theory, field testing, scaling, and equating. *Generalization* involves making inferences from observed scores based on the specific sample of questions on the test or the sample of observations scored by raters to the universe of questions/observations from which they were sampled. Within classical test theory, this is represented by the relationship between the observed score and the true score. Generalization is impacted by errors of measurement, which typically are random; systematic errors also may exist, and when they do, they may be both difficult to identify and damaging to score interpretations. *Extrapolation* relates to the ability to make inferences about real-world performance based on the observed scores. The fourth component of the validity argument, *interpretation/use*, refers to using the test scores to draw a conclusion about the test taker or to inform a decision such as the granting of a license.

The more ambitious the claims one seeks to make based on assessment outcomes, the more validity evidence is required. Yet the more ambitious claims typically are harder to validate because *all* inferences in the interpretive argument must hold for the interpretation to be considered valid. In licensing and certification, the concept of validity has expanded beyond the question of whether the test measures what it was intended to measure. It also emphasizes the idea that the testing organization must take broad responsibility for the consequences of the testing outcomes. A claim might be that those who pass the assessment and are deemed competent should perform competently in real-world settings. This is an ambitious claim and one that is difficult to validate, because assessments typically focus on constructs that rarely can be isolated in real life. For instance, medical assessments often test knowledge/clinical judgment in a discipline, but patient care clearly reflects more than just discipline-specific knowledge. Patient-care decisions are influenced by a myriad of factors including patient compliance, professionalism, communication skills, and systems factors such as teamwork. Although good performance on an assessment of knowledge may relate to higher quality patient care, it is difficult to control all other factors that influence patient care in a real-world setting when trying to determine the strength of that relationship. In addition, knowing the right thing to do on a multiple-choice test taken in an artificial setting is not a guarantee that the test taker would do the same thing in practice. Although some credentialing programs still use oral examinations to test practice-relevant skills, many are transitioning to sophisticated multiple-choice items that evaluate clinical judgment and the ability to synthesize information. Innovative item types also have been introduced in an attempt to address these challenges, and though initial results are encouraging, additional empirical evidence is needed to evaluate whether they are better than sophisticated multiple-choice items for assessing the desired competencies (Swanson & Hawkins, 2017). Similarly, in medical contexts, assessment approaches based on case records or logs (e.g., patient charts from electronic health records) eventually may supplement or replace multiple-choice questions as metrics based on actual practice become more universally accessible.

Importance of Extrapolation and Interpretation

All claims from Kane's framework are important in establishing the chain of evidence. For professionally developed credentialing assessments, evidence to support the scoring and generalization aspects of Kane's framework typically is much easier to produce. In most testing organizations, great effort is placed on test construction procedures: Practice analysis helps to ensure relevance to practice, standardization of testing procedures helps to ensure fairness, and scoring processes help to ensure accuracy. In addition, generalizability of test scores is demonstrated both with longer assessments covering the breadth of the field and by controlling for content and statistical specifications included in the blueprint. These are well-understood processes that have undergone significant specification and refinement over time.

Providing evidence to support the appropriateness of both *extrapolation* from test scores to real-life situations and score *interpretations/uses* is much more challenging. The high-stakes nature of licensure and certification makes the extrapolation and interpretation components critical with respect to validity. If claims are being made about the assessment that go beyond the actual test setting, an evaluation of whether these claims hold true should be done by conducting a program of research designed to generate a preponderance of evidence that either supports or disproves the claims. The higher the stakes and the claims made about the assessment results, the stronger the research program will need to be to support validity arguments. In medical licensing and certification, there is a growing body of peer-reviewed literature that provides evidence related to extrapolation to real-life situations; unfortunately, this work remains limited because definitive outcome measures are limited.

The gold standard for validity evidence in credentialing contexts is the ability to demonstrate that those who pass the assessment perform competently in practice and those who do not pass do not perform competently. In licensure contexts, however, this evidence is impossible to obtain because those who fail the examination(s) never receive a license. This type of evidence is feasible for certification exams, because certification typically is not mandated for practice. For example, a considerable amount of evidence exists to support the claim that being certified or performing better on a certification exam is linked to fewer disciplinary actions by state medical licensing boards. In internal medicine, a board-certified physician is five times less likely to have a disciplinary action than a noncertified physician (Lipner et al., 2016), and the higher the physician's score on the certification exam, the less likely they are to have a disciplinary action (Papadakis et al., 2008). This relationship has been shown in many studies comprising numerous specialties in medicine (Jones et al., 2018, 2020; Kinney et al., 2019, 2020; Kocher et al., 2008; Kopp et al., 2020; Lipner et al., 2016; F. McDonald et al., 2018; Nelson et al., 2019; Papadakis et al., 2008; Peabody et al., 2019; Zhou et al., 2017, 2018, 2019).

Other studies have sought to provide evidence to support or refute extrapolation claims by examining the relationship between measures of performance on the assessment and measures of performance in practice. One study showed that, for patients with acute myocardial infarction, treatment by a board-certified internist

or cardiologist was associated with a 19% reduction in mortality compared with treatment by a noncertified internist or cardiologist (Norcini et al., 2002). Another study showed that receiving care from an internist who scored in the top quartile of their exam was associated with a 17% increase in odds of *guideline-compliant* diabetes care compared to those who scored in the bottom quartile (Holmboe et al., 2008). A third study showed that physicians who maintain certification at 20 years after initial certification have better care management on the Healthcare Effectiveness Data and Information Set performance measures (Gray, Vandergrift, Landon, et al., 2018)—including diabetes care, mammography screening, and coronary artery disease—compared to similar physicians who did not maintain certification. In Quebec's universal healthcare system, scores achieved on licensing and certification examinations show a persistent relationship, over 4 to 7 years, with specific measures of preventive care and acute and chronic disease management in primary care practice (Tamblyn et al., 2002). Additionally, research has found a strong link between a physician's diagnostic knowledge and likelihood of patient death, emergency department visits, or hospitalizations (Gray, Vandergrift, McCoy, et al., 2021), that physicians who score higher on certification exams are less likely to prescribe inappropriate medication to geriatric patients (Vandergrift et al., 2021), and that physicians who do not keep medical knowledge current are more likely to overprescribe opioids for back pain (Gray, Vandergrift, Weng, et al., 2021).

These examples represent just a few of the studies linking performance in practice with performance on credentialing exams. This type of research is extremely challenging, and controversy exists over whether correlational studies like these are sufficient or whether studies must demonstrate a more direct link between program/exam performance and outcomes as a necessary condition for supporting the extrapolation inference. Showing a causal relationship in medical education research is extremely difficult because randomized controlled trials are rare. Other studies using quasi-experimental designs have the potential to get closer to the randomized controlled trials design; two studies that did so (possibly due to a policy change that occurred within a particular time frame) revealed that physicians required to maintain certification save the healthcare system \$167 per Medicare patient, per physician, per year without sacrificing quality (compared to those not required to maintain certification). This result translates into roughly \$5 billion per year in Medicare cost savings (Gray et al., 2014). In addition, women who had not received prior mammography screening were 8.5% more likely to get screened when seen by a general internist required to maintain certification (Gray, Vandergrift, & Lipner, 2018). These studies are closer to a randomized controlled trial design than correlational studies because they compare physicians who are very close in age and demographics and who have very similar patient populations before and after a policy change. With a preponderance of correlational studies showing positive relationships between status in a program or performance on an assessment and patient care outcomes, a convincing argument can be made that assessment performance matters to patient care. At a minimum, the

evidence is beneficial to patients who, when selecting a provider, should know which physicians “know enough” to practice in their specialty.

The other concern about procuring evidence to support or refute extrapolation claims is that, even in simulated scenarios, examinations typically test knowledge and judgment but not other important behaviors (e.g., professionalism, communication skills, or ability to function effectively within their current system) that are needed by practitioners. These other behaviors undoubtedly impact practice performance differently, such that poor performance in practice could be associated with high assessment scores. However, in the studies cited previously, this seems to be the exception and not the norm. With appropriate designs, attempting to control for many of these other behaviors is possible although far from perfect. For instance, a study can attempt to control for types of systems by identifying practice type (e.g., academic or community setting) or for communication skills using ratings provided by program directors during residency and fellowship training. Solid research designs that use matched samples, nesting of patients within physicians (generalized estimating equations), and patient risk adjustments are critical to studying the relationships between performance on examinations and practice setting outcomes.

As a final comment on correlational studies, it is worth noting that Kane (2013) does not give this type of study much consideration in his discussion of validity. He argues that demonstrating correlations with another measure simply creates the need for a new validity argument for the criterion measure.

Threats to Validity

This section will cover a variety of topics that have a potential impact on the validity of testing processes and score interpretations. These are especially important in the context of high-stakes credentialing decisions.

Test Security

Test security plays a critical role in the validity of interpretations based on test scores. For large-scale, high-stakes examinations, the ability of testing agencies to offer frequent—if not continuous—testing leads to increased item exposure. This presents a significant security challenge because item exposure can provide test takers with advanced knowledge of the questions, leading to an unfair advantage on the test and undermining the validity of score interpretations. Item exposure is an ongoing issue for high-stakes testing (Way et al., 2014), and contemporary testing innovations—including frequent administrations, larger items banks, and communication technologies—have added to the security risk (Foster, 2016).

A number of technology-based advancements that use modeling approaches to content development such as evidence-centered assessment design (Mislevy & Haertel, 2006), assessment engineering (Luecht, 2012), and AIG (e.g., Gierl & Lai, 2015) are intended to improve efficiency in item production. Several studies have demonstrated AIG’s ability to generate hundreds or thousands of test items in very short periods of time, often in just seconds (Gierl et al., 2012; Gierl & Alves, 2011, as cited in Morrison

& Embretson, 2018). As long as the generated items are psychometrically equivalent and meet other quality assurance requirements, these items can be used to populate the item bank and expand the pool of active items from which tests can be assembled. This, in turn, prevents test takers from becoming familiar with item content in advance of the examination.

Automated test assembly provides a platform to build item exposure controls into the test development process through heuristics and algorithms. This can help reduce the overexposure of individual items and promote broader utilization of the full test bank. For example, in computer adaptive testing, item exposure is a frequent problem because of the tendency to select highly discriminating items more frequently than others (Hau & Chang, 2001). Exposure controls—such as limiting the number of times any one item from a bank can be used—can mitigate this tendency. Notably, while embedded exposure controls theoretically have been available for quite some time, the technological improvements that have allowed for them to be operationalized have only been made available more recently (van der Linden & Li, 2016).

It should be noted that our comments regarding AIG reflect on the potential promise of these methods. Actual results have lagged behind that promise. There are few (if any) published results showing that these items can be used in high-stakes testing without careful selection and postproduction editing. Additionally, the available evidence suggests that it will not be practical to use these items without pretesting because evaluations of the current technology for predicting item parameters based on item characteristics—or from the parameters that have been estimated for other items from the same model—are not encouraging. Finally, there are few, if any, studies that provide evidence to support the contention that items from the same model are sufficiently different, so that advanced access to one (or more) item(s) from the model will not improve the probability of a correct answer to the next item from that same model. Nevertheless, with continued technological developments, including significant advances in machine learning and artificial intelligence, realization of the promise of some of these methods may not be far in the future.

PREKNOWLEDGE AND UNETHICAL BEHAVIOR Preknowledge of examination content is a threat to validity that can unfairly change the construct that the test is intended to measure. Many review or test-preparation courses exist to prepare test takers for credentialing examinations, and these courses may *teach to the test* (or even teach the content of the actual test) instead of focusing on the construct the test is intended to measure. If these courses truly are construct focused, there is no inherent problem; if, however, the focus is on teaching tactics to pass the test, this raises concerns about the inferences that can be made based on test performance. Medical schools and training programs capitalize on using test blueprints to guide curricula. This practice could be viewed as positive in that these curricula improve professional education by covering a complete spectrum of the field. Alternatively, if the curriculum neglects important aspects of practice that are not on the test because the focus is solely on passing the test, the approach is problematic.

As the consequences of passing an examination become more important for a test taker's career, the likelihood of test takers attempting to engage in unethical behaviors increases. Security challenges associated with high-stakes assessments have changed along with advances in technology for computer delivery and remote testing (see Shermis et al. and Bennett et al., this volume). These testing improprieties threaten the validity of the inferences that can be made based on the resulting scores (Cizek & Wollack, 2017). This is critically important in terms of being able to attest that the professional whose name is on a credential did in fact *ethically* master the test. Without this validation, the credential would hold little meaning for stakeholders—especially, and, perhaps most importantly, the public. Testing organizations may employ numerous strategies to prevent potential security threats. Test takers typically are required to sign a code of conduct that clearly specifies the policies of the examination program and the consequences for not adhering to the code of conduct. Verifying test-taker identity is a critical step to help prevent proxy test takers from subverting the system. Prevention methods in test centers have improved in that test takers often do not sit near one other and questions can be easily scrambled or different forms of the test can be used. Finally, surveillance by test proctors, video recording of test takers while testing, documentation of unscheduled break time, and records of response time data collected routinely for both live and pretest items are all part of the detection and data forensic processes.

CONTINUOUS TESTING A further development in the continuous certification arena is a testing paradigm in which test takers answer questions on a year-round basis in a combined formative/summative assessment process (Continuing Board Certification, 2019). As previously mentioned, testing organizations have been under significant pressure to loosen security measures and increase convenience and flexibility; as a result, at-home, unproctored testing at the test taker's convenience is becoming the norm. In addition, questions and answers along with rationales and references are provided immediately after the question is answered to serve formative assessment purposes. To keep the assessment secure, new questions are written and field tested every year because there is no longer the traditional concept of a large, stored item bank with questions that can be reused numerous times. Field-tested questions that survive then can be used as live scored questions. Although (generous) time limits typically are imposed per question, test delivery procedures allow access to external resources during the test. This new testing paradigm intensifies security issues, because, in addition to the demand for a large number of test questions and the test being taken at home at any time of the day, the message that the program is both for learning *and* for assessment may be confusing. Learning typically allows for working in groups or consulting with peers, but in this situation it does not; security breaches are obviously harder to prevent and detect within such a paradigm. Watermarking and encoding test material have been introduced to trace information back to any individual who tries to subvert the system. Codes of conduct need to be enforced and strengthened, and more sophisticated web-patrolling programs and data forensics techniques must be implemented.

Guidelines have been written about security measures in online testing (Foster, 2013). However, there are unique challenges associated with at-home, online, unproctored tests, and more research is needed to help make informed decisions about the most effective way(s) to incorporate these requests without increased security breaches that may go undetected and ultimately affect the validity of score interpretations. The increasing demand for more flexible and convenient test delivery models has made the move away from brick-and-mortar centers to at-home delivery a reality that will necessitate significant enhancements in prevention and detection techniques, possibly taking advantage of the explosion of artificial intelligence capabilities.

Construct-Irrelevant Variance

Unintended factors that influence test performance pose additional threats to the validity of inferences drawn from examination results. One such factor is content bias, which can advantage certain subgroups over others. Predictive bias is concerning if the exam is meant to measure a construct for the population but is found to give different predictions for subgroups of that population who should be equivalent on that construct (e.g., females and males, Asians and Caucasians). When bias exists, we are measuring construct-irrelevant variance and the test may be seen as unfair.

Use of a statistical method known as differential item functioning is a common initial analytic step for identifying biased items. After running the differential item functioning analysis, items displaying differential item functioning are presented to experts who carefully review them and determine whether the content is truly biased (e.g., Holland & Wainer, 1993). Eliminating questions containing bias is an extremely important step in maintaining the fairness of an examination. In licensing and certification, differences in performance between groups often can be explained by other relevant factors, rather than being indicative of true bias (O'Neill et al., 2022). For instance, medical oncologists who are female more often focus on breast cancer, whereas more male oncologists focus on prostate cancer. These practice tendencies may help to explain a difference in performance that is *not* considered bias.

With computer-based testing, the automatic collection of metadata such as response time and answer changes has contributed to exponential growth in the study of aberrant behaviors (e.g., Lu & Sireci, 2007; Margolis & Feinberg, 2020). Examination time limits are important from a practical, administrative viewpoint and might be important to the construct if the testing organization believes that answering a question within a realistic time frame is important. This issue becomes especially relevant when testing is in the open-book format because typically the construct is not about whether a test taker can look up the correct answer, but rather whether they can synthesize information in a timely manner to arrive at the correct answer. If a layperson can pass a licensing examination by looking up answers over an unlimited time period, the interpretation of any performance on the examination would be meaningless. Time limits are necessary in most contexts, but those that impose unrealistic constraints introduce construct-irrelevant variance into measurement of the construct.

Other Threats to Validity

Less-obvious threats to validity in the credentialing arena can arise from disciplinary pressure to create more individualized certifications—even in well-established areas—resulting in highly specialized credentials for very small populations. (Continuing Board Certification, 2019). Certificate programs have been established in disciplines that may have fewer than 50 test takers a year. The small number of test takers in these populations presents challenges in following best practices in measurement, including field-testing questions, estimating item parameters (calibration), and scoring and equating across forms (Finch & French, 2019). Sample size affects the accuracy and efficiency of model parameter estimates that are used in making decisions about individuals. When high-stakes decisions—such as admission to training programs or employment—are based on exam performance, small sample sizes can undermine the validity of the resulting inferences. In fact, *Applied Measurement in Education* devoted an entire journal issue to studies that seek solutions to the limitations associated with small sample sizes (2020, Volume 33, Issue 1).

A final threat to validity relates to situations in which credentialing programs permit test takers to narrow the focus or scope of their assessment. This approach questions the general construct that is being tested and how that credential is being represented to the public. For instance, if test takers whose primary clinical focus is breast cancer take an assessment that focuses on breast cancer but then are provided with a certificate in general medical oncology, there are consequences for patients who might not be aware of this narrower examination focus. This begs the question of who the certificate is for: the physician, the employer, or the patient population (Vandergrift et al., 2020). Confusion over what exactly the certificate means could raise threats to the validity of the inferences based on test performance. However, asking questions that are irrelevant to those physicians that narrow the scope of their practice also can be seen as a threat to validity in that it is not measuring exactly what they are doing in practice but more what the typical physician practices in the discipline. More narrow scopes and credential designations have the potential to address this controversial issue.

Validity considerations are central to any testing program. In high-stakes contexts, where credentialing examination scores influence critical decisions about individuals, collecting robust evidence to support score interpretation and use becomes even more essential. A validity argument is only as strong as the weakest link in the chain of evidence; attention to the strength of the argument is paramount.

STANDARD SETTING

In educational testing, standard setting refers to the process of determining “how much is enough” with respect to test performance (Kane, 2017). In credentialing contexts, the question more specifically becomes, What level of competence is enough to consider a candidate minimally qualified to enter practice or to use a specific practice

designation? In these contexts, standard setting begins with the assumption that any given discipline can be defined by an underlying body of knowledge, skills, and abilities that are required for practice (Way & Gialluca, 2017). Proficiency in a domain can be measured along a continuum, and there is a theoretical point at which the difference between competence and lack of competence can be distinguished. The intent of the standard-setting process is to first describe that body of knowledge, skills, and abilities and then to estimate the point along the continuum that best distinguishes between those candidates who have enough of what is needed for safe and competent practice and those who do not (Way & Gialluca, 2017).

The above logic indicates that standard setting involves specifying two types of standards: content standards and performance standards. *Content standards* are “collections of statements that describe specific learning outcomes or objectives” (Cizek, 2012); they relate to the underlying domain of knowledge, skills, and abilities in a given discipline and the need to review the domain to identify what must be mastered for a particular purpose. In credentialing, the domain review typically focuses on what is necessary to be considered competent versus not competent to receive the credential. *Performance standards* are defined by the “distinctions between two adjacent categories of performance (e.g., between acceptable performance and unacceptable performance” (Kane, 1998, p. 130). Setting performance standards therefore refers to specifying the level of performance that indicates that the content standards have been met. Once content and performance standards have been specified, there is yet another step: determining the *passing score* (the point on the score scale that corresponds to the identified performance standard; Kane, 1998). As Kane (2017) explained, a performance standard is a *minimally adequate level of performance* for the given purpose, and a passing score is a *point on a score scale* that divides test takers by the level of performance. Passing scores therefore provide an objective way to answer the central policy question about the adequacy of a given test performance.

Though standard-setting considerations are largely similar across educational and credentialing contexts, a number of areas specific to credentialing are addressed in the *Standards* (AERA et al., 2014). In the following section, we touch on some areas that we feel warrant explicit consideration in the context of credentialing examinations. For a comprehensive review of standard setting in educational and credentialing contexts, including a detailed review of standard-setting methods and activities, the interested reader is referred to Cizek (2012), Cizek and Bunch (2007), Hambleton and Pitoniak (2006), and Ferrara et al. (this volume).

Standard-Setting Methods

Standard setting for credentialing examinations typically involves using one (or more) of many judgment-based processes to collect information from content experts about the level of performance that is necessary to meet the content standards; this information is used to determine the examination score that is associated with the minimum acceptable

level of test performance (Institute for Credentialing Excellence, 2018). Perhaps the most important consideration with respect to the selection of a standard-setting methodology is the extent to which that methodology aligns with the purpose of the testing program and its associated models of achievement (Kane, 1998).

There are two overarching categories of standard-setting approaches: test centered and test taker centered. Test-centered approaches are those in which panelists review test items or tasks and, for each one, make judgments about the expected level of performance for minimally qualified test takers (those just meeting the performance standard); item-level judgments then are aggregated to produce a passing score. In test-taker-centered approaches, panelists provide judgments about test-taker performance based on an external criterion or overall test performance; the passing score is set by identifying a point on the score scale that is most consistent with the judgments (Kane, 1998; Kane et al., 1999). Test-centered approaches are used most commonly in licensing and certification; this likely is because of the preponderance of credentialing programs that use objective (rather than performance-based) tests in the credentialing process (Buckendahl & Davis-Becker, 2012; Institute for Credentialing Excellence, 2018; Kane, 1998; I. L. Smith & Springer, 2009). (To the extent that licensing and certification examinations move toward more performance-based testing and away from multiple-choice testing, this balance could shift.) Despite the existence of numerous test-centered methods that promote different approaches to data collection, relatively few are used consistently in licensing and certification, with the Angoff method and its derivative (modified Angoff) procedures being used most frequently (Buckendahl & Davis-Becker, 2012; Hurtz & Auerbach, 2003; Institute for Credentialing Excellence, 2018; Way & Gialluca, 2017).

As typically implemented, modified Angoff procedures require panelists to review test items and provide estimates of the proportion of minimally qualified candidates that would answer each item correctly; the average of the sums of the probabilities from all experts across the set of items becomes the panel's final passing score. This procedure is attractive in its simplicity and in its flexible applications, such as being able to adapt it to a variety of item types (Buckendahl & Davis-Becker, 2012; Plake & Cizek, 2012). Despite these general strengths, these procedures have several associated limitations, perhaps most notable of which is that the task (of estimating the probability of a minimally qualified candidate answering questions correctly) tends to be a difficult one. For example, panelists—particularly those for whom more time has passed since initial licensure or certification—may struggle with appropriate expectations for a minimally qualified candidate, which results in passing scores that the testing program would consider unreasonable (Professional Testing Corporation, 2019). That is, unless panelists have been licensed or certified relatively recently, they may not have a clear sense of the level of knowledge and experience of a test taker seeking the credential, and this may lead them to overestimate the performance of a minimally qualified candidate. Another concern is that panelists may not have a clear understanding of the

extent to which test takers prepare for credentialing examinations, and therefore they may underestimate the performance of the minimally qualified candidate. These concerns lead to questions about the meaningfulness of the resulting data (Busch & Jaeger, 1990; B. E. Clauser et al., 2002; B.E. Clauser, Harik et al., 2009; B. E. Clauser, Mee, et al., 2009; B. E. Clauser et al., 2013; Mee et al., 2013).

To address these concerns, supplementary methods can be used alongside the Angoff process to offer panelists alternative perspectives on this critical task. For example, using a compromise approach such as the Hofstee method (Cizek, 2006; Ferrara et al., this volume; Thompson, 2018) and presenting those results to panelists along with their Angoff judgments allows them to see the outcomes and impact of their item-level Angoff judgments (i.e., passing scores, percentage of items answered correctly, associated fail rates), compare those results with their normative expectations for fail rates and content mastery (i.e., minimum and maximum failure rates and minimum and maximum percentages of items answered correctly), and make any necessary/desired adjustments to their judgments. (If these data are not presented to panelists for review and modification, they can be shared with the decision-makers as they consider all relevant information.)

Though criterion-referenced standard-setting approaches are most appropriate for credentialing examinations (AERA et al., 2014), the reality is that incorporating some consideration of the performance of the population of test takers can provide panelists with valuable context and allow them to make more meaningful judgments (Bowers & Shindoll, 1989). The preceding example illustrates tensions that may exist between making criterion-referenced versus norm-referenced judgments and is intended to convey one aspect of the complexity associated with standard setting in credentialing contexts. There are certain standard-setting methods that may be more or less appropriate for credentialing examinations, but that does not mean that there is a single approach or procedure that is best for all credentialing contexts. The specific features of each context must be evaluated, the benefits and challenges of relevant approaches should be reviewed, and a method or combination of methods should be selected that is most likely to yield meaningful and, perhaps most important, defensible results.

Standard-Setting Activities

Content-based standard setting involves numerous steps that include, but certainly are not limited to, recruiting content experts to serve as standard-setting panelists (or judges) and provide the required judgments, facilitating the standard-setting meeting(s), and collecting or assembling data from additional sources to aid policy makers in making a passing score decision. These general activities tend to be similar across credentialing (and many other) contexts; the differences are in the details and in the way(s) that specific organizations approach and prioritize those details. In the sections that follow, we briefly describe aspects of the above activities that we believe warrant explicit consideration for credentialing examinations.

Panel Selection

Because the judgments of panelists directly affect passing scores and the overall credibility of the standard-setting process, panel composition is of critical importance to the process (Plake et al., 1991). Raymond and Reid (2001) asserted that panelists should meet two critical requirements:

1. Individually, participants should have extensive knowledge of and experience with both the subject matter and the test-taker population; and,
2. As a group, participants should be representative of all stakeholder groups.

An additional requirement, which may be assumed but should in fact be explicit, is that participants must have a commitment to protecting the security of the testing materials (Nancy Tippins, personal communication, September 10, 2023).

When identifying relevant stakeholder groups, Buckendahl and Davis-Becker (2012) argued that stakeholders differ between licensure and certification programs. In licensure testing, the primary stakeholder is the public, which is interested in protection from harm caused by unqualified practitioners. Industry professionals, who have an interest in protecting the integrity and reputation of the profession, and educators, who may use testing information to evaluate and inform curricula, instruction, and accreditation, also are relevant licensing stakeholders. Finally, though candidates themselves are stakeholders, their *opinions* are not of primary importance because they likely have a strong self-interest with respect to entering the profession. That said, the candidates' interest in ensuring that entrance into the profession is not unduly restrictive is completely legitimate and should be reflected in the final decision.

Conversely, certification typically is a voluntary pursuit where the candidate seeks to demonstrate greater knowledge, skills, or abilities than is required of entry-level practitioners (Buckendahl & Davis-Becker, 2012). Therefore, relevant stakeholders for certification exams differ from stakeholders in licensure exams. The primary stakeholders in certification may be the candidates themselves, who seek to enhance their credentials for a variety of reasons. Employers—many of whom consider certification status when determining eligibility for a position or for making hiring decisions—also may be considered a primary stakeholder in the certification process (Buckendahl & Davis-Becker, 2012). (In some professions, the public will be the employer and so will have a clear interest in the integrity of the certification.) The professional community, which has an interest in maintaining the integrity of the profession, also is likely to be an interested stakeholder. Patients sometimes are considered stakeholders, as certification can be a process to let the public know about candidates' competency in specialized areas. Finally, credential-sponsoring organizations are stakeholders in that they have an interest in promoting awareness and use of their products and/or services.

Any standard-setting process that influences public policy will inevitably impact stakeholders (Cizek, 1993; Cronbach, 1982). As such, researchers agree that participants should adequately represent stakeholders in the standard-setting process (Hambleton & Pitoniak, 2006; Loomis, 2012; Raymond & Reid, 2001). Buckendahl and

Davis-Becker (2012) explained that in the context of licensure, recently credentialed practitioners offer a thorough understanding of the content and expectations of professionals with the target credential. Experienced practitioners may have more specialized practices and so may have more advanced skills and knowledge in some areas; they also may lack proficiency in some areas in which they no longer practice. Educators have a strong knowledge of curricula and are most familiar with the target population, but they may lack a thorough understanding of what is required in practice.

Increasing stakeholder representation also can present a number of challenges. Buckendahl and Davis-Becker (2012) noted that broad panel composition may be complicated by stakeholders with competing interests. Policy decisions require the integration of content-based knowledge and stakeholder values. However, stakeholders may have differences in opinions and motivations that are not easily reconciled (Kane, 1994b). For example, experienced practitioners may desire higher passing standards if they result in a less-saturated professional market. In contrast, trainers and educators who use student performance as evidence of programmatic success may desire lower passing standards. Recently licensed professionals also may have diverse interests: Some may push for higher standards to preserve the level of rigor they were faced with; others may represent student-level groups that actively advocate for the elimination of licensure exams in favor of diploma privilege. In an effort to balance conflicts of interest, Buckendahl and Davis-Becker (2012) recommended equivalent participation by experienced practitioners, recently licensed or certified practitioners, and educators.

In credentialing examinations, there is a debate over the inclusion of panelists who lack expert-level knowledge given the focus on increased representation from diverse stakeholders. Certification and licensing exams typically cover a wide range of topics. However, it is the nature of an expert to have specialized knowledge (Raymond & Reid, 2001). Content expertise has been regarded as the most important qualification for judges (Buckendahl & Davis-Becker, 2012; Downing et al., 2006), and a lack of expertise could undermine the credibility of the judges and the soundness of the standard-setting procedure (J. C. Clauser et al., 2017; Norcini & Shea, 1997). Kane (1994b) suggested that panelists who lack the requisite expertise to knowledgeably rate all items should only respond to items that they are qualified to address. However, additional data analysis would be required to account for the missing information. There are, of course, standard-setting contexts in which important stakeholders are likely to completely lack the knowledge and experience to make the judgments required of panel members; for example, members of the public cannot make the probability judgments required of the Angoff procedure for items from a medical licensing test. In this circumstance, the interests of that stakeholder group can be incorporated into the process as part of the instructions to the panelists. In addition, in situations in which the estimated passing score from the standard-setting exercise is reviewed and approved by examination governance, the interests of otherwise unrepresented stakeholders can be reflected in their decision process.

Nonetheless, it remains critically important to consider stakeholder perspectives in the standard-setting process because they represent the interests of groups with bona fide stakes in the outcome of a testing program (Hambleton & Powell, 1983). As noted by Kane (1994b), stakeholder input is a time-honored tradition and part of the observed democratic processes for establishing public policy, thereby providing evidence of the reasonableness of policy decisions related to a particular standard.

Procedural Factors: Training and Practice

We cannot underscore enough the importance of providing ample training and practice opportunities for panelists during the content-based standard-setting activity. As previously mentioned, panelists are recruited because of their content expertise and their experience with the relevant population of test takers. There is no reason to believe that they have special skills in content-based standard setting; in fact, in some contexts there is an explicit requirement that panelists *do not* have such experience. As such, it is wise to consider the training and practice aspects of the process to be as important as, if not even more important than, the process of collecting the operational judgments.

This training and practice can come in many forms. The first relates to providing specific information about the examination of interest. A thorough review of the examination purpose and structure is a good way to ensure that all panelists are beginning the process with a reasonable understanding of the test they are about to review. Similarly, it often is beneficial to have panelists participate in a session during which they complete a set of items much like a test taker would; this provides a general sense of the test-taker experience, which is directly relevant to their standard-setting judgments. The judgment task is to make decisions about an item based on how a minimally qualified candidate *would* answer the item; focus on the *would* (rather than the *should*) represents consideration of many factors, including the reality of the testing situation. Having the panelists take the test as the test takers do, for example, including a set of questions (a) without access to the correct answers and (b) with the same time limits that are used for the operational test, can provide valuable insight into the test-taker experience, particularly for panelists who are farther away in time from the credentialing process. Engaging in several rounds of judgments has been another feature of standard-setting activities that benefits the process by allowing panelists to practice with the overall task—and its component parts—prior to providing judgments for the data set that will be used to derive the cut score. Many different approaches to this iterative process have been described in the literature, and there is no single approach that has proven to be best. Please refer to Ferrara et al. (this volume) for additional information about workshop design and execution.

A final recommendation relates to replications of the content-based standard-setting process: Programs that have the resources to do so should consider repeating the process with different panels on multiple occasions. This provides examination governance with important information about the precision of the estimated passing score.

Decision-Making: A Policy Perspective

Although standard setting is typically viewed as a statistical and procedural process, it also involves elements of policy-based judgment (Cizek, 2006). As the *Standards* noted, the process of standard setting incorporates both value judgment and empirical considerations (AERA et al., 2014). Results from content-based standard-setting panels are one of the most important factors in establishing a passing score, but that source of data is not the only one used to inform a final passing score decision. Results typically are combined with additional sources of diverse, relevant, and often policy-related information to arrive at the most appropriate recommendation for a passing score in a given credentialing context (Geisinger & McCormick, 2010).

Proposed test score interpretations are not valid unless they are supported by evidence (Kane, 1994a; Kane 1994b). That is, the standard-setting process must be supported by evidence to validate a performance standard as an interpretation of a passing score. Specifically, Kane argued that validity of a pass/fail decision depends on the plausibility of two assumptions supporting the inference that a test taker's achievement is adequate if and only if their observed score is greater than or equal to the passing score. The first assumption, termed the *descriptive assumption*, is that the passing score corresponds with a particular performance standard. The second assumption, the *policy assumption*, is that the performance standard is appropriate for the purpose of the decision. The descriptive assumption, which relates to the content-based aspect of the standard, can be empirically evaluated. The policy assumption is more complex. Policy decisions regarding "how much is enough" (e.g., how much knowledge is required to demonstrate competence) are based on assumptions about the consequences of various choices and the values they reflect. Some assumptions about the consequences of choices that frame policy decisions can be empirically confirmed, but assumptions about values necessarily imply judgment. Therefore, to validate the policy aspect of the standard-setting process, evidence must demonstrate that the passing score and associated performance standard are reasonable. The following sections briefly describe several sources of evidence that we feel are of particular importance in credentialing contexts.

STANDARD ERROR Evidence supporting the policy assumption can be drawn from a number of different sources. The standard errors of various methods, for example, can provide procedural evidence of the reasonableness of the process (Andrew & Hecht, 1976; Brennan & Lockwood, 1980; Cross et al., 1984; R. L. Smith & Smith, 1988). The standard error of a passing score refers to the likely variation in passing scores that would result if the standard-setting activity were repeated with different items and/or panels (Kane, 1994b).

PSYCHOMETRIC INFORMATION Presenting pass rates and other psychometric information can promote consistency in how judges approach the standard-setting activity and also provides useful procedural evidence supporting the validity of the

policy portion of the standard-setting process (Hambleton & Powell, 1983; Jaeger, 1989; Kane, 1994b; Linn, 1978; Shepard, 1980). Statistical data on the performance of test-taker groups, including pass rates, can aid judges in setting cut scores at realistic levels. As Loomis (2012) described, in many standard-setting methods judges make initial recommendations and are subsequently provided with estimated pass rates associated with their recommendation. They then are given the opportunity to adjust their recommendations in light of the data.

In many credentialing organizations, the results of the standard-setting exercise are not used directly to establish a cut score but instead are considered one source of data intended to inform the governance group that is responsible for establishing the final cut score. That group has the authority to accept or modify the recommended cut score, and they may adjust the recommendation to ensure that different pass rates withstand public scrutiny and meet the demands of the profession (Geisinger & McCormick, 2010). For example, a decision-making body may want to compare expected pass rates with the pass rates of previous years because a substantial disparity would undermine the public confidence in and validity of the cut score. However, decision-makers should avoid adjusting cut scores to conform to a desired passing rate, especially if doing so is contrary to the goals of the standard-setting process (AERA et al., 2014; Geisinger & McCormick, 2010). In licensing, the goal of standard setting is to determine a cut score that identifies which candidates have the competence required for safe and effective practice. As such, pass rates cannot justify alterations that move the cut score outside the range of minimal competence.

CLASSIFICATION ACCURACY Data on classification accuracy is a critical source of evidence that may be used to support the policy portion of standard setting. False positives occur when a candidate's true score is below the cut score and their observed score is at or above the cut score; false negatives occur when a candidate's true score is above the cut score and their observed score is at or below the cut score (B. E. Clauser et al., 2006). In licensing and certification, it often is the case that classification errors are not equally important. For example, passing an incompetent physician may be deemed more problematic than failing a competent one. In such situations, it is reasonable for normative data to impact the recommended or adopted standards (Hambleton & Powell, 1983).

In credentialing contexts, the individual test takers bear the cost of false negatives and society bears the cost of false positives. These costs are difficult to approximate and balance. Nonetheless, balancing classification accuracies is an important tool for policy-related decision-making because it accounts for the societal costs of various decisions (Geisinger & McCormick, 2010).

Some sources of evidence are subject to stronger critique than others. For example, while the nature of the professional market is often a supplemental factor in determining cut scores for employment testing, the use of this information in credential-

ing assessments is far more dubious. The *Standards* explicitly state that this is not appropriate in the credentialing context (AERA et al., 2014). However, Millman (1989) found that cut scores on licensing tests often were lowered in situations where the supply of professionals was not able to meet market demand (Geisinger & McCormick, 2010).

Providing opportunities to retake a failed exam also has the potential to influence policy decisions because these opportunities can change the consequence of cut scores. For example, decision-makers may raise cut scores to allow for a higher initial failure rate (Geisinger & McCormick, 2010) but a lower false-positive rate across test administrations. Some have even suggested raising the cut score for subsequent examinations for test takers who have failed in a previous administration (B. E. Clauser & Nungester, 1999; Millman, 1989). However, any policy decision that incorporates retesting as a factor should first consider whether the standard-setting panel was instructed to consider retesting opportunities; if they were, further adjustment may be inappropriate.

In credentialing, this distinction is critical because achieving an examination score above the cut score is interpreted as an indication that the test taker has the requisite knowledge to receive the credential (or is a step toward receiving the credential if multiple examinations are required). Standard setting in credentialing contexts therefore has direct and potentially significant consequences on the test taker and the public with respect to permitting or denying either entry to a profession or the ability to use a specific designation to practice.

The Role of Judgment

Standards (and cut scores) for a given examination are fundamentally the product of human judgment (Kane, 1994b) and represent the intersection between a complex set of policy decisions informed by empirical data and the interests of a diverse group of stakeholders. As such, the inherent subjectivity of the standard-setting process has led to criticism about the “arbitrariness” of cut scores (Glass, 1978). Cut scores typically result from a mathematical transformation of the judgments made by a group of standard-setting panelists onto a score scale; the resulting cut score then may be presented to the policy makers so that they can make the final decision about where on the score scale the cut score should be located. These activities represent a string of judgment-based processes that understandably might lead to the perceived arbitrary nature of cut scores: panelists make judgments about test material or test-taker performance, the recommendation of a single cut score based on the panelists’ judgments often proposes only one score from a range of legitimate scores, and the credentialing bodies have the authority to use their judgment to accept or modify cut score recommendations (Kane, 1994b). The inclusion of human judgment is unavoidable, however, because there is no statistical answer to the question, How much is enough? (Kane, 1998, 2002). Although aspects of the process may be perceived as arbitrary because of its foundations in human judgment, it is important to note that an arbitrary standard is not necessarily a capricious standard (Hambleton, 1978; Hambleton & Pitoniak,

2006). Capricious standards may undermine the validity and integrity of the process (Geisinger, 1991; Kane, 1994b), but arbitrary standards may escape the perception of capriciousness if they demonstrate that the standards align with the goals of the testing program. This demonstration requires methodical design and documentation of standard-setting processes that yield cut scores with a data-informed, empirical basis (AERA et al., 2014; Kane, 2017; Hambleton & Powell, 1983). The importance of this process is perhaps most critical in credentialing contexts where the risks of making decisions that are *not* based on sound methodology have implications for the safety of the public and the careers of the candidates.

As such, it is important for practitioners involved in standard-setting activities to (a) be aware of the myriad factors that have the potential to influence standard-setting judgments and (b) do their best to mitigate the associated risks. Ferrara et al. (this volume) provide a detailed description of hypotheses about factors that influence standard-setting judgments. These include task features, cognitive processes, judgmental heuristics, and cognitive biases. We strongly recommend review and consideration of this information for those seeking to implement standard setting in credentialing contexts. The authors also present a framework to guide both the design of standard-setting workshops and a structured approach to gathering evidence to support the validity of cut score interpretations (see Ferrara et al., Table 12.3, this volume). Careful attention to the guidance provided here and by Ferrara et al. will help ensure that standard setting for credentialing examinations is intentional, aligned with best practices, and results in defensible cut scores.

Major Influences on the Practice of Assessment for Licensing and Certification

Substantive changes in assessment for licensing and certification have been influenced by four markers. These include: (a) the rapid evolution of information and advances of technology and tools including more sophisticated psychometric approaches (Norcini et al., 2013); (b) the rise of competency-based education (Hauer et al., 2016); (c) an increased focus on the need for integrating learning and assessment over a professional's career (Baron, 2016; Continuing Board Certification, 2019); and (d) the rise of antitesting and antiregulation sentiments (Flier et al., 2016; Teirstein, 2015).

Rapid Evolution of Information and Advances of Technology and Tools

Recent decades have seen an explosion of information and, though keeping pace with it is essential, the task is increasingly challenging. Advances in cognitive psychology have deepened our understanding of how people use knowledge and information. At the same time, technological innovations are transforming assessment practices; for example, the Dental Interactive Simulation Corporation is doing important work using simulations to assess problem solving in dental hygiene (Williamson et al., 2006).

The challenge is making sense of the complex data resulting from this type of novel assessment format.

Technological advances abound, many of which directly support healthcare professions: these include the mandate of electronic health systems for all physician practices in the United States, increased use of point-of-care resources, precision medicine, the genome project, health wearables, 3D printing, robotic surgery, and decision support systems (Waldren et al., 2017). New assessment approaches are trying to incorporate some of these advances into the testing experience to make it more authentic to actual practice, such as allowing access to online external resources (e.g., UpToDate, an electronic clinical tool) during the testing experience and using simulation technology to assess performance more directly (Levine et al., 2012; Lipner et al., 2017). However, it is important to balance the cost and feasibility of these approaches against the additional value they provide in evaluating the desired construct(s). As mentioned previously, the technology itself inadvertently may introduce construct-irrelevant variance into the measurement. As such, design and impact of the new assessment should be researched thoroughly before it is used for making high-stakes decisions about test takers.

Item response theory (IRT) has become the standard psychometric model used in large-scale testing programs (see Cai et al., this volume, for discussion of IRT and other models). Its use has expanded in recent years in part due to sophisticated technology like computerized adaptive testing, as well as because of extensions of IRT for handling polytomous items and measuring multiple traits. There also has been increased interest in assessments that reflect how people practice their work. This has led to the development of more complex assessments that use advanced psychometric techniques such as computational psychometrics to assess both cognitive and noncognitive skills (von Davier, 2017). Computational psychometrics is quite sophisticated, combining mathematical models, machine learning, and data mining approaches as well as theory-driven psychometric approaches like evidence-centered design to measure latent abilities. The psychometric models that deal with complex data generally are IRT and Bayesian networks (Levy & Mislevy, 2016). These more complex models are important in credentialing settings because they allow for emulating real-world situations, such as using the Internal Revenue Service tax code on the Association of International Certified Public Accountants (AICPA) exams. Psychometric approaches also have become more sophisticated, particularly in areas such as data forensics. This field involves statistical analysis of the rich information automatically collected during computer-based testing—such as test taker responses, keystroke logs, and timing data—and prior performance to detect aberrant behavior and test fraud (de Klerk et al., 2019).

Rise of Competency-Based Education

In 1999, the Accreditation Council for Graduate Medical Education and the ABMS introduced six core competencies to define the relevant skills, knowledge, and attitudes that a trainee or physician should possess to provide quality health care

(Accreditation Council for Graduate Medical Education, 2020). Soon after, the competency-based education movement arose in residency and fellowship training programs; this movement resulted in defining subcompetencies and milestones for each of the six competencies to track a trainee's developmental progress within each competency and provide a structured approach to providing developmental feedback (Nasca et al., 2012). Instead of the traditional paradigm in which time spent in a training program is the primary indicator of a trainee's progression, mastery of knowledge and skills is the key to assessing progression. An outcomes-based approach is used to evaluate a trainee's progress in the medical program using the milestones framework. Assessment is both formative (giving feedback to enhance learning) and summative (making a decision about whether a trainee has achieved a certain level of competence). Research on the validity of the inferences based on milestone ratings is growing in the medical community, and undoubtedly the milestones will continue to be refined as the community learns more about the effectiveness of the framework (Hauer et al., 2018).

With the rise of competency-based education, the concept of programmatic assessment also has evolved. This approach combines various assessment instruments to provide a more holistic evaluation of a trainee (Schuwirth & van der Vleuten, 2012; Uijtdehaage & Schuwirth, 2018). The notion is based on the fact that each assessment instrument has its own inherent advantages and disadvantages, and it focuses on the meaningful triangulation across instruments, the stakes involved in the decision-making, and how the validity evidence is collected as the keys to success. The approach appears to be most beneficial in controlled environments such as training programs where it is largely associated with lower-stakes use cases (i.e., in the assessment *for* learning paradigm). It is less clear how this approach could be implemented for professionals in practice where there are few controlled environments. Furthermore, combining programs of assessment *for* and *of* learning (formative and summative) must be done with careful planning, especially with respect to validity considerations. Although there is appeal to approaching individual assessment from a programmatic perspective, and there is some evidence that it can work, more research is needed (Bok et al., 2018).

Increased Focus on Integrating Learning and Assessment Over a Professional's Career

One of the most significant changes in assessment relates to efforts to combine different assessment methods (e.g., formative and summative) into a cohesive, longitudinal program that supports a professional's development throughout their career. Much controversy has existed around programs for recertification (i.e., the maintenance of certification and continuing certification for medical professionals). As a result, a commission was formed that included public members as well as representatives from physician-led organizations. *The Continuing Board Certification: Vision for the Future Commission Final Report* (American Board of Medical Specialties, 2019),

which resulted from this effort, suggests that continuing certification programs for physicians should emphasize ongoing professionalism, focusing on learning and improvement in addition to assessment of current competence, with the ultimate goal of providing high-quality patient care. Initial certification programs, representing a culmination of training and traditional point-in-time assessments, sufficed for this purpose. Maintenance of certification, however, should be more continuous in nature. The American Board of Anesthesiology was the first of the ABMS boards to restructure its maintenance of certification program to a longitudinal program, called MOCA Minute, which claims to enable physicians to continuously assess themselves and identify knowledge gaps using an online portal (American Board of Anesthesiology, n.d.). Other ABMS boards soon followed. This is not just the case in medicine: Nursing and physician assistant credentials all have certification renewal programs (American Nursing Credentialing Center, n.d.; National Commission on Certification of Physician Assistants, n.d.).

From a measurement perspective, the challenge for these programs is being able to a) deliver enough quality questions in a nonsecure environment and to b) provide good educational feedback that includes identifying and remediating areas of weakness while c) maintaining a reliable and valid summative decision after 5 years (i.e., the time span for most of the medical education programs). There are many obstacles to doing this well; some of these include threats to security (because the questions and answers typically are exposed immediately after a question is answered), the difficulty of field testing enough questions with small sample sizes, maintaining the same standard over a period of time (e.g., 5 years), and choosing a scoring model that can adjust over time to allow for improvement. Strong research agendas are critical to evaluate the success of these longitudinal programs in terms of acceptability, feasibility, and meaningful learning and measurement.

The Rise of Antitesting and Antiregulation Sentiments

There has been a growing sentiment against testing and regulation across all of testing. For instance, in 2020 the University of California system announced that the SAT and ACT would no longer be required for undergraduate admissions (Hubler, 2021; see also Camara et al., this volume). For licensure and certification, most of the controversy has centered on healthcare, particularly regarding continuing certification programs and the Step 2 Clinical Skills examination for U.S. medical students (Flier et al., 2016; Teirstein, 2015; Teirstein & Topol, 2015). In 2018, the Institute for Credentialing Excellence, a leading developer for standards for certification programs, and the American Society of Association Executives formed a Professional Certification Coalition (Professional Certification Coalition, 2023). This coalition aims to counteract the negative impact of attempts to enact state legislation that undermines certification programs designed to provide data-driven, external validation of practitioners' competence by nongovernment private certification organizations. This legislation is directly working to weaken professional standards in the healthcare industry.

Weakened criteria for certificates could have serious consequences for patient care, particularly if the certificate is meaningless due to being obtainable solely through monetary exchange. Although the issue of weakened credentialing criteria is not the same as the proliferation of fake organizations offering phony certificates (Marcus, 2021), it still threaten the value of programs that maintain defensible standards and have conducted legitimate research to demonstrate that the assessments are meaningful and relevant.

CONCLUSION

Assessment for licensing and certification represents a segment of testing focused on protecting the public from unqualified practitioners. As this chapter has demonstrated, though assessment in this context shares similarities with other testing contexts, it is the differences that set it apart from tests used for other purposes. These differences are the focus of this chapter.

From a practical standpoint, the primary issues for credentialing bodies relate to test development and measurement considerations that impact the resulting examination and, by extension, examination outcomes. Validity evidence for the procedures used to develop, administer, score, and set passing scores for the test is central to the inferences made about candidates based on the test results. The stakes associated with licensing and certification examinations—including the risks of granting credentials to unqualified candidates and creating barriers to employment, thereby limiting the public's access to practitioners—make these considerations even more critical.

ACKNOWLEDGMENTS

First and foremost, thank you to our esteemed editors Linda Cook and Mary Pitoniak for inviting us to contribute to this prestigious volume and for providing unwavering support and patience throughout the entire production process. Even a global pandemic could not stop this dynamic duo! Thank you to our reviewer collaborators, Dave Swanson, Leslie Keng, and Nancy Tippins, for their insightful recommendations that yielded a much more concise (believe it or not!) and informative chapter. Finally, thank you to Benjamin Chesluk, Brian Clauser, Joanna Gorin, Michelle Johnson, Maxamillia Moroni, and Sidhartha Reddy, whose hard work and thoughtful contributions to our manuscript were invaluable!
